# Regularized KL-Divergence for Well-Defined Function-Space Variational Inference in Bayesian Neural Networks

Tristan Cinquin University of Tübingen tristan.cinquin@uni-tuebingen.de Robert Bamler University of Tübingen robert.bamler@uni-tuebingen.de

# Abstract

Bayesian neural networks (BNN) promise to combine the predictive performance of neural networks with principled uncertainty modeling important for safety-critical systems and decision making. However, posterior uncertainty estimates depend on the choice of prior, and finding informative priors in weight-space has proven difficult. This has motivated variational inference (VI) methods that pose priors directly on the function generated by the BNN rather than on weights. In this paper, we address a fundamental issue with such function-space VI approaches pointed out by Burt et al. (2020), who showed that the objective function (ELBO) is negative infinite for most priors of interest. Our solution builds on generalized VI (Knoblauch et al., 2019) with the regularized KL divergence (Quang, 2019) and is, to the best of our knowledge, the first well-defined variational objective for function-space inference in BNNs with Gaussian process (GP) priors. Experiments show that our method incorporates the properties specified by the GP prior on synthetic and small real-world data sets, and provides competitive uncertainty estimates for regression, classification and out-of-distribution detection compared to BNN baselines with both function and weight-space priors.

# 1 Introduction

Neural networks have shown impressive results in many fields but fail to provide well-calibrated uncertainty estimates, which are essential in applications associated with risk, such as healthcare (Kompa et al., 2021; Abdullah et al., 2022) or finance (Bew et al., 2019; Wong, 2023). Bayesian neural networks (BNNs) offer to combine the scalability and predictive performance of neural networks with principled uncertainty modeling by explicitly capturing epistemic uncertainty, i.e., uncertainty resulting from finite training data. While the choice of prior in the Bayesian framework strongly affects the uncertainty estimates later obtained from the posterior, specifying informative priors on BNN weights has proven difficult and is hypothesized to have limited their practical applicability (Knoblauch et al., 2019; Cinquin et al., 2021; Tran et al., 2022). For instance, the default isotropic Gaussian prior, which is often chosen for tractability rather than for the beliefs it carries (Knoblauch et al., 2019), is known to have pathological behavior in some cases (Tran et al., 2022). A promising approach to solve this issue is to place priors directly on the function represented by the BNN instead of the weights. While being technically more challenging, function-space priors allow incorporating interpretable knowledge into the inference, for instance enabling the use of the extensive Gaussian Process (GP) literature to improve prior selection and design (Williams and Rasmussen, 2006).

A recent line of work has focused on using function-space priors in BNNs with variational inference (VI) (Sun et al., 2019). VI is an appealing method because of its successful application to BNNs, its flexibility in terms of approximate posterior parameterization, and its scalability to large datasets and models (Hoffman et al., 2013; Blundell et al., 2015; Tomczak et al., 2020). Unfortunately, in

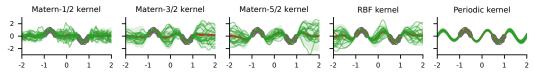

Figure 1: BNN inference on synthetic data (gray circles) with Gaussian process priors encoding different properties such as smoothness (increasing from Matern-1/2 to RBF) and periodicity (periodic).

the context of BNNs with function-space priors, the Kullbach-Leibler (KL) divergence term in the VI objective (ELBO) involves two intractabilities: (i) a supremum over infinitely many subsets and (ii) access to the density of the distribution of function represented by the BNN, which has no closed-form expression. Sun et al. (2019) propose to address problem (i) by approximating the supremum in the KL divergence by an expectation, and problem (ii) by using implicit score function estimators (which make this method difficult to use in practice (Ma and Hernández-Lobato, 2021)). However, the problem is actually more severe. Not only is the KL divergence intractable, it is infinite in many cases of interest (Burt et al., 2020), such as when the prior is a non-degenerate GP or a BNN with a different architecture. Thus, in these (and many more) situations, the KL divergence cannot even be approximated. As a consequence, more recent work abandons using BNNs and instead uses deterministic neural networks to parameterize basis functions (Ma and Hernández-Lobato, 2021) or a GP mean (Wild et al., 2022). The only prior work (Rudner et al., 2022b) on function-space VI in BNNs that overcomes the issue pointed out by Burt et al. (2020) does so by deliberately limiting itself to cases where the KL divergence is known to be finite (by defining the prior as the pushforward of a weight-space distribution). Therefore, the method by Rudner et al. (2022b) suffers from the same issues regarding prior specification as any other weight-space inference method for BNNs.

In this paper, we address the argument by Burt et al. (2020) that VI does not provide a valid objective for inference in BNNs with genuine function-space priors, and we propose to apply the framework of generalized variational inference (Knoblauch et al., 2019). We present a simple method for function-space inference with GP priors that builds on the so-called *regularized* KL divergence (Quang, 2019), which generalizes the conventional KL divergence and is finite for any pair of Gaussian measures. We obtain a Gaussian measure for the variational posterior by considering the linearized BNN from Rudner et al. (2022b), and we are free to choose a prior from a large set of GPs which have an associated Gaussian measure on the considered function space. While the regularized KL divergence is still intractable, it can be consistently estimated from samples with a known error bound. We find that our method effectively incorporates the beliefs specified by GP priors into the inference process (see Figure 1) and provides competitive performance compared to BNN baselines. To the best of our knowledge, our method is the first to provide a well-defined objective for function-space inference in BNNs with informative GP priors. Our contributions are summarized below:

- 1. We propose to use generalized VI with the so-called *regularized* KL divergence to mitigate the issue of an infinite KL divergence when using VI in BNNs with function-space priors.
- 2. We present a new, well-defined objective for function-space inference in the linearized BNN with GP priors, which results in a simple algorithm.
- 3. We analyze our method empirically on synthetic and real-world data sets, and find that it accurately captures structural properties specified by the GP prior and provides competitive uncertainty estimates for regression, classification, and out-of-distribution detection compared to BNN baselines with both function-space and weight-space priors.

The paper is structured as follows. Section 2 introduces function-space VI in BNNs and the regularized KL divergence. Section 3 presents our proposed method for generalized function-space VI (GFSVI) in BNNs. Section 4 presents experimental results. We discuss related work in Section 5 and conclude in Section 6.

# 2 Background

In this section, we provide background on function-space variational inference (VI) in BNNs and discuss the fundamental issue of an infinite KL-divergence. We then introduce the regularized KL divergence, which is the basis for our solution presented in Section 3.

#### 2.1 Function-space VI in BNNs

We consider a neural network  $f(\cdot; w)$  with weights  $w \in \mathbb{R}^p$ , and a data set  $\mathcal{D} = \{(x_i, y_i)\}_{i=1}^N$  with features  $x_i \in \mathcal{X} \subset \mathbb{R}^d$  and values  $y_i \in \mathcal{Y}$ . Bayesian Neural Networks (BNNs) are specified further by a likelihood function  $p(\mathcal{D} | w) = \prod_{i=1}^N p(y_i | f(x_i; w))$  and—traditionally—a prior p(w) on the weights, and one seeks the posterior distribution  $p(w | \mathcal{D}) \propto p(\mathcal{D} | w) p(w)$ . The method proposed in this paper builds on variational inference (VI), which approximates  $p(w | \mathcal{D})$  with a variational distribution  $q_{\phi}(w)$ , whose variational parameters  $\phi$  maximize the evidence lower bound (ELBO),

$$\mathcal{L}(\phi) := \mathbb{E}_{q_{\phi}(\boldsymbol{w})}[\log p(\mathcal{D} \mid \boldsymbol{w})] - D_{\mathrm{KL}}(q_{\phi} \parallel p)$$
(2.1)

where  $D_{\text{KL}}$  is the Kullback-Leibler (KL) divergence

$$D_{\mathrm{KL}}(q_{\phi} \parallel p) := \mathbb{E}_{q_{\phi}(\boldsymbol{w})} \left[ \log(q_{\phi}(\boldsymbol{w})/p(\boldsymbol{w})) \right].$$

$$(2.2)$$

At test time, we approximate the predictive distribution for given features  $\boldsymbol{x}^*$  as  $p(\boldsymbol{y}^* | \boldsymbol{x}^*) = \mathbb{E}_{p(\boldsymbol{w} \mid \mathcal{D})} [p(\boldsymbol{y}^* \mid f(\boldsymbol{x}^*; \boldsymbol{w}))] \approx \mathbb{E}_{q_{\phi}(\boldsymbol{w})} [p(\boldsymbol{y}^* \mid f(\boldsymbol{x}^*; \boldsymbol{w}))].$ 

**Function-space variational inference** Since weights of neural networks are not interpretable, we abandon the weight-space prior p(w) and instead pose a prior  $\mathbb{P}$  directly on the function  $f(\cdot; w)$ , which we denote simply as f when there is no ambiguity. Here, the symbol  $\mathbb{P}$  denotes a probability measure that does not admit a density since the function space is infinite-dimensional. We compute the expected log-likelihood as in the first term of Eq. 2.1, but we calculate the KL-term (Eq. 2.2) using the pushforward of  $q_{\phi}(w)$  along the mapping  $w \mapsto f(\cdot; w)$ , which defines the variational measure  $\mathbb{Q}_{\phi}$ , resulting in the ELBO in function space,

$$\mathcal{L}(\phi) := \mathbb{E}_{q_{\phi}(\boldsymbol{w})}[\log p(\mathcal{D} \mid \boldsymbol{w})] - D_{\mathrm{KL}}(\mathbb{Q}_{\phi} \parallel \mathbb{P})$$
(2.3)

with  $D_{\rm KL}$  the KL divergence between measures given by

$$D_{\mathrm{KL}}(\mathbb{Q}_{\phi} \| \mathbb{P}) = \int \log\left(\frac{d\mathbb{Q}_{\phi}}{d\mathbb{P}}(f)\right) d\mathbb{Q}_{\phi}.$$
(2.4)

Here, the Raydon-Nikodym derivative  $d\mathbb{Q}_{\phi}/d\mathbb{P}$  generalizes the density ratio from Eq. 2.2. Like Eq. 2.1, the ELBO in Eq. 2.3 is a lower bound on the evidence (Burt et al., 2020). In fact, if  $\mathbb{P}$  is the push-forward of p(w) then Eq. 2.3 is a tighter bound than Eq. 2.1 by the data processing inequality,  $D_{\mathrm{KL}}(\mathbb{Q}_{\phi} \parallel \mathbb{P}) \leq D_{\mathrm{KL}}(q_{\phi} \parallel p)$ . However, we motivated function-space VI to avoid weight-space priors, and in this case the bound in Eq. 2.3 can be looser. We will indeed see below that the bound becomes infinitely loose in practice, and we thus propose a different objective in Section 3.

