## ABSTRACT

Black carbon (BC) is an important pollutant aerosol emitted by numerous human activities, including gas flaring. Improper combustion in flaring activities can release large amounts of BC, which is harmful to human health and has a strong climate warming effect. To our knowledge, no study has ever directly monitored BC emissions from satellite imagery. Previous works quantified BC emissions indirectly, by applying emission coefficients to flaring volumes estimated from satellite imagery. Here, we develop a deep learning framework and apply it to Sentinel-2 imagery over North Africa during 2022 to detect and quantify BC emissions from gas flaring. We find that BC emissions in this region amount to about 1 million tCO<sub>2,eq</sub>, or 1 million passenger cars, more than a quarter of which are due to 10 sites alone. This work demonstrates the operational monitoring of BC emissions from flaring, a key step in implementing effective mitigation policies to reduce the climate impact of oil and gas operations.

## 1 INTRODUCTION

Black carbon (BC), commonly known as soot, is a primary aerosol produced by incomplete combustion processes. It is made of almost pure carbon, and is an important atmospheric pollutant with significant health and environmental impacts (Janssen et al., 2012; Bond et al., 2013; Szopa et al., 2021). BC warms the Earth by absorbing visible solar radiation and reducing surface albedo when deposited onto snow or ice (Ramanathan & Carmichael, 2008). While BC is relatively short-lived in the atmosphere (4-10 days), it is estimated to account for about 0.1 W/m<sup>2</sup> of radiative forcing since pre-industrial times (Szopa et al., 2021). In addition, BC is an important constituent of fine particulate matter in air (PM<sub>2.5</sub>), and can easily combine with toxic chemicals (EPA, 2012). Reducing BC emissions can therefore both benefit human health and mitigate climate change.

Major anthropogenic BC sources are fossil fuel and biomass combustion, with the largest being residential/commercial energy (heating and cooking) and industry (Wang et al., 2014; Hoesly et al., 2018). In particular, gas flaring is a significant contributor to industrial BC emissions. Flaring refers to the practice of burning excess natural gas to dispose of it during oil and gas extraction. An inefficient combustion process during flaring can cause vast amounts of BC to be emitted in large plumes (EPA, 2012). Flaring-related BC emissions are overall uncertain: average estimates range between 70 and 150 Gg/yr (Caseiro et al., 2020; Huang & Fu, 2016), but they could be as low as 20 Gg/yr and as high as 230 Gg/yr (Faruolo et al., 2021) (100 Gg/yr amounts to about 1% of global direct anthropogenic BC emissions (Hoesly et al., 2018)).

Such estimates are based on emission factors, which relate BC emissions to the volume or heating value of flared gas (Faruolo et al., 2021). Obtained from field measurements, emission factors for

---

\*Equal contribution

BC typically range from 0.1-1.5 g/m<sup>3</sup>, and vary according to gas composition and flaring temperature (McEwen & Johnson, 2012; Caseiro et al., 2020; Böttcher et al., 2021). Yet, the emission factor approach has several drawbacks which lead to large uncertainties in estimates. Flared gas volumes are uncertain, and emission factors themselves can vary significantly depending on local flare operating conditions, which are unknown and may vary over time (Huang & Fu, 2016). Few measurements are also available to estimate BC emission factors, and most are representative of well-operated flares with no visible BC plumes (Pederstad et al., 2015; Allen et al., 2016; Klimont et al., 2017).

Here, we leverage satellite imagery to monitor BC emissions from gas flaring. Satellite data have already been extensively used to monitor flaring (e.g., Elvidge et al., 2013; Caseiro et al., 2020), specifically to locate gas flares and estimate flared gas volumes and flaring by-products (Faruolo et al., 2021). Satellite data are especially attractive as they can help tackle the legal and technical challenges of monitoring and reporting of gas flaring, as well as provide dense spatio-temporal flaring data (Faruolo et al., 2021). However, to our knowledge, all previous satellite-based attempts at quantifying BC emissions from flaring have relied on emission factors. We instead estimate BC emissions directly from satellite imagery, bypassing the need to characterise flares. We combine traditional flare-identification algorithms with a deep learning model to detect and quantify visible BC plumes around gas flares. We focus on North Africa, namely Algeria, Libya and Egypt, 3 of the 15 countries that flare the most gas according to recent estimates (Caseiro et al., 2020).

