Automated mechanism design (AMD) uses computational methods for mechanism design. *Differentiable economics*is a form of AMD that uses deep learning to learn mechanism designs and has enabled strong progress in AMD in recent years. Nevertheless, a major open problem has been to learn multi-bidder, general, and fully strategy-proof (SP) auctions. We introduce *GEneral Menu-based NETwork* (GEMNET), which significantly extends the menu-based approach of the singlebidder RochetNet [\(Dütting et al.,](#page-42-0) [2024\)](#page-42-0) to the multi-bidder setting. The challenge in achieving SP is to learn bidder-independent menus that are feasible, so that the optimal menu choices for each bidder do not over-allocate items when taken together (we call this *menu compatibility*). GEMNET penalizes the failure of menu compatibility during training, and transforms learned menus after training through price changes, by considering a set of discretized bidder values and reasoning about Lipschitz smoothness to guarantee menu compatibility on the entire value space. This approach is general, leaving trained menus that already satisfy menu compatibility undisturbed and reducing to RochetNet for a single bidder. Mixedinteger linear programs are used for menu transforms, and through a number of optimizations enabled by deep learning, including adaptive grids and methods to skip menu elements, we scale to large auction design problems. GEMNET learns auctions with better revenue than affine maximization methods, achieves exact SP

#### 1. INTRODUCTION

Auctions stand as one of the most enduring and thriving economic activities to this day [\(Cramton et al.,](#page-41-0) [2006,](#page-41-0) [McAfee and McMillan,](#page-42-1) [1996,](#page-42-1) [Milionis et al.,](#page-43-0) [2023,](#page-43-0) [Edelman](#page-42-2) [et al.,](#page-42-2) [2007,](#page-42-2) [Milgrom,](#page-42-3) [2004\)](#page-42-3), and the design of revenue optimal auctions forms a cornerstone problem in economic theory. The seminal work [\(Myerson,](#page-43-1) [1981\)](#page-43-1) solves optimal auctions for selling a single item. While the long-standing significance of auctions is wellestablished, it is notable that decades of theoretical exploration have yet to fully unravel the intricacy of optimal auction design. Considering dominant-strategy incentive compatibility (DSIC, also strategy-proof) auctions, the only analytical results are for variations on the single-bidder setting [\(Daskalakis et al.,](#page-41-1) [2015,](#page-41-1) [Manelli and Vincent,](#page-42-4) [2006,](#page-42-4) [Pavlov,](#page-43-2) [2011,](#page-43-2) [Giannakopoulos and Koutsoupias,](#page-42-5) [2014\)](#page-42-5) and for multiple bidders for the case of two items and value distributions with only two possible values in their support [\(Yao,](#page-44-0) [2017\)](#page-44-0).

The idea of using computational methods to design auctions and mechanisms, coined *automated mechanism design* (AMD), was introduced by [Conitzer and Sandholm](#page-41-2) [\(2002,](#page-41-2) [2004\)](#page-41-3). Whereas the early literature on AMD [\(Conitzer and Sandholm,](#page-41-2) [2002,](#page-41-2) [2004\)](#page-41-3) proposed using linear programming (LP) for mechanism design in discrete value domains, a general LP formulation for strategy-proof mechanisms in continuous value domains has remained elusive [\(Conitzer,](#page-41-4) [2006\)](#page-41-4). Moreover, even in discrete settings, these LP-based formulations suffer from exponential size, making them computationally impractical as the size of the type space increases. In recent years, *differentiable economics* [\(Dütting](#page-42-0) [et al.,](#page-42-0) [2024\)](#page-42-0) has proposed using deep learning to discover optimal, strategy-proof auctions and optimal mechanisms more generally. Machine learning pipelines based on neural networks are used as computational techniques for optimizing within function classes, where the functions represent auction or mechanism rules. This methodology aligns with the paradigm of unsupervised learning by employing appropriately defined loss functions and sampling training data from a known type distribution. Ideally, this approach when

<span id="page-2-1"></span>used to auction design would satisfy the following three properties: (1) *expressive*: revenueoptimal auctions are in the function class represented by the neural network; (2) *strategyproof*: the learned auctions are DSIC; and (3) *multi-bidder*: the framework is able to support multi-item auctions with multiple bidders.

Finding a method that meets all three criteria is a complex challenge, as illustrated in Fig. [1.](#page-2-0) RegretNet [\(Dütting et al.,](#page-42-0) [2024\)](#page-42-0), along with subsequent developments such as ALGNet [\(Rahme et al.,](#page-43-3) [2020\)](#page-43-3) and RegretFormer [\(Ivanov et al.,](#page-42-6) [2022\)](#page-42-6), are expressive and multi-bidder but seek to minimize the DSIC violation during training and lack a guarantee of exact strategy-proofness (SP). Affinemaximizer auctions (AMAs) [\(Curry](#page-41-5) [et al.,](#page-41-5) [2022a,](#page-41-5) [Duan et al.,](#page-41-6) [2023\)](#page-41-6) ensure SP

<span id="page-2-0"></span>

Figure 1.: GEMNET is the first differentiable economics method that is generally expressive, truthful (or strategyproof, DSIC), and supports multiple bidders (and items).

by appealing to generalized, affine-maximizing Vickrey-Clarke-Groves mechanisms [\(Vick](#page-44-1)[rey,](#page-44-1) [1961,](#page-44-1) [Clarke,](#page-41-7) [1971,](#page-41-7) [Groves,](#page-42-7) [1973\)](#page-42-7). Although applicable to multi-bidder scenarios, AMAs are not fully expressive because they are restricted to affine-maximizing mechanisms. Menu-based methods such as RochetNet [\(Dütting et al.,](#page-42-0) [2024\)](#page-42-0) and MenuNet [\(Shen](#page-43-4) [et al.,](#page-43-4) [2019\)](#page-43-4) are expressive and SP, but only support auctions with a single bidder (or settings where the items are non-rival, for example digital content, where an auction with multiple bidders decomposes into single-bidder problems).

An idea for achieving all three criteria is to generalize the RochetNet architecture to multiple bidders while preserving its core features of *self-bid independent menus* (each bidder faces choices that may depend on the bids of others but not its own bid) and *bidderoptimization* (each bidder receives an optimal menu choice given its own bid). This kind of menu-based structure is inherent in SP mechanisms: any SP mechanism can be represented by self-bid independent menus with bidder-optimization [\(Hammond,](#page-42-8) [1979\)](#page-42-8). The challenge in the multi-bidder setting is to ensure that bidder-optimizing menu choices, one for each agent, do not over-allocate items when taken together. We refer to this feasibility property as *menu compatibility*. Fig. [2\(](#page-3-0)a) shows an example where over-allocation occurs. Two bid-

<span id="page-3-0"></span>

FIGURE 2.—Illustrating our method for additive valuations. (a) An example of incompatible menus where the utility-maximizing menu elements over-allocate the first item. (b) Prices are adjusted so that the feasible menu element,  $[0, 1]$  in this case, has greater utility than infeasible elements like  $[1, 1]$ . Menus after price adjustment are compatible at grid points. (c) Extending menu compatibility to off-grid values by introducing safety margins. In this example, the utility of an infeasible bundle  $[1, 1]$  changes from \$1.3 to \$2.7 between two grid points. Here, the safety margin represents the gap between the utilities of feasible and infeasible menu elements at grid points preventing their utility ranges from overlapping.

ders, Squirrel and Panda, are each provided with a menu. Each bidder selects the menu item that maximizes their utility:  $[1,0]$  for Squirrel and  $[1,1]$  for Panda. However, these choices are incompatible because they over-allocate the first item Acorn.

Bridging this gap to enable a multi-bidder RochetNet is important for a number of reasons. First, it may reveal a new structural understanding of optimal auction design, both through the interpretability of menu-based descriptions and from achieving the distinguished property of *exact* strategy-proofness. Second, it drives progress in understanding how well existing solutions such as those coming from AMAs and approximately-SP methods such as RegretNet align with optimal designs. Third, it may provide new opportunities for operational impact, for example in the kinds of systems (advertising and marketing technology, notably) that rely on auctions, through the additional trust that comes through exact SP.

Our Contributions. We close this gap and propose the first differentiable economics method that fulfills all three criteria. Our method, *GEneral Menu-based NETwork* (GEMNET), makes a significant generalization of RochetNet to the multi-bidder, multi-item setting under additive and unit-demand valuations, and is able to guarantee menu compatibility. A neural network is used to learn a self-bid independent menu for each bidder, consisting of a set of bundle-price pairs, each pair representing a menu choice and corre-

<span id="page-4-0"></span>sponding to a bundle of items—actually a distribution on items—and a price. As we explain, the prices associated with the learned menus are transformed after training to ensure menu compatibility over the full domain and SP. Given these adjusted menus, the outcome of an auction corresponds to a bidder-optimizing menu choice for each bidder (i.e., a choice from the bidder's menu that maximizes its utility based on its value for different bundles as represented through its bid). For a network with sufficient capacity (i.e., enough hidden layers and nodes), this menu-based computational framework is without loss of generality, in that it can learn the revenue-optimal auction with access to sufficient training data, due to the universality of menu-based representations [\(Hammond,](#page-42-8) [1979\)](#page-42-8). In the special case of a single bidder, GEMNET reduces to RochetNet.

The primary issue in achieving SP with a menu-based, multi-bidder architecture is to guarantee menu compatibility. Straightforward approaches such as scaling down each bidder's randomized assignment of an item according to the over-assignment of the item fails strategy-proofness. This would create a dependency between a first bidder's scaled menu and the choices of a second bidder, where the choice of this second bidder depends on the first bidder's own reports through the design of the menu for the second bidder. This interdependence contravenes the conditions of self-bid independence and leads to violations of SP.

In achieving menu compatibility, we first develop a suitable loss function to use during training that represents the goal of maximizing revenue while penalizing loss of menu compatibility. Specifically, we design an *incompatibility loss* that penalizes menus for which the simultaneous choice of bidder-optimizing menu elements for each bidder over-allocates items. This incompatibility loss is used together with a loss term corresponding to negated revenue during training. Although the incompatibility loss does not completely address menu incompatibility, it substantially lowers the likelihood of over-allocation. After training, we then modify as needed the prices associated with the elements of menus, with this menu transformation used to ensure the exact menu compatibility of a deployed mechanism over the full value domain. Menu transformation makes small changes to prices so that incompatible choices become less appealing to a bidder than the best compatible choice.

The post-training price transformation involves solving a series of mixed-integer linear programs (MILP). Although the method works on a grid of values for bidders, through Lipschitz smoothness arguments it guarantees menu compatibility on the full, continuous

<span id="page-5-0"></span>

FIGURE 3.—Learned mechanisms in the setting with two additive bidders, two items, and i.i.d. uniform values on  $[0, 1]$ . Bidder 2's values are set at  $(0, 0.6)$ , and the x- and y-axis in each subplot is Bidder 1's value for Item 1 and 2. Rows 1 and 2 show the probability of Bidder 1 getting Item 1 and Item 2, respectively, and row 3 shows the price for Bidder 1. Columns represent different methods. Dotted lines in the second column distinguish the preand post-transformation mechanisms. Compared to RegretNet, GEMNET exhibits a clear decision boundary and thereby improves the interpretability of designed mechanisms. AMenuNet has a large set of types in the left-top region where Bidder 1 receives no items and makes no payments. In contrast, GEMNET increases revenue by allocating Item 1 to Bidder 1 within this region, highlighting the improved expressive capacity enabled by our method.

input domain. For bidder  $i$ , the transform considers a grid of values of the others. Fixing one such value profile  $\tilde{v}_{-i}$ , and thus fixing the menu to bidder i, the transform considers a grid  $V_i$  of possible values  $v_i$  for bidder i. This set of values  $V_i$  induces a MILP corresponding to  $(i, \tilde{v}_{-i})$ , where the decision variables are the possible price changes to make to certain elements in bidder i's menu at  $\tilde{v}_{-i}$ . To construct this MILP, we consider the effect of assuming each  $v_i \in V_i$  as the valuation of bidder *i*. As  $v_i$  changes, so too does the menu of choices offered to each of the other bidders, and for each  $v_i$  we identify the bidder-optimizing menu choice for each of the other bidders at  $\tilde{v}_{-i}$ . These menu choices by  $j \neq i$  may render some elements in bidder i's menu infeasible for this choice of  $v_i \in V_i$ , while other elements remain feasible. For each  $v_i \in V_i$ , the MILP includes constraints on price changes for elements of the menu at  $\tilde{v}_{-i}$  to ensure that bidder i prefers some feasible element over every infeasible element, with an objective to minimize price adjustments.

Similar MILPs are formulated and solved in series for different values  $v_{-i}$  of other bidders, then the process proceeds by adopting the viewpoint of each bidder in turn, using the transformed menus for the bidders already considered and making adjustments to their learned menus as needed. Each transform is always feasible because in the worst-case it can make all the menu elements so expensive that a bidder prefers to choose the empty bundle at zero price.

Fig. [2\(](#page-3-0)b) shows an example of price adjustments considering a grid of values. We fix the bids of Squirrel and consider a grid of values for Panda. When Panda bids  $[2, 6]$ , we keep Squirrel's menu unchanged so it continues to choose bundle  $[1, 0]$ . This renders only one item in Panda's menu feasible. We can change the prices in Panda's menu to make this feasible bundle  $[0, 1]$  the most attractive option. This process is repeated for all Panda's values, setting up a MILP to determine the specific price changes. We then repeat the procedure for Squirrel values in a grid, solving separate MILPs for each case.