Two intractabilities prevent directly maximizing the ELBO in function space (Eq 2.3). First, it is not obvious how to practically evaluate or estimate the KL divergence between two measures in function space in Eq 2.4. Sun et al. (2019) showed that it can be expressed as a supremum of KL divergences between finite-dimensional distributions,

$$D_{\mathrm{KL}}(\mathbb{Q}_{\phi} \| \mathbb{P}) = \sup_{\boldsymbol{x} \in \mathcal{X}^{M}} D_{\mathrm{KL}}(q_{\phi}(f(\boldsymbol{x})) \| p(f(\boldsymbol{x}))).$$
(2.5)

Here,  $\boldsymbol{x} = \{\boldsymbol{x}^{(i)}\}_{i=1}^{M} \in \mathcal{X}^{M}$  is a set of M points in feature space  $\mathcal{X}$ , and  $q_{\phi}(f(\boldsymbol{x}))$  and  $p(f(\boldsymbol{x}))$  are densities of the marginals of  $\mathbb{Q}_{\phi}$  and  $\mathbb{P}$  on  $\{f(\boldsymbol{x}^{(i)})\}_{i=1}^{M}$  respectively. To obtain a tractable approximation of the supremum over infinitely many sets, Sun et al. (2019) replace it by an expectation and Rudner et al. (2022b) estimate it from samples.

Second, we cannot express the pushforward measure  $\mathbb{Q}_{\phi}$  of  $q_{\phi}(w)$  in a closed form because the neural network is nonlinear. Previous work has proposed to mitigate this issue using implicit score function estimators (Sun et al., 2019) or a linearized BNN  $f_L$  to obtain a closed-form Gaussian variational measure (Rudner et al., 2022a,b). Our proposal in Section 3 follows the linearized BNN approach as it only minimally modifies the BNN, preserving most of its inductive bias (Maddox et al., 2021) while considerably simplifying the problem by turning the pushforward of  $q_{\phi}(w)$  into a Gaussian process (GP). More specifically, we consider a Gaussian variational distribution  $q_{\phi}(w) = \mathcal{N}(m, S)$  with parameters  $\phi = \{m, S\}$ , and we obtain  $f_L$  by linearizing f in the weights around w = m,

$$f_L(\boldsymbol{x}; \boldsymbol{w}) := f(\boldsymbol{x}; \boldsymbol{m}) + J(\boldsymbol{x}; \boldsymbol{m})(\boldsymbol{w} - \boldsymbol{m}) \quad \text{where} \quad J(\boldsymbol{x}; \boldsymbol{m}) = \nabla_{\boldsymbol{w}} f(\boldsymbol{x}; \boldsymbol{w})|_{\boldsymbol{w} = \boldsymbol{m}}.$$
 (2.6)  
Thus, for  $\boldsymbol{w} \sim q_{\phi}(\boldsymbol{w})$  we have,  $f_L(\boldsymbol{x}; \boldsymbol{w}) \sim \mathcal{N}(f(\boldsymbol{x}; \boldsymbol{m}), J(\boldsymbol{x}; \boldsymbol{m}) \boldsymbol{S} J(\boldsymbol{x}; \boldsymbol{m})^{\top}) \quad \forall \boldsymbol{x}$ , and the function  $f_L(\cdot; \boldsymbol{w})$  is a degenerate GP (as  $\operatorname{rank}(J(\cdot; \boldsymbol{m}) \boldsymbol{S} J(\cdot; \boldsymbol{m})^{\top}) \leq \operatorname{number}$  of weights  $< \infty$ ),

$$f_L \sim \mathcal{GP}(f(\cdot; \boldsymbol{m}), J(\cdot; \boldsymbol{m})\boldsymbol{S}J(\cdot; \boldsymbol{m})^{\top}).$$
(2.7)

 $D_{\mathrm{KL}}(\mathbb{Q}_{\phi} || \mathbb{P})$  is infinite in most practically relevant cases. Burt et al. (2020) point out an even more severe issue of function-space VI in BNNs:  $D_{\mathrm{KL}}(\mathbb{Q}_{\phi} || \mathbb{P})$  is in fact infinite in many relevant cases, in particular for non-degenerate GP-priors with BNNs. The proof in Burt et al. (2020) is somewhat involved, but the fundamental reason for  $D_{\mathrm{KL}}(\mathbb{Q}_{\phi} || \mathbb{P}) = \infty$  is that  $\mathbb{Q}_{\phi}$  has support on a finite-dimensional submanifold of the infinite-dimensional function space, while the measure  $\mathbb{P}$ induced by a (non-degenerate) GP prior has support on the entire function space. That such a dimensionality mismatch can lead to infinite KL divergence can be seen in a finite-dimensional example: consider the KL-divergence between two Gaussians in  $\mathbb{R}^n$  for some  $n \ge 2$ , one of which has support on the entire  $\mathbb{R}^n$  (i.e., its covariance matrix  $\Sigma_1$  has full rank) while the other one has support only on a proper subspace of  $\mathbb{R}^n$  (i.e., its covariance matrix  $\Sigma_2$  is singular). The KL divergence between two multivariate Gaussians has a closed form expression (Eq 2.9 with  $\gamma = 0$ ) that contains log det  $(\Sigma_2^{-1}\Sigma_1)$ , which is infinite for singular  $\Sigma_2$ .

We find that the fact that  $D_{\text{KL}}(\mathbb{Q}_{\phi} || \mathbb{P}) = \infty$  has severe practical consequences even when the KL divergence is only estimated from samples. It naturally explains the stability issues discussed in Appendix D.1 of Sun et al. (2019) (we compare the authors' solution to this stability issue to our method in Section 3.2). Surprisingly, similar complications arise even in the setup by Rudner et al. (2022b), which performs VI in function space with the pushforward of a weight-space prior. While the KL divergence is technically finite because prior and variational posterior have the same support, numerical errors lead to mismatching supports and thus to stability issues even there.

In summary, the ELBO for VI in BNNs is not well-defined for a large class of interesting functionspace priors. In Section 3, we propose a solution by using the so-called regularized KL divergence, which we introduce next.

#### 2.2 Regularized KL divergence for Gaussian measures

Our solution to the negative infinite function-space ELBO builds on a regularized KL divergence, which is expressed in terms of Gaussian measures for the variational posterior and prior. We obtain these Gaussian measures from corresponding Gaussian processes (GP). We first discuss under which conditions a GP induces a Gaussian measure, and then present the regularized KL divergence.

**Gaussian measures and Gaussian processes** The regularized KL divergence is defined in terms of Gaussian measures, and thus we need to verify that the GP variational posterior induced by the linearized BNN (Eq 2.7) has an associated Gaussian measure. We consider the Hilbert space  $L^2(\mathcal{X}, \rho)$  of square-integrable functions with respect to a probability measure  $\rho$  on a compact set  $\mathcal{X} \subset \mathbb{R}^d$ , with inner product  $\langle f, g \rangle = \int_{\mathcal{X}} f(x)g(x)d\rho(x)$ . This is not a restrictive assumption as we can typically bound the region in feature space that contains the data and any points where we might want to evaluate the BNN.

**Definition 2.1** (Gaussian measure, Kerrigan et al. (2023), Definition 1). Let  $(\Omega, \mathcal{B}, \mathbb{P})$  be a probability space. A measurable function  $F : \Omega \mapsto L^2(\mathcal{X}, \rho)$  is called a Gaussian random element (GRE) if for any  $g \in L^2(\mathcal{X}, \rho)$  the random variable  $\langle g, F \rangle$  has a Gaussian distribution on  $\mathbb{R}$ . For every GRE *F*, there exists a unique mean element  $m \in L^2(\mathcal{X}, \rho)$  and a finite trace linear covariance operator  $C : L^2(\mathcal{X}, \rho) \mapsto L^2(\mathcal{X}, \rho)$  such that  $\langle g, F \rangle \sim \mathcal{N}(\langle g, m \rangle, \langle Cg, g \rangle)$  for all  $g \in L^2(\mathcal{X}, \rho)$ . The pushforward of  $\mathbb{P}$  along *F* denoted  $\mathbb{P}^F := F_{\#}\mathbb{P}$  is a Gaussian (probability) measure on  $L^2(\mathcal{X}, \rho)$ .

Gaussian measures generalize Gaussian distributions to infinite-dimensional spaces where measures do not have associated densities. Following Wild et al. (2022), we notate the Gaussian measure obtained from the GRE F with mean element m and covariance operator C as  $\mathbb{P}^F := \mathcal{N}(m, C)$ .

Gaussian processes provide a convenient method to specify Gaussian measures over functions via mean and covariance functions (Wild et al., 2022; Kerrigan et al., 2023). A GP  $f \sim \mathcal{GP}(\mu, K)$ has an associated Gaussian measures in  $L^2(\mathcal{X}, \rho)$  if its mean function satisfies  $\mu \in L^2(\mathcal{X}, \rho)$ and its covariance function K is trace-class, i.e., if  $\int_{\mathcal{X}} K(x, x) d\rho(x) < \infty$  (Wild et al., 2022, Theorem 1). The GP variational posterior induced by the linearized BNN (Eq 2.7) satisfies both properties as neural networks are well-behaved functions on the compact subset  $\mathcal{X} \subset \mathbb{R}^d$ . It thus induces a Gaussian measure  $\mathbb{Q}_{\phi}^F \sim \mathcal{N}(m_Q, C_Q)$  with mean element  $m_Q = f(\cdot; m)$  and covariance operator  $C_Qg(\cdot) = \int_{\mathcal{X}} J(\cdot; m) SJ(x', m)^{\top} g(x') d\rho(x')$ . It turns out that the infinite KL divergence discussed in Section 2.1 is easier to prove for Gaussian measures, and we provide the proof in Appendix A.1.1 for the interested reader. **Definition 2.2** (Regularized KL divergence, Quang (2022) Definition 5). Let  $\nu_1 = \mathcal{N}(m_1, C_1)$ and  $\nu_2 = \mathcal{N}(m_2, C_2)$  be two Gaussian measures with  $m_1, m_2 \in L^2(\mathcal{X}, \rho)$  and  $C_1, C_2$  bounded, self-adjoint, positive and trace-class linear operators on  $L^2(\mathcal{X}, \rho)$ . Let  $\gamma \in \mathbb{R}, \gamma > 0$  be fixed. The regularized KL divergence is defined as follows,