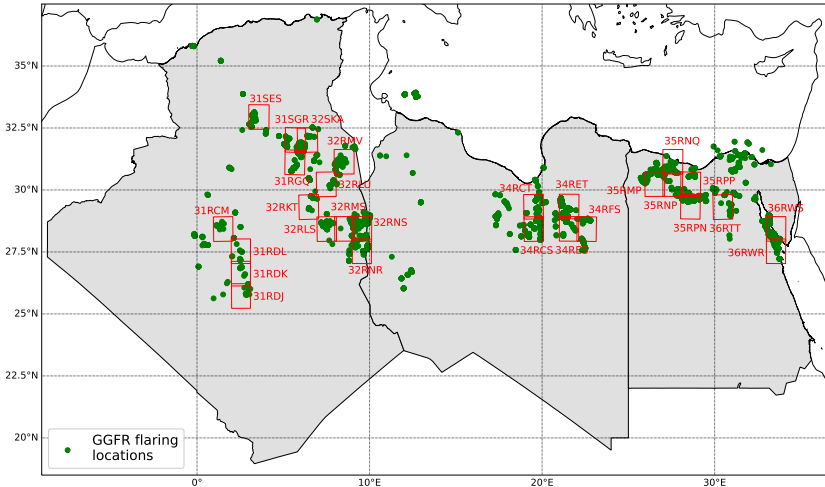

Figure 1: Map of our region of study (Algeria, Libya and Egypt) showing the GGFR flaring locations (green dots) and the set of 28 Sentinel-2 tiles we downloaded for this study (red squares, tile name shown in red).

## 2 PROPOSED METHODOLOGY

We detect BC plumes in 2022 across Algeria, Libya and Egypt in top-of-atmosphere data from the European Space Agency’s Sentinel-2 constellation (Drusch et al., 2012). This region concentrates a large number of gas flaring sites (Figure 1). We restrain ourselves to the 28 Sentinel-2 tiles (≈ 340,000 km<sup>2</sup>) which contain more than 5 flaring sites, based on the World Bank’s Global Gas Flaring Reduction Partnership (GGFR)’s Global Flaring database (NOAA, the Payne Institute at the Colorado School of Mines, World Bank/GGFR, 2023).

### 2.1 MODEL AND TRAINING DATA

We develop a ConvLSTM model Shi et al. (2015) to detect BC plumes in satellite imagery. The model takes as input a time series of two RGB images, corresponding to two neighbouring satellite acquisitions, and returns a segmentation mask for BC plumes present in the second image. We train the models on 128×128 randomly cropped RGB image time series of Sentinel-2 data (taken from

a variety of tiles close to the ones of interest; Figure 1) in which we embed synthetic BC plumes. These synthetic plumes are simulated with a custom 2D LES plume model which implements the 2D Euler equations with finite volume and uses an implicit (*i.e.* numerical) subgrid scale term (Grinstein et al., 2007). We use an FFT-based pseudo-spectral solver to solve the Poisson equation. Our implicit closure lies in the advection scheme: we use WENO-3 reconstruction (Jiang & Shu, 1996) to compute fluxes. This yields fast synthetic plumes simulations, allowing us to generate a large synthetic plumes set in a reasonable computational time.

The reason we use the three RGB channels only (out of the 13 multispectral bands of Sentinel-2) is that the absorption spectrum of BC outside the RGB domain is not well known. Restricting ourselves to RGB thus allows us to easily integrate the synthetic plumes to Sentinel-2 RGB scenes by dimming the original RGB scene brightness by a factor proportional to the plume density (from 0 (no plume) to 1 (total extinction due to plume)) (Figure S2). However, we do use the other 10 channels in the post-processing to remove false positives (see below).

## 2.2 FORMATTING OF SENTINEL-2 DATA

Because flares are not continuously lit, or can be masked by clouds, we first detect flares for each tile and each acquisition with the tri-band spectral algorithms developed for Sentinel-2: the Normalized Hotspot Indices (Marchese et al., 2019) (NHI) and the Thermal Anomaly Index (Liu et al., 2021) (TAI). The performance and limitation of such algorithms have been thoroughly studied (Genzano et al., 2020; Sharma et al., 2017; Fisher & Wooster, 2019). We have found them to be very reliable, with few false negatives, though bright, low-level clouds are sometimes mistaken for lit flares. We then group together flares separated by less than 1 km (for which it is difficult to separately attribute BC plumes). Finally, we crop Sentinel-2 scenes around each flare cluster, by embedding the cluster in a square and expanding this square by 256 pixels in each direction (the crop window is therefore at least  $512 \times 512$ , or  $\approx 5 \times 5$  km).

