Abstract—With the rapid increase in mobile subscribers, there is a drive towards achieving higher data rates, prompting the use of higher frequencies in future wireless communication technologies. Wave propagation channel modeling for these frequencies must be considered in conjunction with measurement results. This paper presents a ray-launching (RL)-based simulation in a complex urban scenario characterized by an undulating terrain with a high density of trees. The simulation results tend to closely match the reported measurements when more details are considered. This underscores the benefits of using the RL method, which provides detailed space-time and angle-delay results.

Index Terms—5G, channel simulation, ray-launching, urban scenario, EMF exposure

I. INTRODUCTION

Wireless communication technologies are permeating through our lives. The proliferating number of mobile service subscribers triggered a demand for higher bandwidths and larger capacities that ensures good quality of service (OoS) and quality of experience (QoE) for the end users. As a result, mobile wireless technologies addressed this demand by pursuing higher frequencies within the radio spectrum. In fifth generation (5G), for instance, new operating frequencies were defined in the sub 6 GHz and the 24.25 GHz to 71.0 GHz millimeter wave (mmWave) frequency ranges, also known as frequency range 1 (FR1) and frequency range 2 (FR2). Consequently, a better understanding of radio waves and their channel propagation models at these frequencies is essential to optimize network planning and deployment of base stations (BSs). It is also pertinent for comprehending the nature of electromagnetic field (EMF) exposure in a given environment,

a topic that has stirred public concerns with the deployment of 5G technologies in recent years.

There are mainly two approaches to gain insights of the channel propagation. One of the simplest and fastest methods is to directly use empirical channel models, which are based on statistical models summarized from a large number of measurement campaigns in different environments, e.g., urban, suburban, or rural areas, and thus they prove useful as efficient channel approximations. However, they tend to be more accurate in environments similar to those from which the models were derived. Moreover, they are not capable of providing precise channel parameters information such as delay and angular spreads.

The second approach to examine wave propagation deterministically is using geometrical optics (GO)-based methods such as ray-tracing (RT) and ray-launching (RL). These simulations can numerically solve Maxwell equations to predict all the possible paths between a transmitter and a receiver. Based on 3D environments, field strength, time delay, angle of departure (AoD) and angle of arrival (AoA) for each paths will be precisely derived involving different wave propagation phenomena. Therefore they have widespread applications. The cost, however; is a significant computational effort and long computation times, such as IHE-RT in [1] which utilizes image method. For instance, to identify reflection paths, an image of the receiver point is generated relative to all planes in the scenario. Connecting the transmit point to this image point will generate a intersection with the plane, which becomes the reflection point. As expected, considering more complex geometries, bigger scenarios, and higher reflection orders escalates computational efforts. The other RL algorithm considers a large number of rays launched from a transmit point and shoot into the scenario. Upon intersecting with a plane, the hit point and the direction of the reflected ray are obtained and calculated. Unlike RT methods, the receiver in RL is modeled as a sphere with certain radius. If this reflected ray can hit the receiver sphere, it will be considered as a valid reflection path and this process is also named as shooting and

bouncing rays (SBR) method [2]. To speed up the calculations, investigations have been conducted on various acceleration strategies. Authors in [3] employ the vertical-plane-launch (VPL) algorithm to divide a 3D simulation area into horizontal and vertical planes. Additionally, leveraging NVIDIA OptiX [4] for parallel computing on GPUs, the program mentioned in [5] focus only on multiple reflections. The newly developed ray-launcher based on [1] also utilizes NVIDIA OptiX and is used in this work, which has accelerated computation times significantly. For reference, a small urban area model, consisting of 2,557 polygons as in Fig. 1b, requires only about 4.5 seconds to compute for each frame, making it an extraordinary fast RL tool. The simulation includes consideration of line of sight (LOS) transmissions, up to second-order reflections, and diffractions.