$$D_{\mathrm{KL}}^{\gamma}(\nu_{1} \| \nu_{2}) := \frac{1}{2} \langle m_{1} - m_{2}, (C_{2} + \gamma \mathbb{I})^{-1}(m_{1} - m_{2}) \rangle + \frac{1}{2} \operatorname{Tr}_{X} \left[ (C_{2} + \gamma \mathbb{I})^{-1}(C_{1} + \gamma \mathbb{I}) - \mathbb{I} \right] - \frac{1}{2} \log \operatorname{det}_{X} \left[ (C_{2} + \gamma \mathbb{I})^{-1}(C_{1} + \gamma \mathbb{I}) \right].$$

$$(2.8)$$

1

For any  $\gamma > 0$ , the regularized KL divergence is well-defined and finite, even if the Gaussian measures are singular (Quang, 2019). It converges to the conventional KL divergence (if it is well-defined) for  $\gamma \rightarrow 0$  (Quang, 2022, Theorem 6). Furthermore, and importantly for our application to VI, if two Gaussian measures  $\nu_1$  and  $\nu_2$  are induced by GPs  $f_i \sim \mathcal{GP}(\mu_i, K_i)$  for i = 1, 2, then  $D_{\text{KL}}^{\gamma}(\nu_1 || \nu_2)$ can be consistently estimated (Quang, 2022) from a finite number M of samples using the estimator

$$\hat{D}_{\mathrm{KL}}^{\gamma}(\nu_{1} \| \nu_{2}) := \frac{1}{2} (\boldsymbol{m}_{1} - \boldsymbol{m}_{2})^{\top} (\boldsymbol{\Sigma}_{2}^{(\gamma)})^{-1} (\boldsymbol{m}_{1} - \boldsymbol{m}_{2}) + \frac{1}{2} \operatorname{Tr} \left[ (\boldsymbol{\Sigma}_{2}^{(\gamma)})^{-1} \boldsymbol{\Sigma}_{1}^{(\gamma)} - \mathbb{I}_{M} \right] - \frac{1}{2} \log \det \left[ (\boldsymbol{\Sigma}_{2}^{(\gamma)})^{-1} \boldsymbol{\Sigma}_{1}^{(\gamma)} \right]$$
(2.9)

with  $\boldsymbol{m}_i := \mu_i(\mathbf{x})$  and  $\boldsymbol{\Sigma}_i^{(\gamma)} := K_i(\mathbf{x}, \mathbf{x}) + \gamma M \mathbb{I}_M$  where  $\mu_i(\mathbf{x})$  and  $K_i(\mathbf{x}, \mathbf{x})$  are the mean vector and the covariance matrix obtained by evaluating  $\mu_i$  and  $K_i$  respectively, at measurement points  $\boldsymbol{x} = \{\boldsymbol{x}^{(i)}\}_{i=1}^M, \boldsymbol{x}^{(1)}, \dots, \boldsymbol{x}^{(M)} \stackrel{\text{i.i.d}}{\sim} \rho(\boldsymbol{x})$ . The right-hand side of Eq. 2.9 is the closed-form expression for the KL-divergence between multivariate Gaussian distributions  $\mathcal{N}(\boldsymbol{m}_1, \boldsymbol{\Sigma}_1^{(\gamma)})$  and  $\mathcal{N}(\boldsymbol{m}_2, \boldsymbol{\Sigma}_2^{(\gamma)})$ . Quang (2022) shows that the absolute error of the estimator is bounded by  $\mathcal{O}(1/M)$  with high probability with constants depending on  $\gamma$  and properties of the GP mean and covariance functions (see Appendix A.1.2 for the exact bound).

# **3** Generalized function-space VI with the regularized KL divergence

This section presents our proposed generalized function-space variational inference (GFSVI) method, which addresses the problem of the infinite KL divergence discussed in Section 2.1, which we take for an indication that VI is too restrictive if one wants to use genuine function-space priors. We instead consider generalized variational inference (Knoblauch et al., 2019), which reinterprets the ELBO in Eq. 2.1 as a regularized expected log-likelihood and explores alternative divergences for the regularizer. Specifically, we propose to use the regularized KL divergence. The presentation in this section builds heavily on tools introduced in Section 2, which turn out to fit together perfectly: the pushforward of a Gaussian variational distribution in weight-space through the linearized neural network (Eq. 2.6) induces a GP variational posterior (Eq. 2.7) that admits a Gaussian measure on  $L^2(\mathcal{X}, \rho)$  (Definition 2.1). Further selecting a GP prior which has an associated Gaussian measure on  $L^2(\mathcal{X}, \rho)$  allows us to use the regularized KL divergence (Eq. 2.8). We present the GFSVI method in Section 3.1 and discuss connections to prior work in Section 3.2.

#### 3.1 Generalized function-space variational inference

1

We present a simple and well-defined objective for function-space inference, and an algorithm for its optimization.

**Objective function** We start from the ELBO in Eq. 2.3, where we use the Gaussian variational measure  $\mathbb{Q}_{\phi}^{F}$  induced by the pushforward of a Gaussian variational distribution  $q_{\phi}(\boldsymbol{w}) = \mathcal{N}(\boldsymbol{w} \mid \boldsymbol{m}, \boldsymbol{S})$  along the linearized network  $f_{L}$  (Eq. 2.6). The function-space prior may be any GP that has an associated Gaussian measure  $\mathbb{P}^{F}$  on  $L^{2}(\mathcal{X}, \rho)$  (see Definition 2.1 and discussion below it). We now replace the KL divergence in the ELBO with the regularized KL divergence  $D_{\text{KL}}^{\gamma}$  (Eq. 2.8), which is well-defined and finite for any pair of Gaussian measures. For a likelihood  $p(\mathcal{D} \mid \boldsymbol{w}) = \prod_{i=1}^{N} p(y_i \mid f_L(\boldsymbol{x}_i; \boldsymbol{w}))$ , we thus obtain

$$\mathcal{L}(\phi) := \sum_{i=1}^{N} \mathbb{E}_{q_{\phi}(\boldsymbol{w})}[\log p(y_i | f_L(\boldsymbol{x}_i; \boldsymbol{w}))] - D_{\mathrm{KL}}^{\gamma} (\mathbb{Q}_{\phi}^F \| \mathbb{P}^F).$$
(3.1)

Estimation and optimization The expected log-likelihood (first term of Eq. 3.1) can be estimated by sampling from  $q_{\phi}(\boldsymbol{w})$ . For a Gaussian likelihood, it can also be computed in closed form because (unlike Rudner et al. (2022b)) we use the linearized network  $f_L$  to parameterize the likelihood function, which made training more stable in our experiments. We estimate the regularized KL divergence (second term of Eq. 3.1) using its consistent estimator (see Eq. 2.9), with  $\boldsymbol{m}_1 = f(\boldsymbol{x}; \boldsymbol{m}), \boldsymbol{\Sigma}_1^{(\gamma)} =$  $J(\boldsymbol{x}; \boldsymbol{m})SJ(\boldsymbol{x}; \boldsymbol{m})^\top + \gamma M\mathbb{I}_M, \boldsymbol{m}_2 = \boldsymbol{\mu}(\boldsymbol{x}),$ and  $\boldsymbol{\Sigma}_2^{(\gamma)} = K(\boldsymbol{x}, \boldsymbol{x}) + \gamma M\mathbb{I}_M$ , where  $\boldsymbol{\mu}$  and Kare the mean function and kernel of the GP prior, and  $\boldsymbol{x} = \{\boldsymbol{x}^{(i)}\}_{i=1}^M, \boldsymbol{x}^{(1)}, \dots, \boldsymbol{x}^{(M)} \stackrel{\text{ind}}{\to} \rho(\boldsymbol{x})$  Algorithm 1: Generalized function-space variational inference (GFSVI)

Input: linearized BNN  $f_L$  with measure  $\mathbb{Q}_{\phi}^F$ , Gaussian process prior  $\mathcal{GP}(\mu, K)$  with measure  $\mathbb{P}^F$ , measurement point distribution  $\rho(\boldsymbol{x})$ , data  $\mathcal{D} = \{(\boldsymbol{x}_i, y_i)\}_{i=1}^N$ , batch size  $B, \gamma > 0$ . for each minibatch  $(\boldsymbol{x}_B, y_B) \sim \mathcal{D}$  do Calculate  $\hat{\ell}_1 = \frac{N}{B} \mathbb{E}_{q_{\phi}(\boldsymbol{w})}[\log p(y_B | f_L(\boldsymbol{x}_B, \boldsymbol{w}))];$ Draw measurement points  $\boldsymbol{x} = \{\boldsymbol{x}^{(i)}\}_{i=1}^M \stackrel{\text{i.i.d.}}{\sim} \rho(\boldsymbol{x});$ Calculate  $\hat{\ell}_2 = \hat{D}_{\text{KL}}^{\gamma}(\mathbb{Q}_{\phi}^F || \mathbb{P}^F)$  using  $\boldsymbol{x}$  (Eq. 2.9); Calculate  $\hat{\mathcal{L}}(\phi) = \hat{\ell}_1 - \hat{\ell}_2;$ Update  $\phi$  using a step in the direction  $\nabla_{\phi} \hat{\mathcal{L}}(\phi);$ end

are measurement points sampled from the probability measure  $\rho(\mathbf{x})$  on  $\mathcal{X}$ . We maximize the estimated objective over the mean  $\mathbf{m}$  and covariance  $\mathbf{S}$  of the Gaussian variational distribution  $q_{\phi}(\mathbf{w})$ , and over any likelihood parameter (e.g.,  $\sigma_y$  for a Gaussian likelihood), see Algorithm 1. Appendix A.2 provides explicit expressions for the estimator with Gaussian and Categorical likelihoods.

**Technical details** ( $\gamma$  and  $\rho$ ) It turns out that increasing  $\gamma$  reduces the influence of the prior on inference (see Figure 17 in Appendix). At the same time,  $\gamma$  acts as jitter that prevents numerical errors (see Section 3.2). We recommend setting  $\gamma$  large enough to avoid numerical errors but sufficiently small to strongly regularize the objective in Eq. 3.1 (see Figure 15 in Appendix). We found that GFSVI is robust to a wide range of values and fixed  $\gamma = 10^{-10}$ . Furthermore, the probability measure  $\rho$  defined with  $L^2(\mathcal{X}, \rho)$  has to assign non-zero probability to any open set of  $\mathcal{X}$  to regularize the BNN on all of its support. Following Rudner et al. (2022b), we draw measurement points from a uniform distribution over  $\mathcal{X}$  when using tabular data and explore different configurations (such as samples from other data sets) when using high-dimensional image data (see Appendix A.3.4).