This illustration of the method in Fig. [2\(](#page-3-0)b) guarantees menu compatibility over the grid. To extend this compatibility to the entire continuous value space, we also need to accommodate utility changes at off-grid bids. For this, we employ network Lipschitz smoothness to bound the menu changes between grid points, leading to estimated utility ranges for off-grid values. The MILP ensures that the utility of feasible elements exceeds that of infeasible elements by a *safety margin* at a grid point. This margin prevents utility ranges of these elements from overlapping, ensuring that infeasible elements cannot be selected at off-grid values. An example is shown in Fig. [2\(](#page-3-0)c). Compared to the scenario in Fig. [2\(](#page-3-0)b), the required price changes in this case are larger.

At deployment, and for a bid profile  $v$  that may not be on the grid and some bidder  $i$ , we feed other bids  $v_{-i}$  to the network and change the network-generated prices by adding the price adjustment from the closest grid point in terms of the  $\ell_{\infty}$ -norm. From this adjusted menu, bidder  $i$  chooses the utility-maximizing bundle.

<span id="page-7-0"></span>We prove that by working with safety margins, this process of menu adjustment guarantees menu compatibility across the entire, continuous value domain (Theorem [3](#page-22-0) and Theorem [4\)](#page-23-0) and SP (Theorem [5\)](#page-24-0). The proof also supports an approach that reduces the grid size by adapting it, locally, to the local Lipschitz constant. Additionally, given that the trained networks exhibit only a small over-allocation rate, it becomes feasible to maintain bidders' choices in the original, trained menu (before adjustment) across the majority of grid points. These strategies, among others, enable a significant reduction in the number of binary variables and the time needed to solve these MILPs. For example, we reduce the number of binary variables from 548,866 to 28 on average for an auction with 2 additive bidders, 2 items, and i.i.d. uniform values from [0, 1], which saves  $> 99.99\%$  of the running time (Table [I\)](#page-18-0).

The price transformation leaves learned menus undisturbed when they are already menucompatible. Moreover, the transformation is not manipulable through misreports because the grid points are self-bid independent and we ensure menu compatibility across the entire value domain and thus bidders cannot benefit by intentionally triggering or avoiding transformation on some part of the domain.

Given that early AMD methods used LP [\(Conitzer and Sandholm,](#page-41-2) [2002,](#page-41-2) [2004,](#page-41-3) [Conitzer,](#page-41-4) [2006\)](#page-41-4) but were restricted in discrete value domains, it is intriguing to ask whether our price-adjustment method could extend to an MILP-only formulation for SP mechanisms in continuous value domains without relying on deep learning. This question is of broader interests in the AMD community. We find that, although it is possible to formulate such MILPs using our ideas like safety margins and menu compatibility, several challenges need to be addressed to make this formulation practical. For example, deep learning initialization allows us to solely focus on price changes; without it, additional decision variables for bundles must be introduced. Moreover, our techniques that significantly accelerate MILPs depend on deep learning initialization. In its absence, MILP-only methods may encounter prohibitively long running times. Until these challenges are resolved, deep learning remains a more scalable solution with manageable complexity.

The experimental results first provide a detailed investigation of the auctions learned by GEMNET, these set against strong baseline algorithms. The comparison with Regret-Net [\(Dütting et al.,](#page-42-0) [2024\)](#page-42-0) demonstrates that GEMNET brings the advantage of menu-based auction design to multi-bidder settings, with clear and interpretable decision boundaries.

No Item 1 item 2 items 3 items

(d) GemNet: Bidder 1's allocation when  $v_2 = v_3$ 0.2,0.2,0.2 in the **3***-***bidder**, 3*-*item setting.

(e) GemNet: Bidder 1's allocation when  $v_2 = (0.5, 0.5, 0.5)$ ,  $v_3 = (0.2, 0.6, 0.7)$  in the 3-bidder, 3-item setting.

(f) GemNet: Bidder 1's allocation when  $v_2$ = $(0.2,0.5,0.9)$ ,  $v_3 = (0.7, 0.5, 0.2)$  in the 3-bidder, 3-item setting.

FIGURE 4.—Three items, additive bidders, i.i.d. uniform values on [0, 1]. The value of a particular bidder for each of three items varies in each cube, and annotation  $G_{\{S\}}$  means the bidder gets items in set S in a region. (a) One bidder. The optimal allocation structure for the 1-bidder case [\(Giannakopoulos and Koutsoupias,](#page-42-5) [2014\)](#page-42-5). An optimal analytical solution is not known for two or more bidders. (b-d) Three bidders. Fix the values of Bidders 2 and 3 to  $v_2 = v_3 = (0.2, 0.2, 0.2)$ , showing the allocation for Bidder 1 learned by AMenuNet [\(Duan](#page-41-6) [et al.,](#page-41-6) [2023\)](#page-41-6), RegretNet [\(Dütting et al.,](#page-42-0) [2024\)](#page-42-0), and GEMNET. AMenuNet learns a sub-optimal mechanism, e.g., Bidder 1 gets Item 2 even when its value is 0 (when  $v_1(2) = 0$ ,  $v_1(1) > 0.5$ ,  $v_1(3) > 0.2$ ). It is interesting that GEMNET obtains an allocation rule conforming to the optimal structure in the 1-bidder case. (e-f) Three bidders. GEMNET adapts the allocation for Bidder 1, while maintaining the highlevel structure, for different values of Bidders 2 and 3.

The comparison with affine-maximization methods [\(Duan et al.,](#page-41-6) [2023\)](#page-41-6) shows how the improved expressive capacity of GEMNET leads to a different mechanism with higher revenue (see Fig [3,](#page-5-0) for example). Working in a 3-bidder, 3-item, and uniform valuation setting and comparing to the Straight-Jacket Auction (SJA) [\(Giannakopoulos and Koutsoupias,](#page-42-5) [2014\)](#page-42-5) (Fig. [4\)](#page-8-0), which is optimal for the single-bidder, 3-item, and uniform valuation setting, we see that GEMNET generates an auction design for multiple bidders that is similar to the analytically optimal single-bidder solution when the other two bidders have identical valuations and reveals new suggested optimal solutions for asymmetric settings. Compared <span id="page-9-0"></span>with RochetNet [\(Dütting et al.,](#page-42-0) [2024\)](#page-42-0) and AMenuNet [\(Duan et al.,](#page-41-6) [2023\)](#page-41-6), it is plain that GEMNET provides enhanced interpretability on the design of optimal auctions.

We also benchmark GEMNET on various auction settings studied in the recent differentiable economics literature, scaling up to 8 bidders and 10 items. GEMNET consistently outperforms the affine-maximization methods across all settings, and gets revenue slightly below that achieved by RegretNet, which does not generate exactly SP auctions. Another validation is that GEMNET is the only deep learning method that can recover what, to our knowledge, is the only existing analytical solution for a multiple-bidder, multi-item SP auction [\(Yao,](#page-44-0) [2017\)](#page-44-0). These findings suggest that GEMNET offers improved expressiveness and substantially advances the state-of-the-art performance that can be accomplished through differentiable economics and AMD more generally.

### 1.1. *Additional related work*

In the context of *Bayesian incentive compatibility* (BIC), there have been advances in automated mechanism design through the use of *interim* representations and characterization results [\(Babaioff et al.,](#page-40-0) [2020,](#page-40-0) [Cai et al.,](#page-40-1) [2012a](#page-40-1)[,b,](#page-40-2) [Daskalakis and Weinberg,](#page-41-8) [2012,](#page-41-8) [Hartline](#page-42-9) [et al.,](#page-42-9) [2011\)](#page-42-9). A key challenge has been to transform an  $\epsilon$ −BIC mechanism, constructed on a discrete (interim) grid to an exact BIC mechanism on a continuous type space. This is similar in motivation to the transformation in the present paper, where we leverage Lipschitz continuity of a trained network in extending menu compatibility on discrete grid points to the entire continuous space. Inspired by [Hartline et al.](#page-42-9) [\(2011\)](#page-42-9), [Daskalakis and Weinberg](#page-41-8) [\(2012\)](#page-41-8) use a two step process to achieve exact BIC, with an agent type first bidding against copies of itself (drawn from the same type distribution as the agent) in a VCG auction to choose the ideal surrogate from those with types sampled on the grid, with the optimized mechanism then running on the chosen surrogates, awarding each agent the allocation and payment of its surrogate. This method and proof relies heavily on distributional analysis specific to the Bayesian setting and is unlike our menu-based, Lipschitz-reasoned transformation. A more naïve approach [\(Chawla et al.,](#page-41-9) [2007\)](#page-41-9), where each agent's reported values are rounded to the nearest grid points, with the prices discounted to preserve the incentive scheme, works in the single bidder case, but as [Daskalakis and Weinberg](#page-41-8) [\(2012\)](#page-41-8) remark, does not generalize to the multi-bidder setting. See also [Conitzer et al.](#page-41-10) [\(2021\)](#page-41-10) and [Cai et al.](#page-41-11)

<span id="page-10-0"></span> $(2021)$  for  $\epsilon$ -BIC to BIC transforms with different kinds of theoretical guarantees, including in [Conitzer et al.](#page-41-10) [\(2021\)](#page-41-10) a transform to BIC for RegretNet in the special case of uniform, independent types. It is worth highlighting that these transforms only work for BIC problems and do not extend to the case of DSIC. To our knowledge, reducing  $\epsilon$ -expected-expost-IC ( $\epsilon$ -EEIC, which is what RegretNet converges to) to DSIC remains an open question. [Conitzer et al.](#page-41-10) [\(2021\)](#page-41-10) demonstrate that  $\epsilon$ -EEIC (Theorem 11) can be reduced to BIC for independent uniform type distributions. But we know of no result for an  $\epsilon$ -EEIC to DSIC reduction. The surrogate matching technique discussed in [Daskalakis and Weinberg](#page-41-8) [\(2012\)](#page-41-8) is limited to BIC and doesn't provide an  $\epsilon$ -IC (or  $\epsilon$ -EEIC) to DSIC reduction (see Appendix K after Lemma 15). See also [Cai et al.](#page-41-11) [\(2021\)](#page-41-11).

Other work in automated mechanism design aims to optimize parametric designs within a restricted family of known SP mechanisms [\(Guo and Conitzer,](#page-42-10) [2010,](#page-42-10) [Sandholm and](#page-43-5) [Likhodedov,](#page-43-5) [2015\)](#page-43-5), e.g., affine maximizer auctions. As with the differentiable approach in [Duan et al.](#page-41-6) [\(2023\)](#page-41-6) and [Curry et al.](#page-41-5) [\(2022a\)](#page-41-5), this restricted search space is not fully expressive.

[Guo](#page-42-11) [\(2024\)](#page-42-11) integrates neural networks with mixed integer programming (MIP) in a study of worst-case VCG redistribution mechanism design for the public project problem. He proposes using a neural network to model the payment function, and makes use of MIP to solve for worst-case type profiles that maximally violate mechanism design constraints. In contrast to our approach, where the MIP is used solely to derive price adjustments ensuring feasibility, [Guo](#page-42-11) [\(2024\)](#page-42-11) uses these worst-case type profiles as training samples to adapt towards better worst-case mechanisms.

Using machine learning approaches, [Narasimhan et al.](#page-43-6) [\(2016\)](#page-43-6) consider automated design in domains without money, and [Dütting et al.](#page-42-12) [\(2015\)](#page-42-12) leverage max-margin methods to learn an optimally incentive-aligned payment rule given an allocation rule (but without finding exactly SP mechanisms except for implementable allocation rules). This paper also sits within the growing body of work integrating machine learning with economic theory and practice, e.g., [Hartford et al.](#page-42-13) [\(2016\)](#page-42-13), [Kuo et al.](#page-42-14) [\(2020\)](#page-42-14), [Ravindranath et al.](#page-43-7) [\(2023\)](#page-43-7), [Wang](#page-44-2) [et al.](#page-44-2) [\(2024a\)](#page-44-2), [Ravindranath et al.](#page-43-8) [\(2021\)](#page-43-8), [Tacchetti et al.](#page-43-9) [\(2019\)](#page-43-9), [Peri et al.](#page-43-10) [\(2021\)](#page-43-10), [Rahme](#page-43-11) [et al.](#page-43-11) [\(2021\)](#page-43-11), [Wang et al.](#page-44-3) [\(2024b\)](#page-44-3).

#### 2. PRELIMINARIES

**Sealed-Bid Auction.** We consider sealed-bid auctions with a set of n bidders,  $N =$  $\{1, \ldots, n\}$ , and m items,  $M = \{1, \ldots, m\}$ , where bidder i has a *valuation function*,  $v_i: 2^M \to \mathbb{R}_{\geq 0}$ . We consider two kinds of valuation functions. For bidders with *additive valuations*, the value for a subset of items  $S \subseteq M$  is  $v_i(S) = \sum_{j \in S} v_i(j)$ , where  $v_i(j)$  is the value for an item  $j \in M$ . Alternatively, bidders can have *unit-demand valuations*, where  $v_i(S) = \max_{j \in S} v_i(j)$  for some  $S \subseteq M$ . Valuation  $v_i$  is drawn independently from a distribution  $F_i$  defined on the space of possible valuation functions  $V_i$ . We consider bounded valuation functions:  $v_i(j) \in [0, v_{\text{max}}]$ , for  $\forall i, j$ , with  $v_{\text{max}} > 0$ . We use  $v_i = (v_i(1), \dots, v_i(m))$ to denote the value of bidder  $i$  for each of the  $m$  items.