In this paper, we will focus on the FR1 frequencies, and in particular the 3700-3800 MHz band. Authors in [6] measured the synchronization signal - reference signal received power (SS-RSRP) within the RPTU Kaiserslautern private campus network (PCN) and made their measurements dataset publicly available. The terrain, as shown in Fig. 1a, is rather undulating, which can be observed from the yellow stair markers. Besides, it is lush with vegetation throughout the campus. This paper does not concentrate on the accuracy or proximity of our simulation results to the reported measurements. Instead, it illustrates how detailed channel information can be extremely beneficial in complex environments, presents methods for handling simulation data, and outlines approaches to address the issue of vegetation.

The rest of this paper is organized as follows. It starts with an overview of related works in Section II. The simulation and measurement environment and parameters are briefly described in Section III. Section IV introduces the results from our simulation and compares it to the reported measurements. A concise discussion of the findings follows in Section V. Finally, conclusions are provided in Section VI.

II. RELATED WORKS

In the spectrum allocated for 5G planning [7], the 3300-3800 MHz band is particularly noteworthy within the sub-6G range because it has been widely adopted around the globe. On the one hand, numerous studies have been published that address measurement campaigns in urban outdoor environments operating at 5G FR1. In [8], 5G channel measurements were conducted on a university campus in China at 3.5 GHz with a bandwidth of 30 MHz and the typical channel parameters were derived. Large-scale fading at same center frequency in an urban-macro scenario were measured and analyzed in [9]. Whereas in [10], small-scale fading effects were also included and the channel quality was investigated in terms of error vector magnitude (EVM). In fact, for greater representatives and to derive wave propagation channels, studies mentioned above conducted measurements in flat terrains and open areas unlike the scenario represented by the measurements in [6] that we base our analysis on.

TABLE I: Applied simulation environment parameters based on the measurement scenario according to [6]

Description	Value
Carrier frequency	3.75 GHz
TX antenna position	49°25'25.5"N 7°45'14.7"E
	and 49°25'25.2"N 7°45'15.4"E
TX antenna height	22 m
TX output power	20 W
TX antenna gain	12.5 dBi
TX HPBW,	azimuth: 65° , elevation: 22°
orientation (from north to east) and tilt	$330^{\circ}, 10^{\circ} \text{ and } 124^{\circ}, 1^{\circ}$
RX antenna height	20 cm
RX antenna gain	4 dBi
RX antenna pattern	Omni-directional
and polarization	vertical

On the other hand, using simulation techniques to gain insights of the wireless channel propagation and EMF exposure patterns has also been addressed by several studies. In [11], an estimation of the EMF exposure levels for the indoor scenario of a commercial passenger airplane was achieved using a 3D RL-based algorithm. The impact of reduced power levels due to EMF exposure limits for 5G indoor scenarios was studied with the help of a RT approach in [12]. Authors in [13] provided a comprehensive assessment of EMF exposure in shopping malls, representing a high node density scenario in an indoor environment, by means of measurements as well as 3D RL-based simulations.

III. SIMULATION AND MEASUREMENTS DESCRIPTION

In [6], three outdoor remote radio headss (RRHs) in total are deployed and their respective SS-RSRP is measured. Among them, the BS with physical cell ID (PCI) 54 is selected for comparison because it is located in the central area of the campus as seen in Fig. 1a. Each RRH comprises two transmitters located in close proximity, each transmitter is equipped with a 2-port sector antenna that supports 2x2 massive multiple input multiple output (MIMO) and operates in the 3.7-3.8 GHz frequency range. The azimuth and elevation half-power beamwidth (HPBW) of these antennas are detailed in Table I, thereby covering the two sectors depicted in yellow and red as shown in Fig. 1a. This surrounding is characterized by the most complex building structures, varied topological slopes, and an abundance of trees in its vicinity. The user equipment (UE) ID is privately assigned within the PCN. The UE can navigate along various paths around the campus. Simulations are conducted based on the same scenario, with building geometry imported from OpenStreetMap (OSM) as depicted in Fig. 1b. In this scenario, the existence of vegetation is initially not considered and the simulation parameters are based on those listed in Table I. Given the relatively narrow bandwidth, it is assumed that the channel is non-selective within this frequency range, and thus, only 3.75 GHz is simulated as the center frequency.