#### 3.2 Connections to prior work

TFSVI (Rudner et al., 2022b) and FVI (Sun et al., 2019) solve stability issues by introducing jitter/noise, which has a similar effect as the regularization in Eq. 2.8. However, as mentioned in Section 2.1, TFSVI introduces jitter only to overcome numerical issues and is fundamentally restricted to prior specification in weight space since its function-space prior is the pushforward of a weight-space prior. FVI does not linearize the BNN, and therefore does not have access to an explicit variational measure in function space. This severely complicates the estimation of (gradients of) the KL divergence, and the authors resort to implicit score function estimators, which make their method difficult to use in practice (Ma and Hernández-Lobato, 2021). Our proposed GFSVI does not suffer from these difficulties as the variational posterior is an explicit (Gaussian) measure. This allows us to estimate the (regularized) KL divergence without sampling any noise or using implicit score function estimators.

# 4 Experiments

In this section, we evaluate our generalized function-space variational inference (GFSVI) method qualitatively on synthetic data (Section 4.1) and quantitatively on real-world data (Section 4.2). We find that GFSVI accurately captures structural properties specified by the GP prior, that it approximates the exact Gaussian process (GP) posterior more faithfully than BNN baselines, and that it performs competitively on regression, classification and out-of-distribution detection tasks. We also discuss the influence of the BNN's inductive biases.

**Baselines** We compare the proposed GFSVI method to two weight-space inference methods (meanfield variational inference (Blundell et al., 2015) and linearized Laplace (Immer et al., 2021)) and to three function-space inference methods (FVI (Sun et al., 2019), TFVSI (Rudner et al., 2022b) and VIP (Ma et al., 2019), where TFSVI performs inference in function space but with the pushforward of a weight-space prior and VIP using a BNN prior). All BNNs have the same architecture and

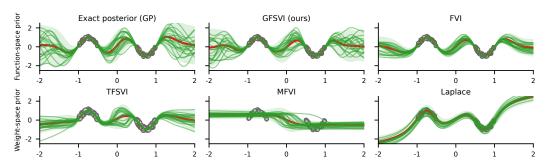

Figure 2: Inference on synthetic data (gray circles) using an RBF prior for function-space methods GFSVI and FVI. The proposed GFSVI provides the best approximation of the exact GP posterior.

fully-factorized Gaussian approximate posterior. We also include results for a sparse GP with a posterior mean parameterized by a neural network (GWI) (Wild et al., 2022), as well as for a Gaussian Process (GP) (Williams and Rasmussen, 2006) (when the size of the dataset allows it), and for a sparse GP (Hensman et al., 2013) for regression tasks. We consider the GP, sparse GP and GWI as gold standards as they represent the exact (or near exact) posterior for models with GP priors.

#### 4.1 Qualitative results on synthetic data

**Regression** We consider synthetic regression data with a one-dimensional feature-space  $\mathcal{X} \subset \mathbb{R}$ , where the values  $y_i$  are randomly sampled around  $\sin(2\pi x_i)$  (circles in Figures 1-11, see Appendix A.3.1). The green lines in Figures 1-8 and 11 show functions sampled from the (approximate) posteriors, and the red lines are the inferred mean functions. Figure 2 compares GFSVI with an RBF GP prior to baselines and to the exact posterior. We find that GFSVI visually matches the true posterior best (the same holds for a Matern-1/2 prior, see Figure 5 in the Appendix). Figure 1 in the Introduction and Figure 6 in the Appendix show that GFSVI notably adapts to varying prior assumptions (varying smoothness and length scale, respectively). In addition, Figures 4 and 8 in the Appendix show that GFSVI provides strong regularization when the data generative process is noisy, and that it can be trained with fewer measurement points M than FVI without significant degradation.

**Classification** We further consider a binary classification task derived from the 2-dimensional two moons data set (Pedregosa et al., 2011), see red and blue dots in Figures 9 and 10 in the Appendix. The first and second row in both figures show the inferred mean probability of class 1 (blue dots) and its 2-standard deviations with respect to posterior samples. Just like for regression, we find that GFSVI captures the beliefs of the RBF and Matern-1/2 GP priors better than all BNN-baselines, and shows greater uncertainty outside of the support of the data than the BNN baselines.

**Inductive biases** Figure 11 in the Appendix compares GFSVI to the exact GP-posterior across two different priors and three model architectures (details in Appendix A.3.1). We find that, with ReLU activations, small models are prone to underfitting for smooth priors (RBF), and to collapsing uncertainty for rough priors (Matern-1/2). By contrast, with smooth activations (Tanh), smaller models suffice, and they are compatible with most standard GP priors (the results shown in Figure 11 extend to RBF, Matern, and Rational Quadratic in our experiments). We also analyzed how the number M of measurement points affects performance. Figures 7 and 14 in Appendix show that capturing the beliefs of rough GP priors and estimating  $D_{\rm XL}^{\circ}$  with these priors requires larger M.

# 4.2 Quantitative results on real-world data

We study the fidelity of GFSVI compared to the true GP-posterior on real data, and evaluate GFSVI on regression, classification, and out-of-distribution detection tasks. In all tables, we bold the highest score and any score whose error bar (standard error) overlaps with the highest score's error bar.

**Ocean current modeling** We consider the problem of modeling ocean currents in the Gulf of Mexico to measure the extend to which GFSVI can incorporate knowledge specified via a GP prior on real-world data. Specifically, we follow the setup by Shalashilin (2024) and Cinquin et al. (2024),

Table 1: Test expected log-likelihood (higher is better) of evaluated methods on regression datasets. GFSVI performs competitively compared to all BNN baselines and obtains the best mean rank.

and use the GulfDrifters dataset (Lilly and Pérez-Brunius, 2021) to estimate ocean currents from 20 two-dimensional velocity vectors collected from drifter buoys. We embed physical properties of fluid motions into the GP prior and to the neural networks by applying the Helmholtz decomposition (Berlinghieri et al., 2023; Cinquin et al., 2024). We compare our GFSVI to a GP and to TFSVI. More details can be found in Appendix A.3.2.

Results are shown in Table 3 and in Figure 3. We find that incorporating prior knowledge via an informative GP prior in GFSVI improves expected log-likelihood (Loglike.) and mean squared-error (MSE) over weight-space priors in TFSVI. However, for this relatively small dataset, exact GP inference is still possible, and it outperforms both BNN-based predictions. This suggests that the physically motivated GP describes the true fluid dynamics well enough that the additional inductive bias introduced by a Table 3: Results for the ocean current modeling task. We find that incorporating prior knowledge via a Gaussian process prior in GFSVI improves score over weight-space priors in TFSVI.

neural network hurts performance rather than helping it. In the following, we consider experiments with larger datasets (making exact GP inference computationally infeasible in many cases), and where structural prior knowledge in function space exists but is not derived from strict laws of nature.

**Regression** We assess the predictive performance of GFSVI on data sets from the UCI repository (Dua and Graff, 2017) (described in Table 6 in the Appendix). Table 1, and Table 7 in the Appendix, show expected log-likelihood and mean squared error, respectively. We perform 5-fold cross validation and report means and standard errors across the test folds. We also rank the methods for each dataset and report the mean rank of each method across all datasets. See Appendix A.3.3 for more details. We find that GFSVI performs competitively compared to baselines and obtains the best mean rank for both metrics, matching the top performing methods on nearly all datasets. In particular, we find that using GP priors in the linearized BNN with GFSVI yields improvements over the weight-space priors used in TFSVI and that GFSVI performs slightly better than FVI.

Table 4: Out-of-distribution accuracy (higher is better) of evaluated methods on regression datasets. GFSVI (ours) performs competitively on OOD detection and obtains the highest mean rank.

**Classification** We further evaluate the classification performance of our method on the MNIST (LeCun et al., 2010) and FashionMNIST (Xiao et al., 2017) image data sets. We fit the models on a random subset of 90% of the training set, use the remaining 10% as validation data, and evaluate on the provided test split. We repeat with 5 different random seeds and report the mean and standard error of the expected log-likelihood, accuracy and expected calibration error (ECE) of the predictive distribution's mean in Table 2. For GFSVI, FVI, and TFSVI, we tested measurement points from both a random (RND) distribution  $\rho(x)$  and from KMNIST (see Algorithm 1 and Appendix A.3.4). We find that GFSVI performs competitively on MNIST, exceeding the expected log-likelihood and accuracy of top-scoring baselines (see Table 2) and similarly to best baselines on FashionMNIST. Additionally, GFSVI yields well-calibrated models with low ECE.

**Out-of-distribution detection** We further evaluate our method by testing if its epistemic uncertainty is predictive of out-of-distribution (OOD) data. We consider two settings: (i) with tabular data and a Gaussian likelihood following Malinin et al. (2020), and (ii) with image data and a categorical likelihood following Osawa et al. (2019). We report the accuracy of classifying OOD from indistribution (ID) data using a (learned) threshold on the predictive uncertainty. Additional details are provided in Appendix A.3.5. In setting (i) (Table 4), we find that GFSVI performs competitively and obtains the highest mean rank. Likewise, in setting (ii) (Table 8 in the Appendix), GFSVI strongly outperforms all baselines when using the KMNIST measurement point distribution highly influences OOD detection accuracy. We provide more details on this point in Appendix A.4.4. In both settings, we find that GFSVI is beneficial, and that GFSVI improves over FVI.

**Variational measure evaluation** Table 5 evaluates our inference method by comparing samples drawn from the exact posterior (where computationally feasible) with the approximate posterior obtained with our method (GFSVI). More details are provided in Appendix A.3.6. We find that GFSVI approximates the exact posterior more accurately that FVI, obtaining a higher mean rank, but worse than the gold standard sparse GP, which demonstrates to be most accurate.

# 5 Related work

In this section, we review related work on function-space variational inference with neural networks, and on approximating functions-space measures with weight-space priors.

**Function-space inference with neural networks** Prior work on function-space VI in BNNs has addressed issues (i) and (ii) mentioned in Section 2.1. Sun et al. (2019) address (i) (intractable variational posterior in function space) by using implicit score function estimators, and (ii) (intractable KL divergence) by replacing the supremum with an expectation. Rudner et al. (2022a,b) address (i) by using a linearized BNN (Khan et al., 2020; Immer et al., 2021; Maddox et al., 2021), and (ii) by replacing the supremum with a maximum over a finite set of samples. Other work abandons approximating the posterior over neural network weights altogether and instead uses a BNN only to specify a prior (Ma et al., 2019), or deterministic neural networks to fit basis functions for Bayesian linear regression (Ma and Hernández-Lobato, 2021) or the mean of a generalized sparse GP with Wasserstein-2 metric (Wild et al., 2022). Our work combines linearized BNNs with generalized variational inference, but we use the regularized KL divergence (Quang, 2019), which naturally generalizes the conventional KL divergence and allows for informative GP priors.