The auctioneer is assumed to know the distribution  $\mathbf{F} = (F_1, \dots, F_n)$ , but not the realized valuation profile  $v = (v_1, \dots, v_n) \in V$ . The bidders report their valuations, perhaps untruthfully, as their *bids*,  $\mathbf{b} = (b_1, \dots, b_n)$ , where  $b_i \in V_i$ . The goal is to design an auction  $(g, p)$  to maximize expected revenue. This is an *allocation rule*,  $g: V \to \mathcal{X}$ , where  $\mathcal X$  is the space of feasible allocations (i.e., no item allocated more than once), and a *payment rule*,  $p_i: V \to \mathbb{R}_{\geq 0}$ , to each bidder *i*. We also write  $g_i(\mathbf{b}) \subseteq M$  to denote the set of items (perhaps empty) allocated to bidder i at bid profile b. The utility to bidder i with valuation function  $v_i$  at bid profile **b** is  $u_i(v_i; \mathbf{b}) = v_i(g_i(\mathbf{b})) - p_i(\mathbf{b})$ . In full generality, the allocation and payment rules may be randomized, with each bidder assumed to be risk neutral and seeking to maximize its expected utility.

In a *dominant-strategy incentive compatible* (DSIC) auction, or *strategy-proof (SP)* auction, each bidder's utility is maximized by bidding its true valuation  $v_i$  regardless of other bids; i.e.,  $u_i(v_i; (v_i, \mathbf{b}_{-i})) \ge u_i(v_i; (b_i, \mathbf{b}_{-i}))$ , for  $\forall i \in \mathbb{N}, v_i \in V_i, b_i \in V_i$ , and  $\mathbf{b}_{-i} \in V_{-i}$ . An auction is *individually rational* (IR) if each bidder receives a non-negative utility when participating and truthfully reporting:  $u_i(v_i; (v_i, \boldsymbol{b}_{-i})) \ge 0$ , for  $\forall i \in N, v_i \in V_i$ , and  $\boldsymbol{b}_{-i} \in V_{-i}$ . Following the revelation principle, it is without loss of generality to focus on direct, SP auctions, as any auction that achieves a particular expected revenue in a dominant-strategy equilibrium can be transformed into an SP auction with the same revenue. Optimal auction design therefore seeks to identify a SP and IR auction that maximizes the expected revenue, i.e.,  $\mathbb{E}_{\boldsymbol{v} \sim \boldsymbol{F}}[\sum_i p_i(\boldsymbol{v})]$ .

<span id="page-12-1"></span>Menu-Based Auction Design. In *menu-based auction design*, the allocation and payment rules for each bidder i are represented through a *menu function*,  $B_i(\mathbf{b})$ , that generates a menu to bidder *i* consisting of  $K \geq 1$  *menu elements* (in general, K may vary by bidder i and input b) for every possible bid profile b. We write  $B_i(\mathbf{b}) = (B_i^{(1)})$  $i_1^{(1)}, \ldots, B_i^{(K)}$ ), and the  $k$ th *menu element*,  $B_i^{(k)}$  $i^{(k)}_i,$  specifies a *bundle*,  $\boldsymbol{\alpha}_i^{(k)} \in [0,1]^m,$  and a *price*,  $\beta_i^{(k)} \in \mathbb{R},$  to bidder *i*. Here, we allow randomization, where  $\alpha_{ij}^{(k)} \in [0,1]$  denotes the probability that item *j* is assigned to agent i in menu element k. We refer to menu functions  $B = (B_1, \ldots, B_n)$  as corresponding to a *menu-based representation of an auction.* The following theorem gives a necessary condition for a menu-based representation of an auction to be SP. Let  $b_i({\boldsymbol\alpha}_i^{(k)})$  $\binom{\kappa}{i}$ denote the expected value (as represented by the bid  $b_i$  of bidder i) for the possibly randomized bundle  $\alpha_i^{(k)}$  $\binom{n}{i}$ .

**Theorem 1** [SP auctions via menus (necessary) [\(Hammond,](#page-42-8) [1979\)](#page-42-8)]. An auction  $(g, p)$  is *SP only if there is a menu-based representation,*  $B = (B_1, \ldots, B_n)$ *, that satisfies,* 

*1.* (Bidder Optimizing) *For every bidder* i*, and every bid profile,* b*,*

$$
(g_i(\boldsymbol{b}), p_i(\boldsymbol{b})) \in \underset{\left(\boldsymbol{\alpha}_i^{(k)}, \boldsymbol{\beta}_i^{(k)}\right) \in B_i(\boldsymbol{b})}{\arg \max} [b_i(\boldsymbol{\alpha}_i^{(k)}) - \boldsymbol{\beta}_i^{(k)}]; \text{ and } (1)
$$

*2.* (Self-Bid Independent) *For each bidder* i*, the menu function,* Bi(b)*, is independent of their own bid,*  $b_i$ *, that is*  $B_i(b_i, \mathbf{b}_{-i}) = B_i(b'_i, \mathbf{b}_{-i})$ *, for all*  $b_i, b'_i$ *, and*  $\mathbf{b}_{-i}$ *.* 

Given a menu-based representation, let  $\alpha_i^*(b)$  and  $\beta_i^*(b)$  denote the bundle and price components of the bidder-optimizing menu element for bidder  $i$  at bid profile  $b$ . In cases where the context is unambiguous, we omit the explicit dependence on b and write  $\alpha_i^*$  and  $\beta_i^*$ . We now define *menu compatibility*, which is required for a menu-based representation to provide a SP auction.

Definition 1 [Menu compatibility]. *The menus available to each bidder are* menu compatible at bid profile *b* if the bidder-optimizing choices,  $\alpha^*(b) = (\alpha_1^*(b), \dots, \alpha_n^*(b))$ , are free from over-allocation, so that  $\sum_i \boldsymbol{\alpha}_i^*(\boldsymbol{b}) \leq 1$ . A menu-based representation  $B =$  $(B_1, \ldots, B_n)$  *is* menu compatible *if the menus are menu compatible for every bid profile*  $b \in V$ .

<span id="page-12-0"></span>In words, menu compatibility requires that the bidder-optimizing choices for each bidder from its menu, at each input to the auction, are always feasible when considered together, in that no item is over-allocated.

<span id="page-13-1"></span>Theorem 2 [SP auctions via menus (sufficient) [\(Hammond,](#page-42-8) [1979\)](#page-42-8)]. *An auction defined through a menu-based representation,*  $B = (B_1, \ldots, B_n)$ *, is SP if the menu-based representation is self-bid independent, choices are bidder optimizing, and these choices satisfy menu compatibility.*

In full generality, one needs to also handle tie-breaking in defining menu compatibility (i.e., there may be ties in bidder-optimizing choices, and it is sufficient that there always exists a way to break ties across equally good, bidder-optimizing choices, so as to not to over-allocate). We do not need this because our computational framework, in the construction of the MILP for price adjustments, ensures that the best menu choices to bidders are (1) menu compatible, and (2) for each bidder, have a utility that is *strictly* larger than that of the second best choice with a safety margin that depends on the Lipschitz constant of the trained network and the distance between grid points.

In the context of menu-based auction design, the optimal auction design problem is to identify a menu-based representation that maximizes expected revenue, i.e.,  $\mathbb{E}_{\bm{v}\sim\bm{F}}[\sum_i \beta_i^*(\bm{v})]$ amongst all self-bid independent and menu compatible representations.

#### 3. THE GENERAL MENU-BASED NETWORK AND PRICE TRANSFORMATION METHOD

In this section, we introduce our method for how to learn revenue-maximizing, SP, and multi-bidder auctions. Our method comprises two key components. Sec. [3.1](#page-13-0) details the training of neural networks for self-bid independent, menu-based representations, where we introduce an *incompatibility loss function* that encourages menu compatibility. In practice, we find that this may leave a small over-allocation rate and thus a small failure of menu compatibility. To address this issue and ensure menu compatibility on the entire value domain, Sec. [3.2](#page-15-0) introduces a novel *menu transformation* technique. In Sec. [4,](#page-21-0) we prove that the auction design after transformation is menu compatible on the entire input domain, and thus exact SP.

### 3.1. *Deep Menu Learning*

<span id="page-13-0"></span>We train a neural network  $B(\theta)$  with parameterization  $\theta$  to learn a menu-based representation that maximizes revenue while also driving down the rate of menu incompatibility. Specifically,  $B(\theta)$  consists of a pair of neural network components,  $(f_{\xi_i}, q_{\zeta_i})$ , for each bidder *i*, where these are parameterized by  $\theta_i = (\xi_i, \zeta_i)$ .  $f_{\xi_i}$  is the *bundle network* for bidder

<span id="page-14-2"></span>i and generates the bundles associated with each menu element, and  $q_{\zeta_i}$  is the *price network* for bidder i and generates the prices associated with each menu element. To meet the requirement of SP (Theorem [2\)](#page-12-0), the inputs to  $f_{\xi_i}$  and  $q_{\zeta_i}$  only depend on the bid profile,  $\bm{b}_{-i}$ , of the other bidders.  $f_{\xi_i}$  generates a set of  $K-1$  bundles,  $\bm{\alpha}_i(\bm{b}_{-i};\xi_i) = f_{\xi_i}(\bm{b}_{-i}) \in$  $[0,1]^{(K-1)\times m}$ , and  $q_{\zeta_i}$  a set of  $K-1$  prices,  $\beta_i(\mathbf{b}_{-i}; \zeta_i) = q_{\zeta_i}(\mathbf{b}_{-i}) \in \mathbb{R}^{K-1}$ . The k-th row of the output of the bundle network and the  $k$ -th element of the output of the price network make up the k-th element in the menu for bidder i,  $(\alpha_i^{(k)})$  $\kappa_i^{(k)}(\boldsymbol{b}_{-i}), \beta_i^{(k)}(\boldsymbol{b}_{-i})$ ). Appendix [A.5](#page-38-0) gives a detailed description and visualization of the network architecture. Hereafter we omit the network parameters for simplicity. To ensure individual rationality (IR), we also include a fixed K-th element, with  $\alpha_i^{(K)}$  $\epsilon_i^{(K)}(\boldsymbol{b}_{-i})=\boldsymbol{0}, \, \beta_i^{(K)}$  $i^{(K)}(b_{-i})=0.$ 

During training we assume truthful inputs since we will attain a SP mechanism, and minimize:

<span id="page-14-0"></span>
$$
\mathcal{L}(\theta) = -\mathcal{L}_{\text{REV}}(\theta) + \lambda_{\text{INCOMP}} \cdot \mathcal{L}_{\text{INCOMP}}(\theta). \tag{2}
$$

The first term in this loss function is for maximizing the empirical revenue, i.e.,

<span id="page-14-1"></span>
$$
\mathcal{L}_{\text{Rev}}(\theta) = \frac{1}{|D|} \sum_{\boldsymbol{v} \in D} \left[ \sum_{i \in N} \sum_{k \in [K]} \boldsymbol{z}_i^{(k)}(\boldsymbol{v}) \beta_i^{(k)}(\boldsymbol{v}_{-i}) \right], \tag{3}
$$

where D is a set of bidders' values sampled from F and  $z_i^{(k)}$  $i^{(k)}(v)$  is obtained by applying the differentiable SoftMax function to the utility of bidder  $i$  being allocated the  $k$ -th menu choice, i.e.,

$$
\boldsymbol{z}_{i}^{(k)}(\boldsymbol{v}) = \text{SoftMax}_{k} \left( \lambda_{\text{SoftMax}} \cdot u_{i}^{(1)}(\boldsymbol{v}), \ldots, \lambda_{\text{SoftMax}} \cdot u_{i}^{(K)}(\boldsymbol{v}) \right). \tag{4}
$$

For additive valuations, the utility  $u_i^{(k)}$  $\boldsymbol{v}_i^{(k)}(\boldsymbol{v}) = \boldsymbol{v}_i^{\text{T}} \boldsymbol{\alpha}_i^{(k)}$  $\beta_i^{(k)}(\boldsymbol{v}_{-i})-\beta_i^{(k)}$  $i^{(\kappa)}(\boldsymbol{v}_{-i})$ . This also applies to unit-demand bidders with the constraint  $\sum_j \alpha_{ij}^{(k)} = 1$ . Also,  $\lambda_{\text{SOFTMAX}} > 0$  is a scaling factor that controls the quality of the approximation.

Incompatibility loss. Until this point, the network formulation generalizes Rochet-Net [\(Dütting et al.,](#page-42-0) [2024\)](#page-42-0), allowing the menu of each bidder to depend on the bids of others. The new challenge in the multi-bidder setting is that bidder optimizing choices may be incompatible, with one or more items needing to be over-allocated, when taking together the choices of each bidder. To address this issue, the second term in the loss function (Eq. [2\)](#page-14-0)

<span id="page-15-2"></span>is the *incompatibility loss*:

<span id="page-15-1"></span>
$$
\mathcal{L}_{\text{INCOMP}}(\theta) = \frac{1}{|D|} \sum_{\boldsymbol{v} \in D} \left[ \text{ReLU} \left( \sum_{i \in N, k \in [K]} z_i^{(k)}(\boldsymbol{v}) \alpha_i^{(k)}(\boldsymbol{v}_{-i}) - (1 - s_f) \right) \right], \quad (5)
$$

where  $s_f > 0$  is a *safety margin*, and this loss term is associated with scaling factor,  $\lambda_{\text{INCOMP}} > 0$ , in Eq. [2,](#page-14-0) balancing revenue and menu incompatibility. This incompatibility loss sums up the SoftMax-weighted bundles selected by each bidder and encourages compatible choices, with a positive loss only when the summed allocation is larger than  $1 - s_f$ for one or more items. The loss (Eq. [2\)](#page-14-0) follows the commonly used structure of Lagrangianbased optimization methods, where the incompatibility term acts as a Lagrange multiplier that encourages feasibility.