## 2.3 POST-PROCESSING OF MODEL OUTPUT

We first average the predictions from 10 separate models to retain plumes detected by at least half of the models. We then filter the detections to remove potential false positives by using a lightGBM classifier that takes as input the 13 spectral channels of Sentinel-2 data. The classifier has false positive and negative rates of about 2-3% each. We subsequently group together all predictions for a given tile and date. From this average, we identify each individual BC plume which we assign to the nearest cluster of flares. Finally, we estimate BC emission rates using the Integrated Mass Enhancement (IME) method (Frankenberg et al., 2016; Varon et al., 2018), as described in Appendix A.1.

## 3 EVALUATION

We identify a total of 1963 individual flares, active for at least one acquisition date during 2022 (Figure S1). They are grouped within 1104 clusters of flares, the vast majority (83%) of which are active for 10% or less of the time. About half of flare clusters are located in Algeria (51%), 12% in Libya and 37% in Egypt. Algeria accounts for 55% of total flaring activity, Libya for 21% and Egypt for 24%.

BC plumes are overall well-captured by our deep learning model (Figure 2). All large plumes are correctly identified by the algorithm, but very small plumes ( $\leq 500$  m in maximum extent) are often missed. Small and medium plumes may also be missed when atmospheric non-BC aerosol concentration (*e.g.*, sand particles) is high and causes haze, which frequently happens in the desert. The model also has a slight tendency to underestimate the true extent of the plumes, especially when these are very diluted.

We detect BC plumes at 372 clusters of flares (297 in Algeria, 55 in Libya and 20 in Egypt). BC plume frequency is highest in Algeria (BC plumes detected in 65% of active flares), followed by Libya (49%) and Egypt (34% only). Annual BC emission rates range between 0.01 and 270 t/yr, with 65% of locations emitting less than 10 t/yr (Figure S3). In total, we estimate that the flares we monitored emitted 6.2 Gg of BC in 2022 [3.1-12.5 Gg]. Algeria accounts for 75% of this total (4.7

Gg [2.3-9.3 Gg]), Libya for 23% (1.4 Gg [0.7-2.8 Gg]) and Egypt for 2% (0.14 Gg [0.07-0.29 Gg]). Regional emissions are dominated by a very small number of locations: the 10 clusters emitting more than 100 t/yr (7 in Algeria, 3 in Libya.) are responsible for 27% of total emissions (Figure S4).

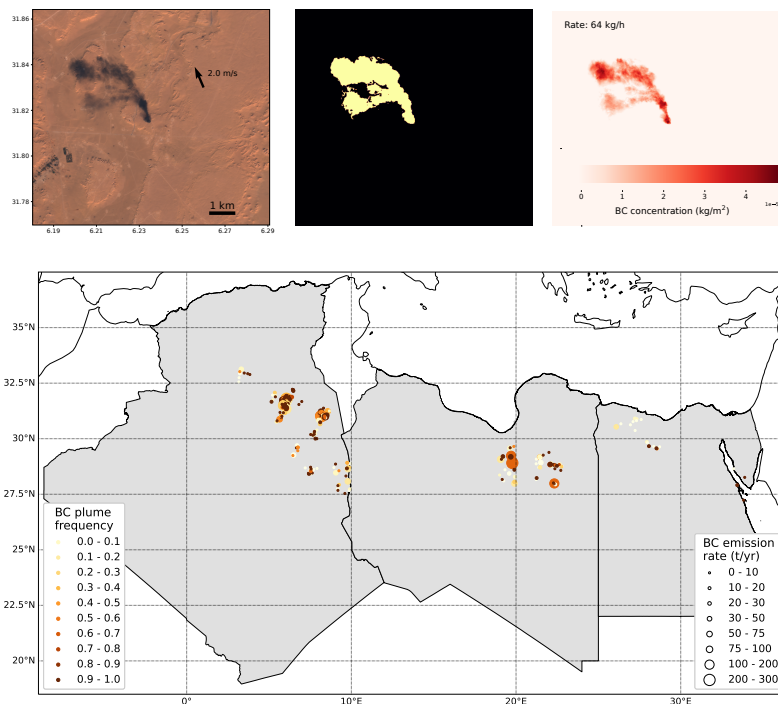

Figure 2: Top panels: example of detected BC plume in Algeria; from left to right: RGB image, plume prediction mask, and BC concentration map (obtained with  $\mu = 8 \text{ m}^2/\text{g}$ , see Appendix A.1). Bottom panel: Map of BC emission rates (in t/yr) across North Africa. The size and colour of the dots depends on the annual flaring frequency of each location.