**Approximating function-space measures with weight-space priors in BNNs** Flam-Shepherd et al. (2017); Tran et al. (2022) minimize a divergence between the BNN's prior predictive and a GP before performing inference on weights, while Wu et al. (2023) directly incorporate the bridging divergence inside the inference objective. Alternatively, Pearce et al. (2020) derive BNN architectures mirroring GPs, and Matsubara et al. (2022) use the Ridgelet transform to design weight-spaces priors approximating a GP in function space. Another line of work considers weight-space priors which regularize in function space by comparing the model's predictions to those of a reference model (Nalisnick et al., 2020) and using an empirical prior (Rudner et al., 2023).

# 6 Discussion

We proposed a simple inference method with a well-defined variational objective function for Bayesian neural networks with Gaussian process (GP) priors in function-space. As standard VI with functions-space priors suffers from an infinite KL divergence problem, we propose to follow the generalized VI framework. Specifically, we substitute the conventional KL divergence in the ELBO by the regularized KL divergence, which is always finite, and which can be estimated consistently within the linearized BNN approximation. We demonstrated that our method allows to incorporate interpretable structural properties via a GP prior, accurately approximates the true GP posterior on synthetic and small real-world data sets, and provides competitive uncertainty estimates for regression, classification and out-of-distribution detection compared to BNN baselines with both function-space and weight-space priors.

Future work should investigate the use of more expressive variational distributions, such as Gaussian with low-rank plus diagonal covariance proposed by Tomczak et al. (2020), which is compatible with our proposed method.

# **A** Appendix

## A.1 Divergences between Gaussian measures

#### A.1.1 The KL divergence is infinite

In this section, we show that the Kullbach-Liebler (KL) divergence between the Gaussian measures  $\mathbb{Q}_{\phi}^{F} \sim \mathcal{N}(m_Q, C_Q)$  and  $\mathbb{P}^{F} \sim \mathcal{N}(m_P, C_P)$ , respectively induced by the linearized BNN in Eq 2.7 and by a non-degenerate Gaussian process satisfying conditions given in Section 2.2, is infinite. While this has already been shown by Burt et al. (2020), the proof is easier for Gaussian measures. We first need the Feldman-Hàjek theorem which tells us when the KL divergence between two Gaussian measures is well-defined.

**Theorem A.1** (Feldman-Hàjek, Quang (2022) Theorem 2, Simpson (2022) Theorem 7). Consider two Gaussian measures  $\nu_1 = \mathcal{N}(m_1, C_1)$  and  $\nu_2 = \mathcal{N}(m_2, C_2)$  on  $L^2(\mathcal{X}, \rho)$ . Then  $\nu_1$  and  $\nu_2$  are called equivalent if and only if the following holds:

- 1.  $m_1 m_2 \in Im(C_2^{1/2})$
- 2. The operator T such that  $C_1 = C_2^{1/2}(I-T)C_2^{1/2}$  is Hilbert-Schmidt, that is T has a countable set of eigenvalues  $\lambda_i$  that satisfy  $\lambda_i < 1$  and  $\sum_{i=1}^{\infty} \lambda_i^2 < \infty$ .

otherwise  $\nu_1$  and  $\nu_2$  are singular. If  $\nu_1$  and  $\nu_2$  are equivalent, then the Radon-Nikodym dervative exists and  $D_{\text{KL}}(\nu_1 || \nu_2)$  admits an explicit formula. Otherwise,  $D_{\text{KL}}(\nu_1 || \nu_2) = \infty$ .

Let us now show that the KL divergence between  $\mathbb{Q}_{\phi}^{F}$  and  $\mathbb{P}^{F}$  is indeed infinite.

Proposition 1. The Gaussian measures  $\mathbb{Q}_{\phi}^{F}$  and  $\mathbb{P}^{F}$  are mutually singular and  $D_{\mathrm{KL}}(\mathbb{Q}_{\phi}^{F}||\mathbb{P}^{F}) = \infty$ .

*Proof.* The proof follows from the Feldman-Hàjek theorem (Theorem A.1). In our case,  $C_Q$  has at most p non-zero eigenvalues as the covariance function of the GP induced by the BNN is degenerate, while  $C_P$  has a set of (countably) infinite non-zeros eigenvalues (prior is non-degenerate as per assumption). Hence, for the equality in condition (2) to hold, T must have eigenvalue 1 which violates the requirement that T is Hilbert-Schmidt i.e. that its eigenvalues  $\{\lambda_i\}_{i=1}^{\infty}$  satisfy  $\lambda_i < 1$  and  $\sum_{i=1}^{\infty} \lambda_i^2 < \infty$ . Therefore,  $\mathbb{Q}_{\phi}^F$  and  $\mathbb{P}^F$  are mutually singular and  $D_{\mathrm{KL}}(\mathbb{Q}_{\phi}^F || \mathbb{P}^F) = \infty$ .

#### A.1.2 The regularized KL divergence

In this section, we provide the bound describing the asymptotic convergence of the regularized KL divergence estimator.

Theorem A.2 (Convergence of estimator, Quang (2022) Theorem 45). Assume the following:

- 1. Let T be a  $\sigma$  compact metric space, that is  $T = \bigcup_{i=1}^{\infty} T_i$ , where  $T_1 \subset T_2 \subset \cdots$  with each  $T_i$  being compact.
- 2.  $\rho$  is a non-degenerate Borel probability measure on T, that is  $\rho(B) > 0$  for each open set  $B \subset T$ .
- 3.  $K_1, K_2 : T \times T \to \mathbb{R}$  are continuous, symmetric, positive definite kernels and there exists  $\kappa_1 > 0, \kappa_2 > 0$  such that  $\int_T K_i(x, x) d\rho(x) \le \kappa_i^2$  for i = 1, 2.
- 4.  $\sup_{x \in T} K_i(x, x) \le \kappa_i^2 \text{ for } i = 1, 2.$
- 5.  $f_i \sim GP(\mu_i, K_i)$ , where  $\mu_i \in L^2(T, \rho)$  for i = 1, 2.
- 6.  $\exists B_i > 0$  such that  $\|\mu_i\|_{\infty} \leq B_i$  for i = 1, 2.

Let  $\boldsymbol{x} = \{\boldsymbol{x}^{(i)}\}_{i=1}^{M}, \boldsymbol{x}^{(1)}, \dots, \boldsymbol{x}^{(M)} \stackrel{\text{i.i.d}}{\sim} \rho(\boldsymbol{x})$ . If Gaussian measures  $\mathcal{N}(m_i, C_i)$  are induced by GPs  $f_i \sim \mathcal{GP}(\mu_i, K_i)$  for i = 1, 2, then for any  $0 < \delta < 1$ , with probability at least  $1 - \delta$ ,

$$D_{\mathrm{KL}}(\mathcal{N}(\mu_{1}(\mathbf{x}), K_{1}(\mathbf{x}, \mathbf{x}) + M\gamma\mathbb{I}_{M}) \| \mathcal{N}(\mu_{2}(\mathbf{x}), K_{2}(\mathbf{x}, \mathbf{x}) + M\gamma\mathbb{I}_{M})) - D_{\mathrm{KL}}^{\gamma}(\mathcal{N}(m_{1}, C_{1}) \| \mathcal{N}(m_{2}, C_{2}))\| \\ \leq \frac{1}{2\gamma} (B_{1} + B_{2})^{2} [1 + \kappa_{2}^{2}/\gamma] \left( \frac{2\log\frac{48}{\gamma}}{M} + \sqrt{\frac{2\log\frac{48}{\gamma}}{M}} \right) \\ + \frac{1}{2\gamma^{2}} [\kappa_{1}^{4} + \kappa_{2}^{4} + \kappa_{1}^{2}\kappa_{2}^{2}(2 + \kappa_{2}^{2}/\gamma)] \left( \frac{2\log\frac{12}{\gamma}}{M} + \sqrt{\frac{2\log\frac{12}{\gamma}}{M}} \right)$$
(A.1)

#### A.2 Additional details on the GFSVI objective estimator

In this section, we present details on the estimation of the generalized function-space variational inference (GFSVI) objective. Let  $f_L(\cdot; \boldsymbol{w})$  be the linearized BNN (Eq 2.6) with weights  $\boldsymbol{w} \in \mathbb{R}^p$ , and  $\mathcal{D} = \{(\boldsymbol{x}_i, y_i)\}_{i=1}^N$  a data set with features  $\boldsymbol{x}_i \in \mathcal{X} \subset \mathbb{R}^d$  and associated values  $y_i \in \mathcal{Y}$ . Assuming a likelihood  $p(\mathcal{D} | \boldsymbol{w}) = \prod_{i=1}^N p(y_i | f(\boldsymbol{x}_i; \boldsymbol{w}))$  and a Gaussian variational distribution on model weights  $q_{\phi}(\boldsymbol{w}) = \mathcal{N}(\boldsymbol{w} | \boldsymbol{m}, \boldsymbol{S})$ , the GFSVI objective function is

$$\mathcal{L}(\phi) = \sum_{i=1}^{N} \mathbb{E}_{q_{\phi}(\boldsymbol{w})}[\log p(y_i \mid f_L(\boldsymbol{x}_i; \boldsymbol{w}))] - D_{\mathrm{KL}}^{\gamma} \left( \mathbb{Q}_{\phi}^F \parallel \mathbb{P}^F \right)$$
(A.2)

where  $\mathbb{Q}_{\phi}^{F}$  and  $\mathbb{P}^{F}$  are the Gaussian measures induced by the linearized BNN and a Gaussian process prior respectively.