Safety margin. We achieve full menu compatibility over the domain through the menu transformation technique introduced in Sec. [3.2.](#page-15-0) There, we setup a series of MILPs to enforce menu compatibility on a grid of bidder values. With the *Lipschitz constant* of the bundle network,  $L_a > 0$ , and the interval (in  $\ell_{\infty}$ -norm) between two grid points used in the price adjustment,  $\epsilon > 0$ , we prove in Sec. [4](#page-21-0) that a safety margin  $s_f = n \cdot \epsilon \cdot L_a/2$  (where n is the number of bidders and  $s_f$  is also used in the construction of the MILP) allows menu compatibility on the grid to extend to the entire continuous value domain. A technical challenge is that a large safety margin can lead to reduced revenue. To limit the size of the safety margin, we constrain the Lipschitz constant of the bundle network using *spectral normalization* [\(Miyato et al.,](#page-43-12) [2018\)](#page-43-12). This technique, when applied to fully connected neural networks, involves dividing the weight matrix of each layer by its largest singular value. In our experiments, the Lipschitz constant  $L_a$  is often in range  $1e-5$  to  $1e-4$  following spectral normalization. Sec. [5.1](#page-25-0) gives more information about our network architecture and training schemes.

### 3.2. *Price Adjustment as Menu Transformation*

<span id="page-15-0"></span>The trained bundle and price networks generate for each bidder i a menu  $B_i(\mathbf{v}_{-i}; \theta_i) =$  $(\alpha_i(v_{-i}),\beta_i(v_{-i}))$  given  $v_{-i}$ . Empirically, we find that these menus suffer from a small rate of incompatibility (i.e., item over-allocation). To address this problem, we introduce a menu transformation technique, applied after training but before using the trained mechanism, to modify the prices in menus and ensure menu compatibility.

The menu transformation adjusts the prices in a menu. For this, we generate a grid of bidders' values  $V = V_i \times V_{-i}$ , which we use to define a series of mixed integer linear programs (MILPs). These programs are designed to determine price changes that ensure bidder-optimizing choices are compatible for all grid points. We prove in Sec. [4](#page-21-0) that menu compatibility on this discrete grid extends to the entire continuous value domain. The transformed mechanism is defined on the entire continuous value domain. For a general input  $v'$  that may not be on the grid and some bidder  $i$ , we use the outputs from the trained bundle and price networks at  $v'_{-i}$  to obtain a pre-transformed menu for i, and then adjust the menu using the price adjustments from the closest grid point in terms of  $\ell_{\infty}$ -norm, i.e.,  $\forall v' \in \{v'' \mid ||v'' - v||_{\infty} \le \epsilon/2\}$  uses the price adjustments at grid point v.

We first illustrate the method in the two-bidder case. For each  $v_{-i} \in V_{-i}$ , we construct a separate MILP, where the decision variables are adjustments to the prices  $\Delta \beta_i^{(k)}$  $i^{(\kappa)}$ ,  $k \in$  $[K-1]$ , the constraints are to ensure that for any  $v_i \in V_i$ , the two bidders will make compatible choices, and the objective is to minimize the sum absolute price adjustment. As  $v_i$ varies, the utility-optimizing choice of i may vary, and so too may the menu of bidder  $-i$ and thus the choice of bidder  $-i$ . We achieve compatibility between the choices by bidder i at grid  $\mathcal{V}_i$  and bidder  $-i$  at value  $\boldsymbol{v}_{-i}$ .

Let  $\mathcal{V}_i = \{ \bm{v}_{i,(\ell)} \}_{\ell=1}^{|\mathcal{V}_i|}$ . For each  $\bm{v}_{i,(\ell)} \in \mathcal{V}_i$  (all  $\bm{v}_{i,(\ell)}$  share the same menu  $B_i(\bm{v}_{-i})$  as  $\bm{v}_{-i}$ is fixed), there are two kinds of menu elements:

(i)  $k \in B_{i(\ell)}^{\text{comp}}$  $\sum_{i,(\ell)}^{\text{comp}}(\boldsymbol{v}_{-i}),$  which means the k-th menu element is compatible with the menu element selected by bidder  $-i$  given  $v_{i,(\ell)}$ :

<span id="page-16-0"></span>
$$
\boldsymbol{\alpha}_{-i}^*(\boldsymbol{v}_{i,(\ell)}) + \boldsymbol{\alpha}_i^{(k)}(\boldsymbol{v}_{-i}) \le 1 - s_f; \tag{6}
$$

(ii)  $k \in B_{i(\ell)}^{\text{incomp}}$  $\sum_{i,(l)}^{\text{incomp}}(v_{-i})$ , which means the k-th menu element is incompatible with the choice of bidder  $-i$ .

Safety margin  $s_f$  is used to define these two kinds of menu elements, which affects the variables in the MILP. We use the following MILP to adjust prices associated with bidder i's menu elements:

> Decision variables: price adjustments $\{\Delta \beta_i^{(k)}\}$  $\{ \binom{k}{i} \}_{k=1}^{K-1}$ ;

Binary variables:  $z^{(\ell k)}$ , for  $l \in [|\mathcal{V}_i|]$ ,  $k \in B_{i}^{comp}$  $\sup_{i,(\ell)}^{\text{comp}}(\boldsymbol{v}_{-i});$  Variables:  $U_{(\ell)}$ ;

<span id="page-17-0"></span>
$$
\min \sum_{k \in [K-1]} |\Delta \beta_i^{(k)}| \tag{Objective}
$$

s.t. For 
$$
\forall \ell, \forall k \in B_{i,(\ell)}^{\text{comp}}(\boldsymbol{v}_{-i})
$$
:  
\n
$$
U_{(\ell)} \ge \mathbf{v}_{i,(\ell)}^{\text{T}} \mathbf{\alpha}_i^{(k)} - \beta_i^{(k)} - \Delta \beta_i^{(k)} + (1 - z^{(\ell k)}) s_m,
$$
\n
$$
U_{(\ell)} \le \mathbf{v}_{i,(\ell)}^{\text{T}} \mathbf{\alpha}_i^{(k)} - \beta_i^{(k)} - \Delta \beta_i^{(k)} + (1 - z^{(\ell k)}) M,
$$
\n
$$
z^{(\ell k)} \in \{0, 1\}, \sum_{k \in B_{i,(\ell)}^{\text{comp}}(\boldsymbol{v}_{-i})} z^{(\ell k)} = 1,
$$
\n(7)

For  $\forall \ell, \forall k' \in B_{i(\ell)}^{\text{incomp}}$  $i,(\ell)$ (Constraint Set 2) ′

<span id="page-17-3"></span><span id="page-17-2"></span><span id="page-17-1"></span>
$$
U_{(\ell)} \geq \boldsymbol{v}_{i,(\ell)}^{\mathrm{T}} \boldsymbol{\alpha}_i^{(k')} - \beta_i^{(k')} - \Delta \beta_i^{(k')} + s_m.
$$
 (8)

As we will explain,  $s_m > 0$  and  $M > 0$  are set to be suitable constants and, in full generality, the price changes may be positive or negative. This MILP ensures that the best compatible choice for i at each possible value  $v_i$ , and fixing some  $v_{-i}$ , is more appealing than any incompatible choice. In [\(Constraint Set 1\)](#page-17-0), we use the "big-M method" and introduce binary variables  $z^{(\ell k)} \in \{0,1\}$  to identify the maximum utility  $U_{(\ell)}$  achievable by compatible elements.  $z^{(\ell k)}$  is 1 only when the k-th menu element is the best choice of bidder *i* of type  $v_{i,(\ell)}$ . M is set to be sufficiently large (see Appendix [A.1](#page-33-0) for the detail). In [\(Constraint Set 2\)](#page-17-1), we enforce that  $U_{(\ell)}$  is larger than the utility of any incompatible element by a second *safety margin*,  $s_m = L_a(mv_{\text{max}}\epsilon + m\epsilon^2/2) + \epsilon L_p + \epsilon$ , where  $\epsilon$  is the interval (in  $\ell_{\infty}$ -norm) between two grid points in V,  $L_a$  the Lipschitz constant of the bundle network, and  $L_p$  the Lipschitz constant of the price network. Similarly, we introduce  $s_m > 0$  in Eq. [7,](#page-17-2) so that the utility gap between the best and the second best compatible choice is at least  $s_m$ . Together, Eq. [7](#page-17-2) and [8](#page-17-3) ensures that the utility of the best menu choice is larger than the others by at least  $s_m$ . We will see in Sec. [4](#page-21-0) that this safety margin allows us to provably establish menu compatibility, though this transformation, on the entire continuous value domain. This also removes any tie-breaking issue in making bidder-optimizing choices.

The objective of the MILP is to minimize the sum absolute price change. We include the IR  $(K-th)$  element when finding the maximum achievable utility of feasible elements

### TABLE I

<span id="page-18-0"></span>REDUCING MILP COMPLEXITY FOR THE 2-BIDDER, 2-ITEM, I.I.D. UNIFORM VALUES ON [0, 1] SETTING.  $100 \times 100$  GRID POINTS ARE USED FOR EACH BIDDER EXCEPT WHEN USING THE ADAPTIVE GRID STRATEGY. STRATEGIES ARE INCREMENTALLY ADDED ROW BY ROW.

Strategy	$#$ MILP	Per MILP Complexity (Mean $\pm$ Var)				
		# Constraints	# Binary Variables	Run Time(s)		
Nothing	10,000	$3,568,866 \pm 271,276$	548,866±271,276	9771±11,985		
$+$ 0-Violation	3527	$3,568,866 \pm 271,276$	548,866±271,276	$9771 \pm 11,985$		
+ Keep-Choice	3527	$2,550,387 \pm 244,295$	$38,312 \pm 18,647$	$629.3 + 154.3$

+ Adaptive Grid	3527	$750 + 456$	$28 + 188.6$	$1.09 + 0.44$		
<b>Overall Reduction</b>	$-64.63\%$	$-99.98\%$	$-99.995\%$	$-99.99\%$		

in [\(Constraint Set 1\)](#page-17-0), as this is always a compatible choice regardless of the selection of bidder  $-i$ , and fix the price of this element to 0 during transformation. For the two-bidder case, it is sufficient to guarantee menu compatibility by only adjusting the menu prices of bidder 1.

For the case of two or more bidders, the price adjustment process proceeds for each bidder in increasing order of bidder index. For bidder  $i$ , we again consider different possible values  $v_{-i}$  on a grid, and consider different values  $v_i \in V_i$  in constructing an MILP for each  $v_{-i}$ . This MILP is the same as in the two-bidder case after identifying compatible menu choices. Considering the already transformed menus for the preceding bidders in the transform order, the  $k$ -th element of bidder  $i$  is compatible if:

<span id="page-18-1"></span>
$$
\boldsymbol{\alpha}_i^{(k)}(\boldsymbol{b}_{-i}) + \min\left(1 - s_f, \sum_{j=1}^{i-1} \tilde{\boldsymbol{\alpha}}_j^*(\boldsymbol{b}_{-j}) + \sum_{j=i+1}^n \boldsymbol{\alpha}_j^*(\boldsymbol{b}_{-j})\right) \le 1 - s_f,
$$
(9)

where  $\tilde{\alpha}^*_i$  $j^*(b_{-j})$  is the optimal choice for bidder  $j < i$  given its already transformed menu. We clip the aggregate allocation of other bidders to  $1 - s_f$  because even a 0 allocation is infeasible if this aggregate allocation of other bidders is larger than  $1 - s_f$ . In Theorem [4,](#page-23-0) we prove that these MILP formulations, when solved for all bidders and considering all grid points of other bidders, ensures menu compatibility on the entire, continuous value domain.

#### 3.3. *Accelerating the MIP*

<span id="page-19-0"></span>The challenge with solving this series of MILPs lies in the computational efficiency. In its basic form, for each  $v_{i,(\ell)} \in V_i$ , a binary variable is assigned to each feasible menu element, resulting in a total of  $\sum_{\ell \in [|\mathcal{V}_i|]} |B_{i, (\ell)}^{\mathsf{comp}}|$  $\sup_{i,(\ell)}^{\text{comp}}(v_{-i})$  binary variables in the MILP to transform *i*'s menu for  $v_{-i}$ . Besides, the number of MILPs grows exponentially with the number of bidders and items because we need a MILP for each grid point  $v_{-i} \in \mathcal{V}_{-i}$ .

Fortunately, our deep learning process already provides a menu representation that is Lipschitz smooth and almost menu compatible, enabling us to develop the following strategies to greatly reduce the running time without sacrificing the guarantee on menu compat-ibility on the full domain. We show in Table [I](#page-18-0) that these strategies allow us to harness our computational pipeline to efficiently find SP, highly revenue-optimizing auctions.

(I) 0-Violation. For those grid points  $v_{-i} \in V_{-i}$  where the menus are already compatible, we do not need to run the MILP. This strategy reduces the number of MILPs to solve.

**(II) Keep-Choice**. In each MILP, for most  $v_{i,(\ell)}$ , the learned networks provide a feasible joint allocation, and we can seek to retain the choice of bidder  $i$  in this case during price transformation. These *keep-choice* (KC) constraints can be described by linear expressions without introducing a binary variable:

$$
\boldsymbol{v}_{i,(\ell)}^{\mathrm{T}} \boldsymbol{\alpha}_i^{(k)} - \beta_i^{(k)} - \Delta \beta_i^{(k)} \leq \boldsymbol{v}_{i,(\ell)}^{\mathrm{T}} \boldsymbol{\alpha}_i^* - \beta_i^* - \Delta \beta_i^*, \ \ \forall k \in [K],
$$
 (KC)

where  $(\alpha_i^*, \beta_i^*)$  is the optimal choice for  $v_{i,(\ell)}$  in the network-generated menus. The critical consideration here is the extent to which we can apply KC constraints. Applying KC indiscriminately to all compatible  $\bm{v}_{i,(\ell)}$  might render the MILP at  $\bm{v}_{-i}$  infeasible. This is because addressing other values of  $v_i$  with over-allocation may require price adjustments that lead to changes in the agent's choice at  $v_{i,(\ell)}$ . We adopt a heuristic approach that works well empirically: sort compatible  $v_{i,(\ell)}$  by ascending difference between the utilities of their best and second-best menu elements, and apply the KC constraint to the top  $c\%$  compatible  $v_{i,(\ell)}$ , for some choice of  $c \geq 0$ . This heuristic is grounded in the observation that our price adjustment process changes the prices only slightly and bidders tend to stick with their initial choices when the alternatives are significantly less favorable. In Table [I,](#page-18-0) we choose  $c = 95$ , and find this strategy reduces the number of binary variables in each MILP by 93.02% on average. If this  $c \ge 0$  value makes an MILP infeasible, we iteratively reduce

 $c$  value by 5 until the MILP becomes feasible, noting that the MILP is always feasible when  $c = 0$ , as all KC constraints are removed.