## 4 CONCLUSION

This work demonstrates the possibility to monitor flaring BC emissions at large scale over desert regions and in real time. BC plumes are a frequent feature of gas flaring across North Africa, especially in Algeria and Libya, some of which even stretch over several square kilometers (Figure 2). Interestingly, BC emissions widely differ across flares. Some flares appear particularly inefficient and emit large quantities of BC, while some very active ones have much smaller BC emissions. BC plumes also tend to be intermittent. For most flares that are active  $> 20\%$  of the time, BC plumes are detected in only 10-20% of acquisitions (Figure S3). This suggests that flare operating conditions vary widely during the year.

There remain large uncertainties in our BC emission estimates. The sources of this uncertainty include sampling uncertainties (due to infrequent satellite coverage or cloud cover), model uncertainties (accuracy and estimation of plume masks), and uncertainties in plume rate estimates (IME method, imperfect wind data). Still, our estimates are comparable to previous ones based on emission factors (*e.g.*, Caseiro et al., 2020). The originality of our method consists in directly detecting BC emissions and being able to pinpoint the most emissive sites.

BC being an important – but short-lived – climate forcer, reducing flaring-related BC emissions where flaring infrastructure is particularly inefficient can yield substantial benefits at the short term. Assuming a 100-year global warming potential of BC of 500-1000 (Reddy & Boucher, 2007; Bond et al., 2013), flaring BC emissions in North Africa in 2022 are equivalent to 3.1-6.2 million tCO<sub>2</sub>, or 0.7-1.3 million gas-powered passenger cars (EPA, 2023). Detected BC plumes also indicate improper flare combustion, which may also release other pollutants, like methane, that have even larger

environmental impacts. Most of this is accounted for by a handful of sites, meaning that limited investments in efficient flaring infrastructure or to improve operating practices are realistic and could considerably decrease the environmental and health impacts of gas flaring in North Africa.

## A APPENDIX

### A.1 ESTIMATING BC EMISSION RATES

We give here a brief description of the Integrated Mass Enhancement (IME) method (Frankenberg et al., 2016; Varon et al., 2018) we use to quantify BC plume emission rates. Denoting by  $\Delta\Omega$  the BC concentration field (in  $\text{kg m}^{-2}$ ) and  $\mathcal{P}$  the plume mask, the total BC mass within the plume is equal to:

$$IME = \sum_{i \in \mathcal{P}} \Delta\Omega(i)A(i) \quad (1)$$

where  $A(i)$  is the area of grid cell  $i$  (in  $\text{m}^2$ ). The plume rate  $Q$  is then empirically related to  $IME$  by way of an effective wind speed  $U_{eff}$  (in  $\text{m s}^{-1}$ ), and an effective plume size  $L$  (in  $\text{m}$ ) through:

$$Q = \frac{U_{eff}IME}{L} \quad (2)$$

Varon et al. (2018) found in the case of methane that  $U_{eff}$  could be derived from the local 10-meter wind speed  $U_{10}$  through  $U_{eff} = 0.9 \log(U_{10}) + 0.6$ . We obtain 10-meter wind speed from the hourly GEOS-FP global reanalysis (Molod et al., 2015). Finally, we retrieve  $\Delta\Omega$  with radiative transfer theory and the Beer-Lambert relationship. The latter relates light extinction in the Sentinel-2 B3 band (green;  $\approx 535\text{-}585$  nm) to total BC column concentration as follows:

$$\frac{I_{BC}^{B3}}{I_0^{B3}} = \int_{\lambda \in B3} w(\lambda) e^{-\gamma \mu \rho} d\lambda \quad (3)$$

where  $\gamma$  is the atmospheric mass factor (function of the solar zenith and satellite viewing angle),  $\mu$  is the BC mass extinction coefficient (in  $\text{m}^2/\text{g}$ ) and  $\rho$  the total BC column concentration (in  $\text{g}/\text{m}^2$ ).

$\frac{I_{BC}^{B3}}{I_0^{B3}}$  is the B3 transmittance between the target scene (which includes a BC plume) and a reference scene (in which the BC plume is absent).  $w(\lambda)$  is the B3 spectral weight. In theory,  $\mu$  is not constant with  $\lambda$ , but the difference is small over the limited wavelength range of B3. We use experimental values of  $\mu$  at 550 nm given in the literature. Estimates vary across studies, but most fall in the 4-20  $\text{m}^2/\text{g}$  range (Weyant et al., 2016; Conrad & Johnson, 2019; Lee et al., 2022).

We assume in equation (3) that BC is solely responsible for light extinction in B3. In particular, we neglect the effect of organic carbon (OC), also present in the plume (up to 20% of the flared aerosol mass; McEwen & Johnson, 2012; Klimont et al., 2017). The mass extinction coefficient of OC is however much smaller than that of BC, in particular around 550 nm (Kirchstetter et al., 2004).