**Expected log-likelihood** When considering a Gaussian likelihood, we use the closed form expression available due to the Gaussian variational measure over functions induced by the linearized BNN

$$\mathbb{E}_{q_{\phi}(\boldsymbol{w})}\left[\log \mathcal{N}\left(y_{i} \mid f_{L}(\boldsymbol{x}_{i}; \boldsymbol{w}), \sigma_{y}^{2}\right)\right] = -\frac{1}{2}\log\left(2\pi\sigma_{y}^{2}\right) - \frac{(y_{i} - f(\boldsymbol{x}_{i}; \boldsymbol{m}))^{2} + J(\boldsymbol{x}_{i}; \boldsymbol{m})\boldsymbol{S}J(\boldsymbol{x}_{i}; \boldsymbol{m})^{\top}}{2\sigma_{y}^{2}}$$
(A.3)

When considering a Categorical likelihood with C different classes, we estimate the expected loglikelihood term using Monte-Carlo integration as

$$\mathbb{E}_{q_{\phi}(\boldsymbol{w})}[\log \operatorname{Cat}(y_{i} \mid \sigma(f_{L}(\boldsymbol{x}_{i}; \boldsymbol{w})))] = \frac{1}{K} \sum_{k=1}^{K} \sum_{c=1}^{C} \mathbb{I}[y_{i} = c] \Big[ f_{L}^{c}(\boldsymbol{x}_{i}; \boldsymbol{w}^{(k)}) - \log \left[ \sum_{c'=1}^{C} \exp \left( f_{L}^{c'}(\boldsymbol{x}_{i}; \boldsymbol{w}^{(k)}) \right) \right] \Big]$$
(A.4)

where  $\boldsymbol{w}^{(k)} \sim q_{\phi}(\boldsymbol{w})$  for k = 1, ..., K,  $\mathbb{I}[\cdot]$  is the indicator function,  $\sigma(\cdot)$  is the softmax function and  $f_L^c(\cdot; \boldsymbol{w})$  is the logit for class c obtained from  $f_L$ .

**Regularized KL divergence** We estimate the regularized KL divergence using its consistent estimator (Eq. 2.9)

$$\hat{D}_{\mathrm{KL}}^{\gamma} \left( \mathbb{Q}_{\phi}^{F} \| \mathbb{P}^{F} \right) = \frac{1}{2} (f(\boldsymbol{x}; \boldsymbol{m}) - \boldsymbol{\mu}(\boldsymbol{x}))^{\top} (K(\boldsymbol{x}, \boldsymbol{x}) + \gamma M \mathbb{I}_{M})^{-1} (f(\boldsymbol{x}; \boldsymbol{m}) - \boldsymbol{\mu}(\boldsymbol{x})) + \frac{1}{2} \operatorname{Tr} \left[ (K(\boldsymbol{x}, \boldsymbol{x}) + \gamma M \mathbb{I}_{M})^{-1} (J(\boldsymbol{x}; \boldsymbol{m}) S J(\boldsymbol{x}; \boldsymbol{m})^{\top} + \gamma M \mathbb{I}_{M}) - \mathbb{I}_{M} \right] - \frac{1}{2} \log \det \left[ (K(\boldsymbol{x}, \boldsymbol{x}) + \gamma M \mathbb{I}_{M})^{-1} (J(\boldsymbol{x}; \boldsymbol{m}) S J(\boldsymbol{x}; \boldsymbol{m})^{\top} + \gamma M \mathbb{I}_{M}) \right] \quad (A.5)$$

with measurement points  $\boldsymbol{x} = \{\boldsymbol{x}^{(i)}\}_{i=1}^{M}, \, \boldsymbol{x}^{(1)}, \dots, \boldsymbol{x}^{(M)} \stackrel{\text{i.i.d}}{\sim} \rho(\boldsymbol{x})$  sampled from a probability measure on  $\mathcal{X}$ .

## A.3 Additional details on the experimental setup

#### A.3.1 Experiments on synthetic data

**Regression** We consider the following generative model for the toy data

$$y_i = \sin(2\pi x_i) + \epsilon \quad \text{with} \quad \epsilon \sim \mathcal{N}(0, \sigma_n^2)$$
 (A.6)

and draw  $x_i \sim \mathcal{U}([-1, -0.5] \cup [0.5, 1])$ . When not otherwise specified, we use  $\sigma_n = 0.1$ . On the plots, the data points are shown as gray circles, inferred mean functions as red lines, their 2-standard-deviations interval around the mean in light green, and functions sampled from the approximate posterior as green lines. In general, we consider two hidden-layer BNNs with 30 neurons per layer and hyperbolic tangent activation (Tanh) functions. Specifically in Figure 11, the small BNN has the

same architecture as above while the large BNN has 100 neurons per layer. All the BNN baselines have the same architecture and fully-factorized Gaussian approximate posterior. The prior scale of TFSVI (Rudner et al., 2022b) is set to  $\sigma_p = 0.2$  and  $\sigma_p = 0.75$  for MFVI (Blundell et al., 2015) and Laplace (Immer et al., 2021). For the Gaussian process posterior baseline, we fit the prior parameters by maximizing the log-marginal likelihood (Williams and Rasmussen, 2006). Apart from the cases where the parameters of the GP prior used for GFSVI (our method) and FVI (Sun et al., 2019) are explicitly stated, we consider a constant zero-mean function and find the parameters of the covariance function by maximizing the log-marginal likelihood from mini-batches (Chen et al., 2021). Except where otherwise stated, we estimate the functional KL divergences with 500 measurement points and use the regularized KL divergence with  $\gamma = 10^{-10}$ .

**Classification** We sample 100 data points perturbed by Gaussian noise with  $\sigma_n = 0.1$  from the two moons data (Pedregosa et al., 2011). On the plots, the data points are shown as red (class 0) and blue (class 1) dots. We plot the mean and 2-standard-deviations of the probability that x belongs to class 1 with respect to the posterior (i.e.  $p(y = 1 | \boldsymbol{w}^{(k)}, \boldsymbol{x}))$  which we estimate from K = 100samples  $w^{(k)} \sim q_{\phi}(w)$  for k = 1, ..., K. We consider two hidden-layer BNNs with 100 neurons per layer and hyperbolic tangent activation (Tanh) functions. All the BNN baselines have the same architecture and fully-factorized Gaussian approximate posterior. The prior scale of MFVI (Blundell et al., 2015) is set to  $\sigma_p = 0.8$  and  $\sigma_p = 1.0$  for TFSVI (Rudner et al., 2022b) and Laplace (Immer et al., 2021). For the Gaussian process posterior baseline, we approximate the intractable posterior using the Laplace approximation and find the prior parameters by maximizing the log-marginal likelihood (Williams and Rasmussen, 2006). The GP prior for GFSVI (our method) and FVI (Sun et al., 2019) has a constant zero-mean function and we find the parameters of the covariance function by maximizing the log-marginal likelihood from mini-batches (Chen et al., 2021) using the method to transform classifications labels into regression targets from Milios et al. (2018). We estimate the functional KL divergences with 500 measurement points and use the regularized KL divergence with  $\gamma = 10^{-10}$ .

# A.3.2 Ocean current modeling experiment

Following Cinquin et al. (2024), we apply the Helmholtz decomposition to the neural network f as

$$f(\cdot, \boldsymbol{w}) = \operatorname{grad} \Phi(\cdot, \boldsymbol{w}_1) + \operatorname{rot} \Psi(\cdot, \boldsymbol{w}_2)$$
(A.7)

where  $w = \{w_1, w_2\}$  and,  $\Phi(\cdot, w_1)$  and  $\Psi(\cdot, w_2)$  are 2-layer fully-connected neural networks with 50 hidden units per layer and hyperbolic tangent activation functions. GFSVI and TFSVI both use 160 fixed context points. The prior scale of TFSVI is set to  $\sigma_p = 0.5$ . We fit the neural networks on the entire dataset and average the scores with respect to five different random seeds.

## A.3.3 Regression experiments with tabular data

**Datasets and pre-processing** We evaluate the predictive performance of our model on regression datasets from the UCI repository (Dua and Graff, 2017) described in Table 6. These datasets are also considered in Sun et al. (2019); Wild et al. (2022) but we include two additional larger ones (Wave and Denmark). We perform 5-fold cross validation, leave out one fold for testing, consider 10% of the remaining 4 folds as validation data and the rest as training data. We report mean and standard-deviation of the average expected log-likelihood and average mean square error on the test fold. We also report the mean rank of the methods across all datasets by assigning rank 1 to the best scoring method as well as any method who's error bars overlap with the highest score's error bars, and recursively apply this procedure to the methods not having yet been assigned a rank. The expected log-likelihood is estimated by Monte Carlo integration when it is not available in closed form (MFVI, TFSVI and FVI) with 100 posterior samples. We preprocess the dataset by encoding categorical features as one-hot vectors and standardizing the features and labels.

**Baseline specification** We compare our GFSVI method to two weight-space inference methods (mean-field variational inference (Blundell et al., 2015) and linearized Laplace (Immer et al., 2021)) and two function-space inference methods (FVI (Sun et al., 2019) and TFSVI (Rudner et al., 2022b)). While FVI uses GP priors, TFSVI performs inference in function space but with the pushforward to function space of the variational distribution and prior on the weights. We compute the function-space (regularized) KL divergence using a set of 500 measurement points sampled from a uniform

Table 6: UCI regression dataset description

DATASET	BOSTON	NAVAL	POWER	PROTEIN	YACHT	CONCRETE	Energy	Kin8nm	WINE	WAVE	DENMARK

distribution for GFSVI and TFSVI, and 50 points drawn from a uniform distribution along with 450 samples from the training batch for FVI as specified in Sun et al. (2019). All the BNN baselines have the same architecture and fully-factorized Gaussian approximate posterior. We also provide results with a GP (Williams and Rasmussen, 2006) when the size of the dataset allows it, and a sparse GP (Hensman et al., 2013). As we restrict our comparison to BNNs, we do not consider the GP and sparse GP as baselines but rather as gold-standards. All models have a Gaussian heteroskedastic noise model with a learned scale parameter. All the BNNs are fit using the Adam optimizer (Kingma and Ba, 2017) using a mini-batch size of 2000 samples. We also perform early stopping when the validation loss stops decreasing.

**Model selection** Hyper-parameter optimization is conducted using the Bayesian optimization tool provided by Wandb (Biewald, 2020). BNN parameters are selected to maximize the average validation expected log-likelihood across the 5 cross-validation folds. We optimize over prior parameters (kernel and prior scale), learning-rate and activation function. We select priors for GFSVI, FVI, sparse GP and GP among the RBF, Matern-1/2, Matern-3/2, Matern-5/2, Linear and Rational Quadratic covariance functions. The GP prior parameters used with GFSVI and FVI are selected by maximizing the log-marginal likelihood from batches as proposed by Chen et al. (2021) and done in Sun et al. (2019). Hyper-parameters for GPs and sparse GPs (kernel parameters and learning-rate) are selected to maximize the mean log-marginal likelihood of the validation data across the 5 cross-validation folds.