**(III) IR-Screening**. For those  $v_{i,(\ell)}$  to which we introduce binary variables and apply the big-M method, we do not need a binary variable for each compatible menu element. We find that most (typically  $> 99\%$ ) of the learned menu elements have a negative utility. By adding a constraint that all price adjustments,  $\Delta \beta_i^{(k)}$  $i^{(k)}$ , are non-negative, the utility of these menu elements remain negative and they are not selected over the null (utility 0) choice that ensures IR. In this way, we can safely remove the corresponding binary variables and constraints for these elements. In Table [I,](#page-18-0) this strategy further removes  $89.71\%$  of the binary variables and  $99.94\%$  of the constraints on average.<sup>[1](#page-20-0)</sup>

(IV) Adaptive Grid. Our theoretical analyses in Sec. [4](#page-21-0) provides for an opportunity to adaptively decrease the size of the grid. Appendix [A.4](#page-35-0) describes this *adaptive grid* strategy in detail.

### 3.4. *Discussion*

Our method makes use of MILPs to ensure the compatibility of learned menus on the entire value domain. An interesting question is whether this approach may also open up a new, purely MILP-based methodology. To the best our knowledge, there is no previous work on computing revenue-maximizing menus from scratch with MILPs and exploring new MILP-only methods, with generalization away from a grid and the new ideas introduced here of safety margins, together with menu-based representations, seems possible and interesting to explore in future work. For example, starting from our MILPs, one could additionally introduce decision variables for menu bundles. Although worth exploring, we identify three challenges stemming from the absence of deep learning initialization and hope to spark further investigation with this brief discussion.

<span id="page-20-0"></span><sup>&</sup>lt;sup>1</sup>Allowing negative price changes has a small positive influence on revenue, but we find empirically that this effect is very limited (e.g., from 5.0207 to 5.0271 in the 3-bidder, 2-item setting with the irregular valuation distribution ( $^3_2 IRR_{\tt Add}$ )). One explanation is that our transform tends to address over-allocation, where increasing prices can help, e.g., by encouraging the null allocation option. Therefore, we recommend adopting non-negative price adjustments along with IR-screening for a good revenue-computational cost tradeoff.

(1) The lack of initialization through deep learning would preclude sequentially changing the menus of individual bidders while keeping the menus of others fixed, because it is hard to distinguish compatible and incompatible menu elements as in Eq. [6](#page-16-0) when constructing MILPs. Rather, a pure MILP approach would naively need to consider the menus of all bidders simultaneously, within a single MILP. This MILP would require an additional  $GKmn$ decision variables to model bundles, where the grid size  $G$  increases exponentially with the number of items  $m$  and the number of bidders  $n$ , and  $K$  is the menu size. It would also necessitate an additional  $O(GKn)$  binary variables and  $O(Gm)$  bilinear (as they involve multiplication of bundle variables with binary variables) menu-compatibility constraints using the big-M method.

(2) Furthermore, techniques in Table 1, which cut price-adjustment time by >99.99%, all depend on initialization through deep learning. For example, the 0-violation and keepchoice methods are applicable when menus are already compatible after deep learning, and IR-screening relies on certain menu elements having negative utilities after deep learning. Without deep initialization, MILP-only methods might suffer from prohibitively long running times.

(3) Another challenge will be determining how to set the MILP's objective. For example, one could seek to maximize a likelihood-weighted, accumulated price at grid points, a bilinear function (as it involves multiplication of price variables with binary variables), but this may result in poor "off-grid" performance if the grid is sparse. Conversely, with deep learning, we can opt to minimize absolute price changes in price transformation, following learning to maximize expected revenue (while also considering menu incompatibility) during deep learning. This formulation of the price transformation problem is well suited to revenue goals and empirically proves effective even when using a relatively coarse grid.

### 4. EXACT STRATEGY-PROOFNESS

<span id="page-21-0"></span>In the price adjustment stage, we use a grid of values to transform the menu. In this section, we establish that the menu compatibility established on this grid extends to the entire continuous value domain. The proof leverages the Lipschitz smoothness of the neural networks, which bounds the changes of the menu across two grid points.

We begin our analysis with the two-bidder case. With the  $\ell_{\infty}$  distance between two grid points being  $\epsilon$ , the proof establishes menu compatibility throughout the entire value domain by proving that menu compatibility at a grid point is maintained for all values within an  $\ell_{\infty}$ distance of  $\frac{\epsilon}{2}$  from the point. The following theorem follows from the use of safety margins  $s<sub>m</sub>$  and  $s<sub>f</sub>$  in the transformation, which are set to depend on  $\epsilon$  and the Lipschitz constants of the menu networks.

<span id="page-22-0"></span>**Theorem 3** [2-Bidder Menu Compatibility]. *For the two-bidder case, if*  $v = (v_1, v_2)$  *is a grid point used in the menu transformation, then the transformed menu is compatible for any*  $v' \in \mathcal{N}_{\frac{\epsilon}{2}} = \{v' \mid ||v' - v||_{\infty} \leq \epsilon/2\}.$ 

PROOF: (I) We first prove that neither bidder will change their menu selection in  $\mathcal{N}_{\frac{\epsilon}{2}}$ . Without loss of generality, we consider bidder  $i$ 's menu, which is generated conditioned on the bidder  $-i$ 's value. The utility changes of the k-th element in bidder i's menu in  $\mathcal{N}_{\frac{\epsilon}{2}}$  is affected by two factors: the changes in its allocation and price due to the varying network input  $v_{-i}$ ; and the changes in value  $v_i$ . Although the utility also depends on the price adjustments, we use the adjustments at v for any  $v' \in \mathcal{N}_{\frac{\epsilon}{2}}$ , which is a constant adjustment and does not result in a utility change in  $\mathcal{N}_{\frac{\epsilon}{2}}$ . Specifically, the changes in the allocation and price are bounded when the menu networks are Lipschitz smooth:  $\|\tilde \Delta \bm\alpha_i^{(k)}\|$  $\|u^{(k)}_i\|_\infty \leq L_a \|\Delta \boldsymbol{v}_{-i}\|_\infty \leq \frac{\epsilon}{2}$  $\frac{\epsilon}{2}L_a$ , and  $\|\tilde{\Delta} \beta_i^{(k)}\|$  $\|u_i^{(k)}\|_\infty \leq L_p \|\Delta \boldsymbol{v}_{-i}\|_\infty \leq \frac{\epsilon}{2}$  $\frac{\epsilon}{2}L_p$ , and the change  $\|\Delta\bm{v}_i\|_\infty$  in  $\bm{v}_i$  is bounded by  $\epsilon/2.$  Therefore, the change in the utility of any menu element  $k$ is upper bounded by:  $\|\tilde{\Delta} u_i^{(k)}\|$  $\| \boldsymbol{\epsilon}_i^{(k)} \| \leq \| \Delta \boldsymbol{v}_i^{\text{T}} \boldsymbol{\alpha}_i^{(k)} \|$  $\hat{u}_i^{(k)} \| + \| \boldsymbol{v}_i^{\text{T}} \tilde{\Delta} \boldsymbol{\alpha}_i^{(k)}$  $\hat{u}_i^{(k)} \| + \| \Delta \boldsymbol{v}_i^T \tilde{\Delta \boldsymbol{\alpha}}_i^{(k)}$  $\binom{k}{i}\|+\|\tilde{\Delta}\beta_i^{(k)}\|$  $||\xi_i^{(\kappa)}|| \leq$  $\|\Delta\bm{v}_i\|_{\infty}+mv_{\max}\|\tilde\Delta\bm{\alpha}_i^{(k)}\|$  $_{i}^{(k)}\|_{\infty}+m\|\tilde{\Delta}\boldsymbol{\alpha}_{i}^{(k)}$  $\hat{u}_i^{(k)}\|_{\infty}\|\Delta\boldsymbol{v}_i\|_{\infty}+\|\tilde{\Delta}\beta_i^{(k)}\|$  $\|\xi_i^{(k)}\| \leq \frac{\epsilon}{2} + m v_{\max} \frac{\epsilon}{2}$  $\frac{\epsilon}{2}L_a +$  $m\frac{\epsilon^2}{4}$  $\frac{\epsilon^2}{4}L_a+\frac{\epsilon}{2}$  $\frac{\epsilon}{2}L_p = s_m/2.$ 

Suppose that the price adjustment to the k-th element is  $\Delta \beta_i^{(k)}$  $i^{(k)}$ , and bidder *i* selects  $(\alpha_i^*, \beta_i^* + \Delta\beta_i^*)$  at  $v_i$ . Then, at  $\forall v' \in \mathcal{N}_{\frac{\epsilon}{2}}$ , for any other menu element k, we have

$$
u_i^*(\mathbf{v}'_i) - u_i^{(k)}(\mathbf{v}'_i) \ge (u_i^*(\mathbf{v}_i) - ||\tilde{\Delta}u_i^*||) - (u_i^{(k)}(\mathbf{v}_i) + ||\tilde{\Delta}u_i^{(k)}||) \ge u_i^*(\mathbf{v}_i) - u_i^{(k)}(\mathbf{v}_i) - s_m.
$$

Including the safety margin  $s_m$  in Eq. [7](#page-17-2) and [8](#page-17-3) ensures that the utility of the best element in the menu is larger than the second best element by at least  $s_m: u_i^*(v_i) - u_i^{(k)}$  $i^{(\kappa)}(\boldsymbol{v}_i) \geq s_m.$ It follows that  $u_i^*(v'_i) - u_i^{(k)}$  $\mathbf{v}_i^{(k)}(\mathbf{v}_i') \geq 0$ , which means the bidder will not change its menu selection.

(II) Since the bidders do not change their selection in  $\mathcal{N}_{\frac{\epsilon}{2}}$ , the only possibility of incompatibility comes from the change in the menu element selected by bidders due to the varying network input. For each bidder *i*, this change is bounded by  $\|\tilde{\Delta} \alpha_i^*\|_{\infty} \le L_a \|\Delta v_{-i}\|_{\infty} \le$  $\epsilon$  $rac{\epsilon}{2}L_a$ .

Here our safety margin  $s_f = n \cdot \epsilon \cdot L_a/2$  comes into play. With  $s_f$  in the incompatibility loss (Eq. [5\)](#page-15-1) and the transformation process (Eq. [6\)](#page-16-0), we have

$$
\begin{aligned} \boldsymbol{\alpha}_i^{(k^*_i)}(\boldsymbol{v}') + \boldsymbol{\alpha}_{-i}^{(k^*_{-i})}(\boldsymbol{v}') \leq \boldsymbol{\alpha}_i^{(k^*_i)}(\boldsymbol{v}) + \boldsymbol{\alpha}_{-i}^{(k^*_{-i})}(\boldsymbol{v}) + \|\tilde{\Delta}\boldsymbol{\alpha}_i^{(k^*_i)}\|_{\infty} + \|\tilde{\Delta}\boldsymbol{\alpha}_{-i}^{(k^*_{-i})}\|_{\infty} \\ \leq 1 - \epsilon L_a + 2\cdot\frac{\epsilon}{2}L_a = 1. \end{aligned}
$$

Here,  $k_i^*$  and  $k_{-i}^*$  is the choice of bidder i and  $-i$  at  $v_i$ , respectively. This means that the joint allocation is always feasible in  $\mathcal{N}_{\frac{\epsilon}{2}}$ . *Q.E.D.*

We now extend the discussion to the cases of more than two bidders.

<span id="page-23-0"></span>**Theorem 4** [General *n*-Bidder Menu Compatibility]. For the *n*-bidder case, if  $v =$  $(v_1, \dots, v_{-n})$  *is a grid point used in the menu transformation, then the transformed menu is compatible for any*  $v' \in \mathcal{N}_{\frac{\epsilon}{2}} = \{v' \mid ||v' - v||_{\infty} \leq \epsilon/2\}.$ 

PROOF: (I) We first prove by contradiction that the joint allocation of bidders at any grid point after transformation is at most  $1 - s_f$ . Assume that, at a grid point, we have  $\sum_{i=1}^{n} \tilde{\alpha}_{ij}^* (\boldsymbol{b}_{-i}) > 1 - s_f$  for some item j, where  $\tilde{\boldsymbol{\alpha}}_i^*$  $i^*(b_{-i})$  is the allocation for bidder i given the transformed menu. Then there must be a bidder  $1 < q \le n$  satisfying that  $\sum_{i=1}^{q-1} \tilde{\alpha}_{ij}^*(b_{-i}) \leq 1 - s_f$  and  $\sum_{i=1}^{q} \tilde{\alpha}_{ij}^*(b_{-i}) > 1 - s_f$ . This is because the allocation to bidder 1 must follow  $\tilde{\alpha}_i^*$  $i^*(b_{-i}) \leq 1 - s_f$ . Otherwise, the left-hand side of Eq. [9](#page-18-1) for bidder 1 is larger than the right-hand side.