$\mu$  is also known to depend on its molecular structure and OC content (Chung et al., 2012; Fierce et al., 2020). OC coating of BC aerosols indeed strongly modifies its radiative properties, namely decreasing its absorption efficiency (Kelesidis et al., 2021). To take these various uncertainties into account, we estimate BC plume emissions using a median value of  $\mu = 8 \text{ m}^2/\text{g}$  and extreme values of  $\mu = 4$  and  $\mu = 20 \text{ m}^2/\text{g}$ .

Finally, we translate the series of BC emission rates for each plume (in  $\text{t}/\text{h}$ ) into annual emission rates (in  $\text{t}/\text{yr}$ ) as follows:

$$Q_{t/yr} = \overline{Q_{t/h}} \times f_{\text{flare}} \times f_{\text{plume}} \times 365 \times 24 \quad (4)$$

where  $\overline{Q_{t/h}}$  is the average hourly BC emission rate over all detected plumes,  $f_{\text{flare}}$  the frequency of flaring activity out of all tile acquisitions, and  $f_{\text{plume}}$  the frequency of BC plume detections among active flaring acquisitions.

### A.2 SUPPLEMENTARY FIGURES

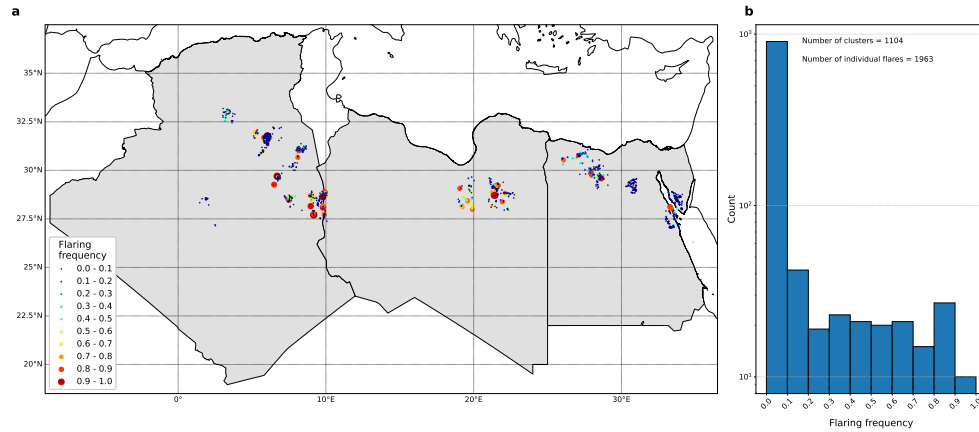

Figure S1: **Identifying flares across North Africa.** (a) Spatial distribution of the clusters of flares across North Africa. The size and colour of the dots depends on the annual flaring frequency of each location. (b) Distribution of flaring frequencies.

Figure S2: Example of synthetic BC plume integration in Sentinel-2 RGB scenes (top panels). The corresponding plume simulations are shown on the bottom panels.

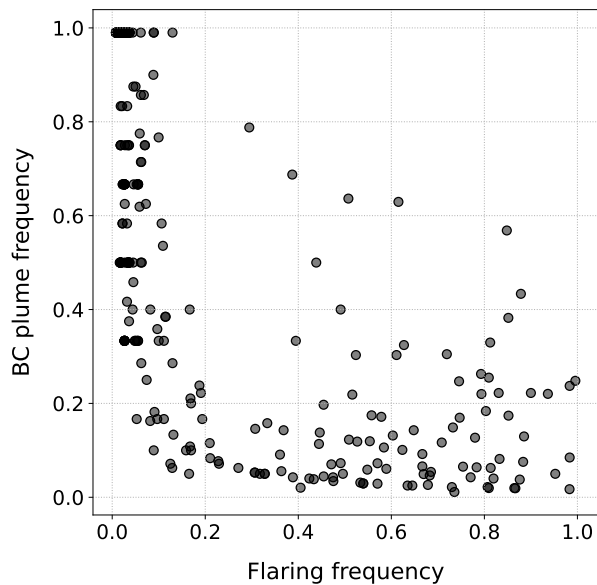

Figure S3: Map of BC emission rates across North Africa. The size and colour of the dots depends on the annual flaring frequency of each location.

Figure S4: Cumulative frequency distributions of BC source rates (left) and of total BC emissions (right) for the 372 flare clusters with detected BC plumes.