# A.3.4 Classification experiments with image data

**Datasets and pre-processing** We further evaluate the predictive performance of our model on classification tasks with the MNIST (LeCun et al., 2010) and Fashion MNIST (Xiao et al., 2017) image data sets. We fit the models on a random subset of 90% of the provided training split, consider the remaining 10% as validation data and evaluate on the provided test split. We repeat this procedure 5 times with different random seeds and report the mean and standard-deviation of the average expected log-likelihood, accuracy and expected calibration error (ECE) of the mean of the predictive distribution on the test set. The expected log-likelihood is estimated by Monte Carlo integration with 100 posterior samples when it is not available in closed form (MFVI, TFSVI and FVI). We estimate the mean of the predictive distribution to compute the accuracy and the ECE with 100 posterior samples. We preprocess the dataset by standardizing the images.

**Baseline specification** We compare our GFSVI method to the same baselines as for the regression experiments (see A.3.3). All the BNN baselines have the same architecture and fully-factorized Gaussian approximate posterior. More specifically, we consider a CNN with three convolutional layers (with output channels 16, 32 and 64) before two fully connected layers (with output size 128 and 10). The convolutional layers use  $3 \times 3$  shaped kernels. Each pair of convolutional layers is interleaved with a max-pooling layer. We consider three different measurement point distributions  $\rho$ to estimate the (regularized) KL divergence in GFSVI, FVI and TFSVI: RANDOM, RANDOM PIXEL and KMNIST. The RANDOM measurement point distribution is sampled from by drawing 50% of the samples from the training data batch and 50% of the samples from a uniform distribution over  $[p_{min}, p_{max}]^{H \times W \times C}$ , where H, W and C are respectively the height, width and number of channels of the images, and  $p_{min} = v_{min} - 0.5 \times \Delta$  and  $p_{max} = v_{max} + 0.5 \times \Delta$  where  $\Delta = v_{max} - v_{min}$  is the difference between the minimal  $(v_{min})$  and maximal  $(v_{max})$  pixel values of the data set. The RANDOM PIXEL measurement point distribution is taken from Rudner et al. (2022b) and is sampled from by randomly choosing each pixel value among the ones available from the training data batch at the same position in the  $28 \times 28$  pixel grid. Finally, the KMNIST measurement point distribution is also taken from Rudner et al. (2022b) and is drawn from by randomly sampling data points from the Kuzushiji-MNIST (KMNIST) dataset (Clanuwat et al., 2018). The KMNIST dataset is a collection of 70'000 gray-scale images of size  $28 \times 28$  which we preprocess by standardizing the images. We sample 10 measurement points when using RANDOM, 25 measurement points when using RANDOM

PIXEL and 20 when using KMNIST. All the BNNs are trained using the Adam optimizer (Kingma and Ba, 2017) using a mini-batch size of 100. We also perform early stopping when the validation loss stops decreasing.

**Model selection** Hyper-parameter optimization is conducted just like for the regression tasks (see A.3.3). The Gaussian process prior parameters used with GFSVI and FVI are selected by maximizing the log-marginal likelihood from batches (Chen et al., 2021) using the method to transform classifications labels into regression targets from Milios et al. (2018). We optimize the same hyper-parameters as for the regression experiments with the exception of the additional  $\alpha_{\epsilon}$  parameter introduced by Milios et al. (2018) for the function-space VI methods with GP priors (FVI and GFSVI).

# A.3.5 OOD detection

**Tabular data with a Gaussian likelihood** Following the setup from Malinin et al. (2020) we take epistemic uncertainty to be the variance of the mean prediction with respect to samples from the posterior. We consider the test data to be in-distribution (ID) data and a subset of the song dataset (Bertin-Mahieux et al., 2011) of equal length and with an equal number of features as out-of-distribution (OOD) data. We use the same preprocessing as for regression as well as the same baselines with the same hyper-parameters (see Appendix A.3.3). We first fit a model, then evaluate the extend by which the epistemic uncertainty under the model is predictive of the ID and OOD data using a single threshold obtained by a depth-1 decision tree fit to minimize the classification loss. We report the mean and standard error of the accuracy of the threshold to classify OOD from ID data based on epistemic uncertainty across the 5 folds of cross-validation. We also provide results obtained using a GP and sparse GP as gold standard.

**Image data with a Categorical likelihood** Following the setup by Osawa et al. (2019), we take the epistemic uncertainty to be the entropy of the mean of the predictive distribution with respect to samples from the posterior. We evaluate models trained on MNIST using MNIST's test split as ID data and a subset of the training set of Fashion MNIST as OOD data. Likewise, we evaluate models trained on Fashion MNIST using Fashion MNIST's test split as ID data and a subset of the training set of MNIST's test split as ID data. We use the same preprocessing as for classification, as well as the same baselines with the same hyper-parameters (see Appendix A.3.4). We first fit a model, then evaluate the extend by which the epistemic uncertainty under the model is predictive of the ID and OOD data using a single threshold obtained by a depth-1 decision tree fit to minimize the classification loss. We estimate mean of the predictive distribution by Monte-Carlo integration using 100 posterior samples. We report the mean and standard error of the accuracy of the threshold to classify OOD from ID data based on epistemic uncertainty for the 5 models trained on different random seeds (see Appendix A.3.4).

#### A.3.6 Variational measure evaluation

We evaluate our inference method by comparing the samples drawn from the exact posterior over functions with the approximate posterior obtained with our method (GFSVI). We follow the setup by Wilson et al. (2022) and we compute the average Wasserstein-2 metric between 1000 samples drawn from a GP posterior with a RBF kernel evaluated at the test points, and samples from the approximate posterior of GFSVI, sparse GP and FVI evaluated at the same points and with the same prior. We consider the Boston, Concrete, Energy, Wine and Yacht datasets for which the exact GP posterior can be computed and use the same preprocessing as for regression (see Appendix A.3.3). We report the mean and standard error of the average Wasserstein-2 metric across the 5 folds of cross-validation. The Wasserstein-2 metric is computed using the Python Optimal Transport library (Flamary et al., 2021).

**Baseline specification** FVI and GFSVI have the same two hidden layer neural network architecture with 100 neurons each and hyperbolic tangent activation. These models are fit with the same learning rate and set of 500 measurement points jointly sampled from a uniform distribution over the feature-space and mini-batch of training samples. We use  $\gamma = 10^{-15}$  for the regularized KL divergence. We further consider a sparse GP with 100 inducing points.

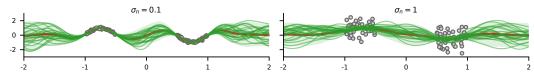

Figure 4: Our method (GFSVI) effectively regularizes functions generated by the Bayesian neural network (BNN) both in settings where the generative process is very noisy ( $\sigma_n = 1$ ) or not ( $\sigma_n = 0.1$ ).

# A.3.7 Software

We use the JAX (Bradbury et al., 2018) and DM-Haiku (Hennigan et al., 2020) Python libraries to implement our Bayesian neural networks. MFVI, linearized Laplace and TFSVI were implemented based on the information in the papers, and code for FVI was adapted to the JAX library from the implementation provided by the authors. We further use the GPJAX Python library for experiments involving Gaussian processes (Pinder and Dodd, 2022).

# A.3.8 Hardware

All models were fit using a single NVIDIA RTX 2080Ti GPU with 11GB of memory.

# A.4 Additional experimental results

In this section, we present additional figures for our qualitative uncertainty evaluation as well as further experimental results on regression, out-of-distribution detection and robustness under input distribution shift tasks. We also provide plots illustrating the eigenvalue decay of different kernels, and figures showing the influence of  $\gamma$  in the regularized KL divergence.

# A.4.1 Qualitative uncertainty evaluation

**Regression** We further find that our method (GFSVI) provides strong regularization when the data generative process is noisy (see Figure 4) and is more robust than FVI to situations where ones computational budget constrains the number of measurement points M to be small (Figure 8). In contrast to FVI, GFSVI accurately approximates the exact GP posterior under rough (Matern-1/2) GP priors effectively incorporating prior knowledge defined by the GP prior to the inference process (see Figure 5). Likewise, GFSVI adapts to the variability of the functions specified by the kernel (see Figure 6). We also find that GFSVI requires a larger number of measurement points to capture the behavior of a rougher prior (see Figure 7).

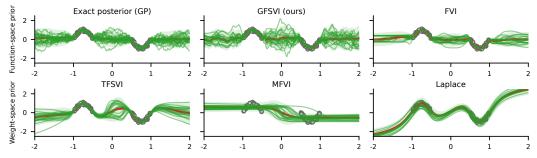

Figure 5: Our method (GFSVI) with a Matern-1/2 Gaussian process (GP) prior accurately approximates the exact GP posterior unlike the function-space prior baseline (FVI). Weight-space prior baselines do not provide a straight-forward mechanism to incorporate prior assumptions regarding the functions generated by BNNs and underestimate the epistemic uncertainty (MFVI, Laplace). The lower row is identical to the one in Figure 2 in the main text and is reproduced here to make comparison easier.

**Classification** We find that GFSVI better captures the beliefs induced by the smooth RBF and rough Matern-1/2 Gaussian process priors compared to FVI (see Figures 9 and 10). Moreover, GFVSI both accurately fits the training data and shows greater uncertainty outside of its support relative

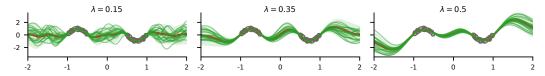

Figure 6: Our method (GFSVI) allows to incorporate prior beliefs in terms of function variability using the characteristic length-scale parameter of the Gaussian process (GP) prior. GFSVI was fit using a GP prior with RBF covariance function.

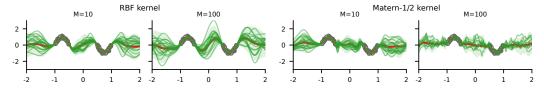

Figure 7: Our method (GFSVI) captures the smooth behavior of a Gaussian process (GP) prior with RBF covariance function even if the number of measurement points is small (M=10). However, in that setting GFSVI fails to reproduce the rough effect of a GP prior with a Matern-1/2 covariance function, and requires a larger amount of measurement points to do so (M=100).

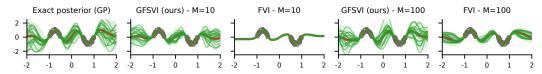

Figure 8: Our method (GFSVI) already provides a reasonable approximation to the exact posterior with small numbers of measurement points (M=10) while function-space baseline FVI requires many more (M=100).

to BNNs baselines with weight-space and function-space priors. Unlike for the toy data regression experiments where the GP posterior was the ground truth, the Laplace (approximate) GP posterior in Figures 9 and 10 only represents a possible approximation to the now in-tractable posterior (due to the softmax inverse link function). Thus the GP should not be considered as the ground truth nor as the optimal approximation in the classification setting, but is nevertheless useful to give a idea of the level of uncertainty a BNN with a GP prior should provide outside of the support of the data.