We take a closer look at bidder q. Suppose it selects  $\tilde{\alpha}_{qj}^*(b_{-i})$  after price adjustment. Due to the formulation of our MILPs (Eq. [9\)](#page-18-1), we have

<span id="page-23-1"></span>
$$
\tilde{\alpha}_{qj}^*(\boldsymbol{b}_{-i}) + \min\left(1 - s_f, \sum_{i=1}^{q-1} \tilde{\alpha}_{ij}^*(\boldsymbol{b}_{-i}) + \sum_{i=q+1}^{n} \alpha_{ij}^*(\boldsymbol{b}_{-i})\right) \le 1 - s_f \tag{10}
$$

We analyze two possible scenarios based on the value of the sum inside the min function. (1) If  $\sum_{i=1}^{q-1} \tilde{\alpha}_{ij}^*(b_{-i}) + \sum_{i=q+1}^n \alpha_{ij}^*(b_{-i}) \ge 1 - s_f$ , it follows from Eq. [10](#page-23-1) that  $\tilde{\alpha}_{qj}^*(b_{-i}) + 1$  $s_f\leq 1-s_f,$  indicating that  $\tilde{\alpha}_{qj}^*(\bm{b}_{-i})=0.$  This contradicts the assumption  $\sum_{i=1}^{q-1}\tilde{\alpha}_{ij}^*(\bm{b}_{-i})\leq 1$  $1 - s_f$  and  $\sum_{i=1}^q \tilde{\alpha}_{ij}^*(b_{-i}) > 1 - s_f$ . (2) If  $\sum_{i=1}^{q-1} \tilde{\alpha}_{ij}^*(b_{-i}) + \sum_{i=q+1}^n \alpha_{ij}^*(b_{-i}) < 1 - s_f$ , we have  $\sum_{i=1}^q \tilde{\alpha}_{ij}^*(b_{-i}) + \sum_{i=q+1}^n \alpha_{ij}^*(b_{-i}) < 1 - s_f$ , which is also impossible because  $\sum_{i=1}^q \tilde{\alpha}_{ij}^* (\bm{b}_{-i}) + \sum_{i=q+1}^n \alpha_{ij}^* (\bm{b}_{-i}) \ge \sum_{i=1}^q \tilde{\alpha}_{ij}^* (\bm{b}_{-i}) > 1 - s_f.$ 

(II) We then follow the case analysis in Theorem [3](#page-22-0) to prove the menu compatibility for any  $v' \in \mathcal{N}_{\frac{\epsilon}{2}}$ . For case (I), for any menu element of any bidder *i*, the utility change in  $\mathcal{N}_{\frac{\epsilon}{2}}$  is still upper bounded by  $s_m/2$ . Therefore, our safety margin in Eq. [7](#page-17-2) and [8](#page-17-3) can still guarantee that no bidder changes their selections in  $\mathcal{N}_{\frac{\epsilon}{2}}$ . For case (II), the bundle selected by each bidder changes by at most  $\epsilon \cdot L_a/2$ . As a result, the sum allocation changes by at most  $n/2 \cdot \epsilon \cdot L_a = s_f /$ , and remains smaller than 1.  $Q.E.D.$ 

With the guarantee of menu compatibility, we get all the components required to prove that our computational pipeline generates exactly SP auctions.

<span id="page-24-0"></span>Theorem 5 [Exact Strategy-Proofness]. *The* GEMNET *framework ensures SP auction mechanisms.*

PROOF: By Theorem [2,](#page-12-0) a menu-based mechanism is SP if (1) menus are self-bid independent, and (2) choices are bidder optimizing, and (3) we have menu compatibility.

(I) The menu networks satisfy conditions (1) and (2). Bidder i's menu is generated by a network conditioned on the bids of others and is self-bid independent. The mechanism then selects for each bidder the menu element with the highest utility according to its report.

(II) The price adjustment process does not violate these two conditions. (1) This step uses a grid that is independent of specific bid values and moreover, specific bids do not exert any influence on the construction of the MILPs. Therefore, the price changes as the outcome of this MILP are independent from specific bids. (2) This step does not alter the logic of the menu-based representation. After price adjustments, each bidder  $i$  still faces a menu that's generated (and transformed) independently of its report (misreporting to any  $v'_i \neq v_i$  does not change the menu bidder  $i$  receives), and bidder  $i$  still gets the menu element with the highest utility based on its report (considering adjusted prices). No bidder can intentionally trigger or avoid the price adjustment process by misreporting.

(III) Menu compatibility is ensured over the entire value domain (Theorem [4\)](#page-23-0). *Q.E.D.*

#### TABLE II

<span id="page-25-2"></span><span id="page-25-1"></span> ${}_m^nU_{\mathtt{Add}/\mathtt{Unit}}$  REPRESENTS  $n$  BIDDERS,  $m$  ITEMS, AND ADDITIVE OR UNIT-DEMAND VALUATIONS, WITH VALUES UNIFORMLY DISTRIBUTED ON  $[0, 1]$ . The revenue of GemNet consistently exceeds all SP BASELINES AND IS CLOSE TO THAT OF REGRETNET, WHICH IS NOT EXACTLY SP. THE LEARNED AUCTIONS ARE VISUALIZED IN FIGS. [3,](#page-5-0) [4,](#page-8-0) AND [5,](#page-26-0) AND SHOW AN IMPROVED ALLOCATION STRUCTURE IN GEMNET. SEE APPENDIX [A.3](#page-35-1) FOR THE DETAILED SETUP OF BASELINES.

In all tables, we report the better performance of RegretNet and RegretFormer. Their IC violation is approximated by using gradient ascent to find a good strategic bid that leads to higher utility. The real regret might be higher than shown.

### 5. EXPERIMENTAL RESULTS

We conduct a comprehensive set of experiments to evaluate GEMNET against various baselines, and to understand how GEMNET works by visualizing and analyzing the learned mechanisms. Specifically, we organize our experiments by answering the following questions: (1) Can GEMNET outperform existing deep auction methods? How closely do existing solutions such as those coming from AMAs and RegretNet approach the optimal designs? (Sec. [5.3\)](#page-28-0); (2) Can GEMNET recover the optimal auctions for settings where an analytical solution is known? (Sec.  $5.4$ ); (3) How are the mechanisms learned by GEM-NET different from those learned by other deep methods? (Sec. [5.2](#page-27-0) and [5.5\)](#page-30-0); and (4) How can we construct adaptive grids? (Appendix. [A.4.](#page-35-0))

# 5.1. *Setup*

<span id="page-25-0"></span>Baselines. We compare our results against the following baselines. (1) The VCG mechanism [\(Vickrey,](#page-44-1) [1961,](#page-44-1) [Clarke,](#page-41-7) [1971,](#page-41-7) [Groves,](#page-42-7) [1973\)](#page-42-7), which is SP. (2) Item-Myerson. This

<span id="page-26-0"></span>

FIGURE 5.—Slicing the GEMNET mechanism in the auction setting with 2 additive bidders, 2 items, and uniform values on [0, 1]. 2D Plots: We vary Bidder 1's values,  $v_1(1)$  and  $v_1(2)$  in each subplot on the x- and y-axis respectively, varying Bidder 2's values,  $v_2(1)$  and  $v_2(2)$ , across each subplot. 3D Plots: We first vary  $v_1(1), v_1(2), v_2(1)$  in each subplot on x-, y-, z-axis, respectively, varying  $v_2(2)$  across each subplot. We then vary  $v_1(1), v_1(2), v_2(2)$  in each subplot, on x-, y-, z-axis, respectively, varying  $v_2(1)$  across each subplot.

<span id="page-27-1"></span>is SP for additive valuations, and independently runs an optimal Myerson auction for each individual item. (3) Affine Maximizers. We compare with *AMenuNet* [\(Duan et al.,](#page-41-6) [2023\)](#page-41-6), which is the state of the art and uses the transformer architecture to learn an affine transformation. Given that AMenuNet has been compared to other affine maximization methods, such as *AMA Lottery* [\(Curry et al.,](#page-41-12) [2022b\)](#page-41-12), we exclude these works from our direct comparison. (4) **RegretNet** [\(Dütting et al.,](#page-42-0) [2024\)](#page-42-0) and **RegretFormer** [\(Ivanov et al.,](#page-42-6) [2022\)](#page-42-6). This serves as a prominent example of methods are that expressive but not exactly SP.

Network architecture and training setup. For training networks, we use a minibatch of size  $2^{13}$  and a menu size  $K = 300$ , unless the number of items is greater than 5, in which case we increase the menu size to 1000 to strengthen the representation capacity. During training, we gradually increase the SoftMax temperature  $\lambda_{\text{SOFIMAX}}$  in Eq. [4,](#page-14-1) as smaller values of  $\lambda_{\text{SOFIMAX}}$  help with initial exploration of the network weights and larger values approximate the argmax operation better. We also gradually increase the scaling factor  $\lambda_{\text{INCOMP}}$ . We evaluate the performance of the network once every 200 epochs using a test set of 200K samples. Of all the checkpoints satisfying an upper bound of compatibility violation (0.1% or 0.5%, depending on task), we pick the one with the best revenue for menu transformation. Appendix [A.2](#page-35-2) gives full details regarding training and price adjustment.

### 5.2. *Representation Capacity*

<span id="page-27-0"></span>We first demonstrate the representation capacity of GEMNET by considering a setting with two additive bidders, two items, and i.i.d. uniform values on [0, 1]  $\binom{2}{2}U_{\text{Add}}$ . This also serves to showcase GEMNET as a method that provides a first look at the structure of what we conjecture the optimal auction design for this problem. In Fig. [3,](#page-5-0) we fix Bidder 2's value for the items to  $(0, 0.6)$ , and show the menu element selected for Bidder 1 with different values. We compare the mechanism learned by GEMNET (pre- and post-transformation), RegretNet, and AMenuNet. For fairness, AMenuNet's menu size was increased to 2048 from the default 512, enhancing its capacity. The comparison with AMenuNet highlights the loss in expressive capacity of affine-maximizing mechanisms. In particular, AMenuNet is unable to learn the top-left region where bidder 1 gets item 2 but not item 1 and instead has a larger set of types for which bidder 1 receives no items and makes zero payment. This serves to illustrate that GEMNET is capable of achieving higher revenue than AMenuNet.

#### TABLE III

<span id="page-28-2"></span><span id="page-28-1"></span> $n$  ADDITIVE BIDDERS, TWO ITEMS, AND VALUATIONS ON SUPPORT SIZE TWO (Y[AO](#page-44-0), [2017\)](#page-44-0). THE OPTIMALITY OF GEMNET IS CONSISTENT ACROSS DIFFERENT SETTINGS: FIRST FOR  $a = 3$ ,  $n = 2$ ,  $p = 0.3$ AND VARYING  $b \in \{7, 5, 4, 7/2\}$ ; AND SECOND WITH  $a = 3$ ,  $b = 4$ ,  $p = 0.3$  AND VARYING  $n \in \{3, 5, 8\}$ . It is INTERESTING THAT THE TRANSFORMATION CAN *increase* THE REVENUE AND REALIZE THE EXACT

	Alg.	Setting (a fixed to 3; $p$ fixed to 0.3.)

Optimal	Yao (2017)	12.7400	9.1504	7.4774	6.72205	7.8309	7.9840	7.9996		

OPTIMAL REVENUE. SEE FIG. [6](#page-31-0) FOR A VISUALIZATION OF THE LEARNED AUCTION.

The comparison to RegretNet is also interesting. Compared with AMenuNet, RegretNet does an arguably better job of identifying the high-level structure of the optimal allocation and payment rule. However, it is "fuzzy" and rendered with a lack of crispness as to the boundaries of regions. In contrast, GEMNET extends the advantage of menu-based methods to this multi-bidder setting, with the bidder-optimizing aspect providing a clear decision boundary between regions. This showcases the improved interpretability of GEMNET over RegretNet. Also, Table [II](#page-25-1) shows the improved revenue of GEMNET in this setting over the SP baselines.

#### 5.3. *Benchmarking* GEMNET *Performance*

<span id="page-28-0"></span>We benchmark GEMNET on auction settings with more than one bidder that have been studied in the previous literature [\(Dütting et al.,](#page-42-0) [2024,](#page-42-0) [Curry et al.,](#page-41-13) [2020,](#page-41-13) [Duan et al.,](#page-41-6) [2023\)](#page-41-6).

In Table [II,](#page-25-1) we show results on settings where bidders' values come from the uniform distribution in the range [0, 1]. The details of the setting are represented by  ${}_{m}^{n}U_{\text{Add/Unit}}$ , where  $m$  is the number of items,  $n$  is the number of bidders, and Add/Unit indicates the <span id="page-29-1"></span>30

bidders' valuation type (additive or unit-demand). GEMNET consistently outperforms all SP baselines and by a large margin. Moreover, the revenue of GEMNET is very close to that achieved by RegretNet; e.g., 0.8979 in  ${}_{2}^{2}U_{\text{Add}}$ , while RegretNet gets 0.908 (as a reminder, RegretNet is not fully SP). These results respond to the questions raised in the introduction. They confirm a gap between the optimal auction and the solutions derived by AMA approaches: even if GEMNET is not optimal, it is SP, and thus a valid lower bound on the revenue from the exactly optimal design. Moreover, under our working hypothesis that GEMNET finds designs that are close to optimal, these results also show that the revenue of RegretNet is not too much higher than the optimal revenue. In Table [IV,](#page-32-0) we also show how GEMNET generalizes to other distributions, considering the Beta distribution with parameters  $\alpha = 1, \beta = 2$ , as well as an irregular distribution, where each bidder's valuation is  $U[0, 3]$  with probability 3/4 and  $U[3, 8]$  with probability 1/4 [\(Hartline,](#page-42-15) [2013\)](#page-42-15). These cases serve to validate the strong performance of GEMNET, For example, Myerson is optimal in the  $n = 1$  case with irregular valuation (making use of ironing), and GEMNET achieves almost the same revenue.