In a RL simulation, each ray undergoes specific attenuation, phase shift, and delay as it travels from the transmitter to the receiver, as a result of various propagation phenomena. The channel frequency response is calculated according to

Fig. 1: Environment characteristics of RPTU Kaiserslautern campus. (a) Measurement scenario from Google Maps. (b) Simulation scenario from Blender.

Equation (1), in which n = 1, ...N represents the different multi-paths. G_T , G_R are the transmitter and receiver antenna gains, respectively. The complex directional pattern of the transmitter and receiver antennas are C_T and C_R , respectively. Whereas, $\Omega_{T,n}$ and $\Omega_{R,n}$ represent the simulated AoD and AoA of a given path n. The full polarimetric transmission matrix is given by T_n and the time delay is τ_n . c_0 is the speed of light and f_c is the center frequency.

$$H(f) = \sqrt{\left(\frac{c_0}{4\pi f_c}\right)^2 G_R G_t} \cdot \sum_{n=1}^N C_R(\Omega_{R,n}) \cdot T_n C_T(\Omega_{T,n}) e^{-j2\pi f \tau_n}$$
$$= \sum_{n=1}^N A_n e^{-j2\pi f \tau_n}.$$
(1)

Where A_n represents the complex amplitude of the n^{th} multi-path. The final received power can be determined by coherently summing up all the path contributions based on Equation (1).

IV. MEASUREMENTS AND SIMULATION RESULTS

In this section, the results of the RL simulation and the reported measurements, where the UE follows the same route indicated by the orange arrow in Fig. 1b, are presented. We will sequentially demonstrate how to deal with this complex scenario and take into account more and more levels of detail into our simulation.

A. Case I: Simulation without trees

Fig. 2 displays the normalized received power, with the maximum simulated received power being in -41 dBm and the maximum measured received power being -82 dBm. It is evident that the simulated received power is considerably higher than the measured values, attributed to the absence of occlusion from tall trees in this simulation scenario, thereby allowing for LOS paths in between. However, this figure still

Fig. 2: Normalized received power from measurements and RL simulation

demonstrates the alignment of the trend between the simulated and measured results. This implies that the simulation results can be readily applied to optimize a BS's communication link to a UE in urban environments. As the UE travels through the city, the BS can dynamically adjust its output power in response to the simulation outcomes. Moreover, this difference in the received power between our simulation and reported measurements could also vary according to other factors such as different weather conditions. However, it can be effectively calibrated by another neighboring BS.

Despite the absence of trees in this scenario, the simulation results also provide valuable insights into EMF exposure issues. As suggested by the International Commission on Non-Ionizing Radiation Protection (ICNIRP) in [14], it is imperative that the EMF exposure (electric field strength, magnetic field strength, power density or specific absorption rate (SAR)) limit must not be exceeded under any circumstances, necessitating the consideration of worst-case scenarios. Considering the significant seasonal foliage density variations, with trees

Fig. 3: Comparison of the measured and simulated received power with additional details (trees and blockers)

being lush in summer and barren in winter, and given the ease of trees felling and planting, excluding the attenuation effect of trees would represent a worst-case scenario in assessing EMF exposure risks.