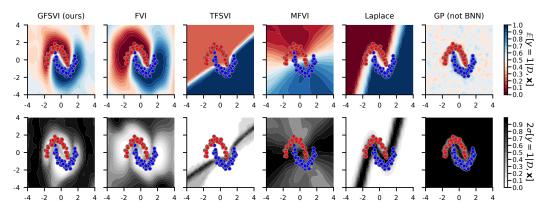

Figure 9: Our method (GFSVI) with a RBF Gaussian process (GP) prior accurately captures the smooth decision boundary induced by the prior and shows high uncertainty outside of the data support. Weight-space baselines do not provide a straight-forward mechanism to incorporate prior assumptions regarding the functions generated by BNNs and underestimate the epistemic uncertainty (TFSVI, Laplace) or underfit the data (MFVI).

**Inductive biases** Figure 11 compares GFSVI to the exact posterior across two different priors and three model architectures (details in A.3.1). We find that the BNN's ability to incorporate the beliefs

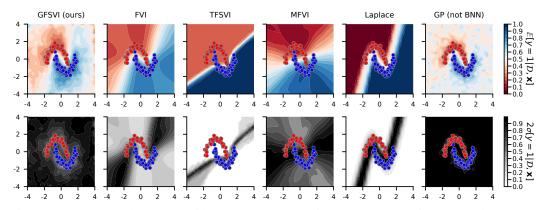

Figure 10: Our method (GFSVI) with a Matern-1/2 Gaussian process (GP) prior accurately captures the rough decision boundary unlike the function-space baseline (FVI). Weight-space baselines do not provide a straight-forward mechanism to incorporate prior assumptions regarding the functions generated by BNNs and underestimate the epistemic uncertainty (TFSVI, Laplace) or underfit the data (MFVI).

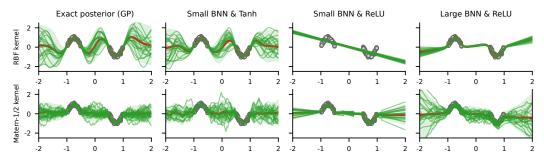

Figure 11: Our method requires that the Bayesian neural network (BNN) and Gaussian process (GP) prior share similar inductive biases to provide an accurate approximation to the exact posterior.

introduced by the GP prior depends on its size and activation function. When using piece-wise linear activations (ReLU), small models are prone to underfitting for smooth priors (RBF), and to collapsing uncertainty for rough priors (Matern-1/2). By contrast, when using smooth activations (Tanh), smaller models suffice, and they are compatible with most standard GP priors (the results shown in Figure 11 extend to RBF, Matern family, and Rational Quadratic in our experiments). We also analyzed how the number M of measurement points affects performance. Figures 7 and 14 show that capturing the properties of rough GP priors and estimating  $D_{KL}^{\gamma}$  with these priors requires larger M.

# A.4.2 Regression on tabular data

Table 7: Test mean square error (MSE) of evaluated methods on regression datasets. We find that GFSVI (ours) also performs competitively in terms of MSE compared to baselines and obtains the best mean rank, matching best the performing methods on nearly all datasets.

MEAN RANK	1.364	2.000	2.182	3.182	1.636	1.727	-	-	-

We present additional regression results reporting the mean square error (MSE) of evaluated methods across the considered baselines, see Table 7. We find that GFSVI also performs competitively in terms of MSE compared to baselines and obtains the best mean rank, matching best the performing

methods on nearly all datasets. In particular, we find that using GP priors in the linearized BNN setup with GFSVI yields improvements over the weight-space priors used in TFSVI and that GFSVI performs slightly better than FVI. Function-space VI methods (TFSVI, GFSVI, FVI) significantly improves over weight-space VI mostly performing similarly to the linearized Laplace approximation. Further improvement over baselines are obtained when considering GP priors with GFSVI and FVI. Finally, GFSVI compares favorably to the GP and sparse GP.

# A.4.3 Out-of-distribution detection with image data

We here show an additional plot from our out-of-distribution detection experiment with image data (details in A.3.5). Figure 12 shows the (normalized) histograms of the entropy of the mean prediction produced by each model on the in-distribution (blue) and out-of-distribution (red) data sets considered in our OOD detection experiment. Methods which estimate the (regularized) KL-divergence in function-space (GFSVI, FVI and TFSVI) use the KMNIST measurement distribution. We find that the entropy produced by GFSVI on in-distribution data highly peaks around 0 while the entropy produced from out-of-distribution data strongly concentrates around its maximum ln(10). GFSVI best partitions ID and OOD data based on predictive entropy improving over the function-space prior (FVI) and weight-space prior (TFSVI, MFVI, Laplace) BNN baselines (see Table 2).

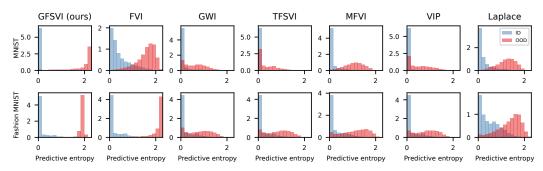

Figure 12: Histograms of the entropy of the mean predictive distribution produced by evaluated methods in the out-of-distribution detection with image data experiment. GFSVI (ours) best partitions in-distribution and out-of-distribution data based on the entropy of its mean predictive distribution.

## A.4.4 Influence of measurement point distribution for image data.

We present additional results evaluating the influence of the measurement point distribution  $\rho$  on the the performance of function-space inference methods when using high-dimensional image data. The measurement point distribution are described in Appendix A.3.4. Just like in Rudner et al. (2022b), we find that the choice of measurement point distribution may highly influence the OOD detection accuracy. While the expected log-likelihood, accuracy and expected calibration error (ECE) of a model generally remains comparable across measurement point distributions, the OOD accuracy of GFSVI is greatly improved by using samples from KMNIST to evaluate the (regularized) KL divergence. The measurement point distribution determines where the BNN is regularized and thus should be carefully selected especially for high dimensional data.

Table 8: Influence of the measurement point distribution  $\rho$  on expected log-likelihood (log-like.), accuracy (acc.), expected calibration error (ECE) and out-of-distribution detection accuracy (OOD acc.).  $\rho$  determines where the BNN will be regularized and strongly influences the out-of-distribution performance of the BNN.

#### A.4.5 Input distribution shift with rotated image data

We here provide an experiment evaluating our method's (GFSVI) robustness in detecting input distribution shift. We expect the predictive uncertainty of a well-calibrated Bayesian model to be low for in-distribution data and to gradually increase as the input distribution shifts further away from the training data distribution. To test this property, we follow the setup by Sensoy et al. (2018); Rudner et al. (2022b) and assume like the related work that increasing the rotation angle of images gradually increases the level of input "distribution shift". We report the mean and standard-deviation of the average mean predictive entropy of models fit on MNIST (LeCun et al., 2010) and Fashion MNIST (Xiao et al., 2017) for increasingly large angles of rotation of their respective test data partition. We find that GFSVI is confident (low predictive entropy) for images with small rotation angles, and that its predictive entropy increases with the angle. GFSVI therefore exhibits the expected behavior of a well-calibrated Bayesian model. We note that FVI, Laplace and MFVI tend to be under-confident (high predictive entropy) for small rotation angles, which might be a symptom of underfitting further supported by the results in Table 2. Also, with the exception of TFSVI, the predictive entropy of baselines across different rotation angles is generally higher than the one produced by GFSVI.

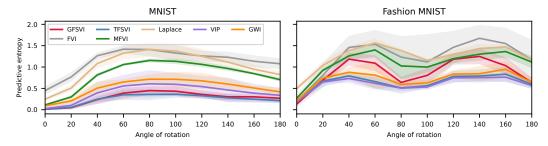

Figure 13: Average predictive entropy of models trained on MNIST and Fashion MNIST and evaluated for different rotation angles of their respective test data partitions. We see that our method (GFSVI) exhibits the behavior of a well-calibrated Bayesian model.

## A.4.6 Additional plots for kernel eigenvalue decay

Figure 14 shows a plot demonstrating the decay rate of the eigenvalues of RBF and Matern-1/2 kernels evaluated at points sampled uniformly over  $\mathcal{X}$ . The rate of decay of covariance operator's eigenvalues gives important information about the smoothness of stationary kernels (Williams and Rasmussen, 2006) and that increased smoothness of the kernel leads to faster decay of eigenvalues Santin and Schaback (2016). For instance, RBF covariance operator eigenvalues decay at near exponential rate independent of the underlying measure (Belkin, 2018) and Matern kernels eigenvalues decay polynomialy (Chen et al., 2021). We find that the kernel evaluated at points sampled from a uniform distribution over  $\mathcal{X}$  share this same behavior (see Figure 14).

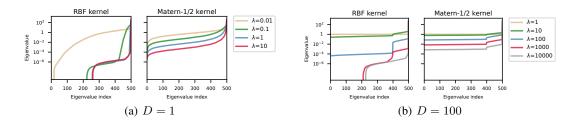

Figure 14: Mean eigenvalues of the Gram matrix obtained for different kernels and for varying length-scales over 10 draws from a uniform distribution on  $[-2, 2]^D$ . The mean eigenvalues are arranged in increasing order. The eigenvalues of the Gram matrix associated with the smooth RBF kernel decays much faster than those of the Matern-1/2. Furthermore, the eigenvalues decay at a slower rate in high dimensions (D=100).

# A.4.7 Additional plots for choosing $\gamma$ in $D_{\text{KL}}^{\gamma}$

The  $\gamma$  parameter controls the magnitude of the regularized KL divergence (see Figure 17) and adjusts the relative weight of the regularized KL divergence and expected log-likelihood term in the training objective (see Figure 15). Furthermore,  $\gamma$  also acts as "jitter" preventing numerical errors. We recommend choosing  $\gamma$  large enough to avoid numerical errors while remaining small enough to provide strong regularization.

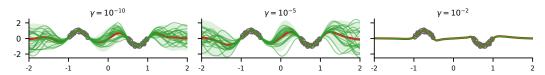

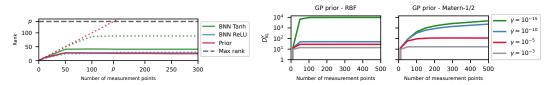

Figure 15: The  $\gamma$  parameter of the regularized KL divergence controls the magnitude of the regularizer in the objective and should be small enough to provide strong regularization.