## 5.4. *Recovering Theoretically Optimal, Multi-Bidder Designs*

<span id="page-29-0"></span>To our knowledge, the only theoretical work that handles settings involving two or more bidders and items is the study by [Yao](#page-44-0)  $(2017)$ . The setting considered has two items,  $n > 1$  additive bidders, and valuations sampled i.i.d. from a distribution  $Pr\{v_i(j) = a\} = p$ and  $Pr{v_i(j) = b} = 1 - p$ , for different values of a and b. [Yao](#page-44-0) [\(2017\)](#page-44-0) proves the maximum revenue achievable under any SP and IR auction is  $R_{n,a,b,p} = 2(1 - p^n)b +$  $p_0 \left[ 2a - \frac{1-p^2}{n^2} \right]$  $\frac{-p^2}{p^2}(b-a)$  $+ p_1 \left[ a - \frac{1-p}{2p} \right]$  $\frac{-p}{2p}(b-a)$  $+ p_2 \left[ a - \frac{1-p}{p} \right]$  $\left[\frac{-p}{p}(b-a)\right]$  $,$  where  $[x]_+ =$  $max\{x, 0\}$ ,  $p_0 = p^{2n}$ ,  $p_1 = 2np^{2n-1}(1-p)$ , and  $p_2 = 2p^n(1-p^n - np^{n-1}(1-p))$ . The optimal auction depends on which of the following intervals contains b:  $b \in (a, \frac{1+p^2}{1+p^2})$  $\frac{1+p^2}{1+p^2}a$ );  $\left[1+p^2\right]$  $\frac{1+p^2}{1+p^2}a, \frac{1}{1-p}a\Big); \left[\frac{1}{1-p}\right]$  $\frac{1}{1-p}a, \frac{1+p}{1-p}$  $\frac{1+p}{1-p}a$ );  $\left[\frac{1+p}{1-p}\right]$  $rac{1+p}{1-p}a,\infty$ ).

We evaluate GEMNET in all four cases, and with different numbers of bidders. We fix  $p = 0.3$ ,  $a = 3$  and select b from  $\{3.5, 4, 5, 7\}$ . For  $a = 3$  and  $b = 4$ , we vary n within {2, 3, 5, 8}. In Table [III,](#page-28-1) we show that GEMNET accurately recovers the optimal revenue in each setting. By contrast, the other deep methods, except for RegretNet, which is not quite SP, do not approximate optimality. Fig. [6](#page-31-0) further validates that GEMNET's mechanism <span id="page-30-2"></span>aligns with the optimal, echoing the auction prescription of Algorithm 1 from [Yao](#page-44-0) [\(2017\)](#page-44-0). Moreover, price adjustments align prices with the optimal solution, notably in Fig. [6'](#page-31-0)s first two columns. Although the deep learning phase secures optimal allocation, it requires postprocessing for accurate pricing. This highlights the role of price adjustment beyond fixing menu incompatibility, significantly contributing here to overall revenue optimality. It is also interesting that AMenuNet comes closer than RegretNet to the optimal in this setting.<sup>[2](#page-30-1)</sup>

### 5.5. *Mechanism Analysis*

<span id="page-30-0"></span>In this section, we seek to better understand the improved performance achieved by GEMNET by visualizing the learned auction rules.

(I)  ${}_{2}^{2}U_{\text{Add}}$ . In Fig. [3,](#page-5-0) we already compared the mechanisms learned in this case by different methods. Here, we take a closer look at the auction rule learned by GEMNET, using both 2-dimensional (2D) and 3-dimensional (3D) visualizations to gain an understanding of its behavior under different bidder valuations.

2D Plots Analysis. In the 2D visualizations of Fig. [5,](#page-26-0) we vary the values of Bidder 2, specifically  $v_2(1)$  and  $v_2(2)$ , across different subplots. Each subplot plots the allocation to Bidder 1 as its value for item 1  $(v_1(1))$  and item 2  $(v_1(2))$  vary along the x- and y-axes, respectively. The learned auction conforms to a specific structure which is similar to the optimal single-bidder structure [\(Manelli and Vincent,](#page-42-4) [2006\)](#page-42-4), revealed here for the first time through GEMNET. 3D Plots Analysis. Moving to the 3D plots in Fig. [5,](#page-26-0) we fix the value of item 2 for Bidder 2 ( $v_2(2)$ ) to different values and examine the interaction between  $v_1(1)$ ,  $v_1(2)$ , and  $v_2(1)$  across the x-, y-, and z-axes, respectively. We further fix the value of  $v_2(1)$ to different values, and vary  $v_1(1)$ ,  $v_1(2)$ , and  $v_2(2)$  in the second row of the 3D plot. It is interesting to see that these plots are characterized by a clear symmetric structure.

<span id="page-30-1"></span><sup>&</sup>lt;sup>2</sup>Since the valuation domain in this example is discrete, a linear program can also solve Yao's problem. It has  $O(2^{2n})$  variables and constraints, where the IC constraints enumerate each agent's possible deviations. For the experiments in Table [III,](#page-28-1) with moderate sizes of  $n$ , this linear program can be efficiently solved. Our main focus in this paper is on auctions with continuous valuation, of which there's no known, SP linear program formulation. However, since we know of no theoretical results for multi-buyer multi-item auctions except for [Yao](#page-44-0) [\(2017\)](#page-44-0), we include this as an additional validation that GEMNET is able to learn optimal auctions, lending credibility to its performance.

<span id="page-31-1"></span><span id="page-31-0"></span>

FIGURE 6.—2 additive bidders, 2 items, and valuations on support size two [\(Yao,](#page-44-0) [2017\)](#page-44-0) with  $n = 2$ ,  $a = 3$ ,  $b = 7$ ,  $p = 0.3$ . In each subplot, x- and y-axis is the values of Bidder 1 and 2, respectively, on each of the two items. GEMNET recovers the optimal auction after transformation (Column 1), while other deep methods cannot (Columns 3, 4). The deep learning phase of GEMNET provides the perfect allocation mechanism (Column 2), but it does not accurately set prices. The menu transformation resolves this discrepancy (Column 1), with this price adjustment having a critical role in realizing revenue optimality. Fig. [A.1](#page-36-0) shows the full mechanism.

(II)  ${}^{3}_{3}U_{\text{Add}}$ . In Fig. [4,](#page-8-0) we explore the learned GEMNET auction design for a setting with three additive bidders competing for three items, with their values uniformly distributed on [0, 1]. The analysis fixes the valuations of Bidders 2 and 3 at  $v_2 = v_3 = (0.2, 0.2, 0.2)$ , and looks to understand how Bidder 1's value for each item, represented across three axes, influences its own allocation. It is interesting to compare with the optimal allocation structure for a simpler, single-bidder three-item setting with the same value distribution, as previously solved by [Giannakopoulos and Koutsoupias](#page-42-5) [\(2014\)](#page-42-5) (their Straight-Jacket Auction). We also compare AMenuNet, RegretNet, and GEMNET in Fig. [4](#page-8-0) (b), (c), and (d), respectively. AMenuNet learns a very sub-optimal allocation rule in this setting, even allocating an item to Bidder 1 when its value for the item is zero; e.g., for  $v_1 = (0.6, 0, 0.3)$ . This contrasts sharply with the allocation rule obtained by GEMNET, which has a structure that

#### TABLE IV

<span id="page-32-1"></span><span id="page-32-0"></span>BIDDER VALUES COMING FROM  $Beta (\alpha = 1, \beta = 2)$  and from an Irregular distribution (U[0,3] WITH PROBABILITY  $3/4$  and  $U[3,8]$  with probability  $1/4$ ). Myerson [\(1981\)](#page-43-1) with ironing gives THE OPTIMAL SOLUTION IN SINGLE-ITEM AUCTIONS WITH THE IRREGULAR DISTRIBUTION, WHERE GEMNET ALSO ACHIEVES NEAR-OPTIMAL REVENUE. IN ALL OTHER CASES, WHERE THE OPTIMAL

SOLUTION IS UNKNOWN, OUR METHOD OUTPERFORMS ALL SP BASELINES.

closely mirrors the optimal, one-bidder structure. Correspondingly, as shown in Table [II,](#page-25-1) AMenuNet achieves lower revenue (1.6322) than GEMNET (1.6546). RegretNet is closer at capturing the macro-structure in the GEMNET design but loses the specific detail revealed by GEMNET. Further tests with GEMNET examine how the allocation to Bidder 1 changes for different valuations of Bidders 2 and 3. We observe that GEMNET continues to maintain a similar high-level structure in the allocation rule. However, the structure might exhibit asymmetric, as illustrated in Fig. [4](#page-8-0) (e, f).

### 6. CLOSING REMARKS

In this paper, we have introduced the first expressive (i.e., general), strategy-proof, method for learning revenue-optimizing, multi-bidder and multi-item auctions under additive and unit-demand valuations. The innovation of GEMNET is to use a menu-based representation for the learned, multi-bidder auction designs, which provides both exact strategy-proofness as well as interpretability. The technical challenge is to achieve menu compatibility, so that the bidder-optimizing choice for each bidder can be selected simultaneously without leading to infeasibility (i.e., no item is allocated more than once). We <span id="page-33-3"></span>achieve this through a specific choice of incompatibility loss during training and by carefully transforming prices in learned menus, post-training, to achieve compatibility margins that are sufficient to ensure compatibility with probability 1 throughout the value domain given Lipschitz smoothness of the learned networks. GEMNET outperforms all previous SP baselines, and reveals for the first time the structure in what we conjecture to be essentially optimal auction design for various multi-bidder multi-item settings considered in this paper. There are many directions for future work, including establishing sample complexity bounds similar to [Dütting et al.](#page-42-0) [\(2024\)](#page-42-0), further scaling-up the menu transformation method, developing open-access tools for use by theoretical economists, exploring whether RegretNet provides a useful (i.e., empirical) upper-bound on revenue coming from GEM-NET, extending duality theory to prove optimality in these multi-bidder settings [\(Cai et al.,](#page-41-14) [2016\)](#page-41-14), extending from additive and unit-demand valuations to problems with combinatorial valuations, improved visualization methods, adopting other objectives, and considering other mechanism design problems.

## APPENDIX A: EXPERIMENTS

## <span id="page-33-1"></span>A.1. *The value of Big* M

<span id="page-33-0"></span>In this section, we discuss the appropriate values for  $M$ . Recall that the constraint involving  $M$  in the MILP is:

$$
U_{(\ell)} \leq \boldsymbol{v}_{i,(\ell)}^{\mathrm{T}} \boldsymbol{\alpha}_i^{(k)} - \beta_i^{(k)} - \Delta \beta_i^{(k)} + (1 - z^{(\ell k)}) M. \tag{11}
$$

For a fixed  $\ell$ , we want  $z^{(\ell k^*)} = 1$  for the optimal menu item  $k^*$  that gives the max utility to bidder *i* with value  $v_{i,(\ell)}$ , and  $z^{(\ell k)} = 0$  for all the other menu items  $k \neq k^*$ . When  $z^{(\ell k^*)} =$ 1, and also considering constraint,  $U_{(\ell)} \ge \mathbf{v}_{i,(\ell)}^{\mathrm{T}} \mathbf{\alpha}_i^{(k)} - \beta_i^{(k)} - \Delta \beta_i^{(k)} + (1 - z^{(\ell k)})s_m$ , we have

<span id="page-33-2"></span>
$$
U_{(\ell)} = \boldsymbol{v}_{i,(\ell)}^{\mathrm{T}} \boldsymbol{\alpha}_i^{(k^*)} - \beta_i^{(k^*)} - \Delta \beta_i^{(k^*)}.
$$
 (12)

We expand Constraint [11](#page-33-1) using Eq. [12:](#page-33-2)

$$
\boldsymbol{v}_{i,(\ell)}^{\mathrm{T}} \boldsymbol{\alpha}_{i}^{(k^*)} - \beta_{i}^{(k^*)} - \Delta \beta_{i}^{(k^*)} \leq \boldsymbol{v}_{i,(\ell)}^{\mathrm{T}} \boldsymbol{\alpha}_{i}^{(k')} - \beta_{i}^{(k')} - \Delta \beta_{i}^{(k')} + M, \quad \forall k' \neq k^*.
$$

It follows that for feasibility we need,

$$
M \geq \boldsymbol{v}_{i,(\ell)}^{\mathrm{T}} \boldsymbol{\alpha}_{i}^{(k^*)} - \beta_{i}^{(k^*)} - \Delta \beta_{i}^{(k^*)} - (\boldsymbol{v}_{i,(\ell)}^{\mathrm{T}} \boldsymbol{\alpha}_{i}^{(k')} - \beta_{i}^{(k')} - \Delta \beta_{i}^{(k')}), \quad \forall k' \neq k^*,
$$

and M should be at least the gap between the maximum and minimum possible utility of all compatible menu elements. We first focus on the additive valuation function, and derive an upper and lower bound on bidder utility in the following lemma.