B. Case II: Simulation with trees

As illustrated by the actual scenario in Fig. 1a, trees in the vicinity of the measurement route are exceptionally dense and form a continuous cover. Therefore, to align the simulation more closely with the real-world environment, the inclusion of dense trees is necessary. These trees have been incorporated into the simulation environment, represented by the green cuboids in Fig. 4a. The UE path is still represented by the orange arrow. Due to their density, we assume that these trees do not allow any propagation paths and are treated as simple blockers. A comparison between the simulation results based on this environment and the actual reported measurements, as seen by the green and orange lines in Fig. 5 respectively, reveals that the simulated received power is getting closer with the measured values in contrast to Fig. 2. However, it can be observed that at the beginning of the path, the simulated received power still significantly exceeds the measured value. This discrepancy is attributed to the presence of a strong firstorder diffraction path, as depicted by the red line with arrow in Fig. 4a. Towards the end of the UE route along the street, the simulated received power slightly underestimates the measured values. This is due to the tall trees acting as blockers on both sides, which over-suppress the signal paths. In reality, certain paths can still penetrate between the trunk or through the foliage and reach the UE.

C. Case III: Manual blocking

By integrating real-world environmental factors, the simulation results can be further refined. As illustrated in Fig. 4b, the actual environment features a building on the left with a RRH transmitter on the rooftop. Adjacent to it on the right is a building associated with the diffraction path mentioned in the

subsection IV-B, which is depicted by a red dashed line in Fig. 4b. However, it can be spotted that the building on the left is constructed on a lower level, indicating the terrain in this area is not flat. Nevertheless, acquiring precise information about terrain undulations is always challenging. Normally, assistance from the Land Bureau or other governmental agencies would be required to obtain accurate terrain models. Even in the absence of terrain information, this issue can be adequately addressed as follows. The imported building models in Fig. 4a are based on the same ground level, and only the height information of the buildings can be obtained. Nevertheless, utilizing RL simulation, specific interaction points can be obtained. Given the variance in ground elevation, the altitude of the RRH transmitter atop the left building is not higher than the right building, therefore, the diffraction path can be excluded reasonably. By manually removing this path, the simulation result, as shown by the violet curve in Fig. 5, align more closely with the measured results, particularly evident in the initial positions of route.

V. DISCUSSION

Multiple positions for a UE traveling in the campus area have been measured and simulated. Measurement results over the territory are illustrated in Fig. 5a, whereas simulated results for the entire area, without any trees, are depicted in Fig. 5b. As expected, all simulated results in Fig. 5b exceed the measured values, particularly for the positions in the upper left, which are close to the RRH and possess a strong LOS path. Across the 168 positions evaluated, the root mean square error (RMSE) between simulated and measured results is calculated to be 43.4 dB, significantly higher than the measured values but the overall trend still aligns as shown in Section III.A. Following the incorporation of trees as described in Section III.B, the simulated results, presented in Fig. 5c, exhibit a reduction in the RMSE to 9.9 dB, closely approximating the measured values. Further adjustments to block certain paths considering reality, as outlined in Section III.C, result in the simulated outcomes depicted in Fig. 5d, achieving an RMSE of only 7.5 dB when compared to the measurements.

VI. CONCLUSIONS

In this paper, the benefit of utilizing the RL method for simulating the received power in the sub-6 GHz band has been demonstrated. A complex scenario within the university campus of RPTU Kaiserslautern, characterized by uneven terrain and an abundance of trees, was intentionally chosen. Simulations were initially conducted for scenarios without considering any trees. Although the simulated received power was higher than that measured, the former followed the overall trend of the latter. Subsequently, trees were incorporated as blockers, bringing the simulation results closer to the measured ones, albeit with some discrepancies. By leveraging detailed RL outputs to identify interaction points and manually removing paths that could not exist in reality, the simulation results were significantly aligned with the measured data. Further simulations across various positions achieved an overall RMSE

Fig. 4: (a) Simulation scenario from Blender with trees. (b) Reality of the buildings from Google Maps. The dashed red line represents the strong diffraction path, which is similarly depicted as the solid red arrow line in (a).

Fig. 5: (a) Measured received power. (b) Simulated received power without any trees. (c) Simulated received power with trees and manually blocking.

of 7.5 dB, which closely approximates the measurements. This step-by-step improvement highlights the necessity of incorporating a higher level of detail within the RL simulation scenario to achieve simulation results that closely reflect the actual measurements.