<span id="page-34-0"></span>Lemma 6 [Menu Element Utility Bounds]. *The following are valid utility bounds on menu elements, for an additive valuation bidder,*  $m \geq 1$  *items, and*  $v_{\text{max}} > 0$  *maximum value for a single item,*

$$
\min_{i,k,\ell} \left[ \boldsymbol{v}_{i,(\ell)}^{\mathrm{T}} \boldsymbol{\alpha}_i^{(k)} - \beta_i^{(k)} - \Delta \beta_i^{(k)} \right] \ge -m \cdot v_{\mathrm{max}},\tag{13}
$$

$$
\max_{i,k,\ell} \left[ \boldsymbol{v}_{i,(\ell)}^{\mathrm{T}} \boldsymbol{\alpha}_i^{(k)} - \beta_i^{(k)} - \Delta \beta_i^{(k)} \right] \le 2m \cdot v_{\text{max}}.
$$
 (14)

PROOF: For the lower bound, suppose that for some  $i, \ell, k$ ,  $\mathbf{v}_{i,(\ell)}^{\text{T}} \alpha_i^{(k)} - \beta_i^{(k)} - \Delta \beta_i^{(k)} \geq 0$  $-m \cdot v_{\text{max}}$  does not hold. Since values are non-negative, we must have  $\beta_i^{(k)} + \Delta \beta_i^{(k)}$  $m \cdot v_{\text{max}}$  for the price. However, when a menu element has a price greater than  $m \cdot v_{\text{max}}$ , it can never be selected. This is because the value of items a bidder can get is upper bounded by  $\bm{v}_{i,(\ell)}^{\rm T}\bm{\alpha}_i^{(k)}$   $\leq m\cdot v_{max}.$  If a price is higher than  $m\cdot v_{\max}$ , the corresponding menu element will always be less attractive than the IR option (no allocation, and zero price). Therefore, we can construct an equivalent mechanism by removing all menu elements with a price larger than  $m \cdot v_{\text{max}}$ .

For the upper bound, suppose that for some  $i, \ell, k, \bm{v}_{i,(\ell)}^{\rm T} \bm{\alpha}_i^{(k)} - \beta_i^{(k)} - \Delta \beta_i^{(k)} \leq 2m \cdot v_{\max}$ does not hold. Since the value of items a bidder can get is upper bounded by  $\bm{v}_{i,(\ell)}^{\text{T}}\bm{\alpha}_i^{(k)}$  $m \cdot v_{max}$ , we must have  $\beta_i^{(k)} + \Delta \beta_i^{(k)} < -m \cdot v_{max}$  for the price. Such a low price means that the bidder, whatever its value is, will always choose items with a negative price. This is because for any menu element with a positive price, its utility to the bidder is less than the values of all items, which is less than  $m \cdot v_{\text{max}}$ . In this way, the revenue for the seller is negative, and the seller can do better by only giving the null option (0 allocation and 0 price) in the menu without introducing over-allocation. *Q.E.D.*

Based on Lemma [6,](#page-34-0)  $M \ge 3m \cdot v_{\text{max}}$  should be sufficiently large. The analysis for unitdemand valuations is similar, and we can derive that  $M \geq 3v_{\text{max}}$  is sufficiently large in this <span id="page-35-3"></span>case. These bounds used for deriving the value of  $M$  are loose. Empirically, it is possible to make the big- $M$  values tighter by considering the actual menu.

### A.2. *Setup of Our Framework*

<span id="page-35-2"></span>We train the neural network GEMNET on a single NVIDIA Tesla V100 GPU.

For the price adjustment process, the "big- $M$ " is set to 10. Since the price charged to buyers are non-negative, the utility of a buyer is at most the upper bound of its valuation times the number of items. Since both Uniform and Beta distributions are upper bounded by 1, setting  $M = 10$  suffices for the experiments in this paper. We use the Gurobi optimizer [\(Gurobi Optimization, LLC,](#page-42-16) [2023\)](#page-42-16) to solve the MILPs, and we adhere to the default parameters provided by Gurobi. The transformation uses a Linux machine with 2 vcpus and 64 GB memory.

#### A.3. *Baselines*

<span id="page-35-1"></span>For Baselines, we use the GitHub repository in [Duan et al.](#page-41-6) [\(2023\)](#page-41-6) for our AMenuNet baselines results and [Ivanov et al.](#page-42-6) [\(2022\)](#page-42-6) for the RegretNet and RegretFormer baselines. For AMenuNet, we use the default hyperparameters for the transformer architecture, running a minimum of 2000 iterations of training steps until it converges. For RegretNet, we use the default setting of 3 hidden layers, each containing 100 neurons. We run 50 steps of gradient descent for regret calculation in each iteration, and a total of 800, 000 iterations of training, or less if it converges.

### A.4. *Adaptive grid*

<span id="page-35-0"></span>In menu transformation, we use a grid of bidder values to adjust prices in learned menus. As discussed in Sec. [3.3,](#page-19-0) the density (or size) of this grid affects the computational efficiency of this MILP-based adjustment method. In this section, we introduce a method to adaptively reduce the density of the grid by exploiting the local Lipschitz smoothness of the learned menu networks.

The major factor that we need to consider when constructing an adaptive grid is to ensure that the proof of our menu compatibility theorem (Theorem [3](#page-22-0) and [4\)](#page-23-0) can still go through. Specifically, the distance in the  $\ell_{\infty}$ -norm of two adjacent grid points,  $\epsilon$ , controls the value of

<span id="page-36-1"></span><span id="page-36-0"></span>

FIGURE A.1.—The full mechanisms learned by different methods on the problem with 2 additive bidders, two items, and valuations on support size two [\(Yao,](#page-44-0) [2017\)](#page-44-0) ( $n = 2$ ,  $a = 3$ ,  $b = 7$ ,  $p = 0.3$ ). In every subplot, the x-axis represents the bids of the first bidder and the y-axis those of the second bidder for both items. GEMNET successfully identifies the optimal mechanism post-transformation (Column 1). In contrast, other deep auction learning methods cannot (Columns 3 and 4). The deep learning phase of GEMNET achieves the ideal allocation mechanism (Column 2); however, it falls short in setting precise prices. This issue is addressed through the menu transformation process (Column 1), demonstrating that the price adjustment plays a pivotal role in achieving optimal revenue.

<span id="page-37-0"></span>

FIGURE A.2.—Adaptive grid for the setting with two additive bidders, two items, and i.i.d. values from the uniform distribution on [0, 1]. Fix  $v_2 = (0, 0.6)$ , and consider the grid of Bidder 1. (a) The upper limit of the distance between two adjacent grid points  $(\epsilon)$  that can still guarantee menu compatibility. (b) For a uniform,  $30 \times 30$  grid,  $\epsilon = 1/30$  is significantly smaller than the upper limit for the majority of the value space, giving us the opportunity to generate an adaptive grid. (c) The adaptive grid: we remove 95% grid points, and now  $\epsilon$  is just slightly below its upper limit.

two safety margins  $s_f = \epsilon \cdot L_a$  and  $s_m = L_a(m \cdot v_{\text{max}}\epsilon + m\epsilon^2) + \epsilon L_p + \epsilon$ . The requirement is that the sum bundle of bidders is at least  $n \cdot s_f$  smaller than 1, and the utility difference between the best and the second best element in a menu is larger than  $s_m > 0$ :

$$
1 - \sum_{i} \alpha_i^* \ge n \cdot s_f; \tag{15}
$$

$$
\forall i, \; u_i^{(k^*)}(\boldsymbol{v}_{-i}) - u_i^{(k)}(\boldsymbol{v}_{-i}) \ge s_m. \tag{16}
$$

To adaptively adjust the distance between adjacent grid points, we can empirically calculate the actual value of  $\tilde{s}_f$  (one minus the actual sum bundle) and  $\tilde{s}_m$  (the actual utility difference between the best and the second best element) and thereby calculate the upper bound of  $\epsilon$ .

We give an example in Fig. [A.2.](#page-37-0) Fig. [A.2](#page-37-0) (a) shows the upper limit of  $\epsilon$  in an auction with two additive bidders, two items, and values with i.i.d. uniform distribution on  $[0, 1]$ . We fix the value of Bidder 2 to  $v_2 = (0, 0.6)$ , and focus on the grid of Bidder 1's values. We do not consider values under which Bidder 1 prefers the IR option (0 allocation with 0 price). This is because, as discussed in Section [3.3,](#page-19-0) these values are safe and cannot introduce infeasibility as long as the price adjustments are non-negative. Fig.  $A.2$  (b) shows that, if we use a uniform grid of  $30 \times 30$ , then  $\epsilon = 1/30$  falls beneath the calculated upper limit for the majority of regions within this grid. This means in these regions the network is smooth

<span id="page-38-1"></span>with a low local Lipschitz constant, and we are free from incompatibility after transforming with a  $30 \times 30$  grid.

However, we only require that  $\epsilon$  is *just* below the surface shown here to guarantee menu compatibility over the entire value space, indicating that it is feasible to construct an adaptive grid without compromising the menu compatibility guarantee. As shown in Fig. [A.2](#page-37-0) (c), the adoption of an adaptive grid results in the elimination of 95% of the original grid points, positioning  $\epsilon$  just marginally below the upper limit surface throughout the grid. Such an adaptive grid can greatly reduce the running time required by the price adjustment process as shown in Table. [I.](#page-18-0)

### A.5. *Neural Network Architecture and Training*

<span id="page-38-0"></span>The neural Network architecture for both the allocation and payment networks uses two hidden layers, with each layer containing 1024 neurons. The architecture for the case with n additive buyers and m items is shown in Figure [A.3](#page-39-0) and the case for n unit demand buyers and  $m$  items is shown in Figure [A.4.](#page-40-3) The activation function used in each layer is the *Gaussian Error Linear Unit (GELU)* [\(Hendrycks and Gimpel,](#page-42-17) [2016\)](#page-42-17). We applied spectral normalization to each layer of the network by normalizing the weights using the largest singular value of the weight matrix.

We initialize the softmax lambda  $\lambda_{\text{SOFIMAX}}$  in Eq. [4](#page-14-1) as 5, and the scaling factor  $\lambda_{\text{INCOMP}}$ in Eq. [5](#page-15-1) as 0.1. We train, using a minibatch of size  $2^{13}$ , for a fix number of iterations (e.g. 20, 000), and stop unless the violation rate is still above the desired threshold, in which case we continue to increase  $\lambda_{\text{INCOMP}}$  until violation rate goes below the desired level. During training, we gradually increase the SoftMax temperature  $\lambda_{\text{SOFIMAX}}$  in Eq. [4,](#page-14-1) as smaller values of  $\lambda_{\text{SOFTMAX}}$  help with initial exploration of the network weights and larger values approximate the argmax operation better. We also gradually increase the scaling factor  $\lambda_{\text{INCOMP}}$ . An example schedule we used is to increase  $\lambda_{\text{SOFIMAX}}$  by 2 times per 3000 until it reaches 2000. We also increase  $\lambda_{\text{INCOMP}}$  by  $\max(0.01, \mathcal{L}_{\text{INCOMP}}(\theta)).$ 

We evaluate the performance of the network once every 100 epochs using a test set of  $50K$  samples. Of all the checkpoints satisfying the an upper bar (0.1% or 0.5%, depending on task) of feasibility violation, we pick the one with the best revenue for the subsequent menu transformation.

<span id="page-39-1"></span><span id="page-39-0"></span>

FIGURE A.3.—Neural network architecture of GEMNET for Bidder 1 in the settings with  $n$  additive bidders and m items. The inputs are the reported types  $v_{-1}$  of other bidders. The Bundle Network  $f_1$  outputs K menu items each of size  $m$ , and the Price Network  $q_1$  outputs K item prices each of size 1. We add an *item-wise sigmoid* on each element in the output of the Bundle Network, ensuring that the allocation probability is well-defined. The network architecture is the same for any other bidder  $i' \neq 1$ , where the inputs will be  $v_{-i'}$ , and the rest of the architecture remains the same. An agent  $i$ 's allocation and payment is the bundle that maximizes the utility for their report type  $v_i$ .

We normally set the number of menus to be  $K = 300$ , as empirically this yields good performance. When the number of items is large  $> 5$ , we need to increase this number (e.g.  $K = 1000$ ) to capture a more rich space of allocation over items. We use Adam as the optimizer and a learning rate of 0.005. When the revenue and violation rate starts to converge (change in revenue is  $\leq 0.03$  and change in violation is  $\leq 0.01$ ) across 2 consecutive validation evaluations (which occurs once every 200 epochs), we initiate a linear decay of the learning rate, decreasing it by a factor of 1/10 every 2,000 iterations.

On a typical task of 3 bidders and 2 items, the training time for 1000 iterations is an average of 50.88 seconds. The results provided in the training are typically obtained on  $\sim$  20,000 iterations, which takes about 15 minutes. Compared to RegretNet [\(Dütting et al.,](#page-42-0) [2024\)](#page-42-0), we do not need to run an inner loop of gradient descent to find optimal misreport in order to calculate the regret, resulting in a faster runtime. We note, though, that the exact training time varies according our objective. A result close to that of baselines (AMenuNet [\(Duan et al.,](#page-41-6) [2023\)](#page-41-6) specifically) can typically be obtained in  $\sim$  5000 iterations, taking less

<span id="page-40-3"></span>

FIGURE A.4.—Neural network architecture of GEMNET for Bidder 1 in the settings with n unit demand bidders and m items. The inputs are the reported types  $v_{-1}$  of other bidders. The Bundle Network  $f_1$  outputs K menu items each of size  $m + 1$ , and the Price Network  $q_1$  outputs K item prices each of size 1. The output space include a dummy element  $a_{1(m+1)}^{(k)}$  for each bundle k (the output size of the network is thus  $K \times (m+1)$ ), and we perform a *row (bundle) -wise SoftMax* on the output of the Bundle Network, normalizing each bundle such that the sum of the selection probabilities for all items within a single bundle does not exceed 1. This can be viewed as a lottery giving the bidder either one or no item (if the dummy item is chosen) according to the bundle probabilities, in line with the unit demand setup. The network architecture is the same for any other bidder  $i' \neq 1$ , where the inputs will be  $v_{-i'}$ , and the rest of the architecture remains the same. An agent i's allocation and payment is the bundle that maximizes the utility for their report type  $v_i$ .

than 5 minutes. To achieve notable improvement over the baselines, on the other hand, might take longer training time (up to a few hours). We can control this tradeoff at our discretion.
