Here we derive and experimentally test a free energy functional that captures the adhesion of DNA-coated emulsion droplets. Generalizing previous approaches, the theory combines important energetic and entropic effects of microscopic DNA mechanics and droplet elasticity. It simultaneously predicts adhesion size, morphology, and binder concentration as a function of experimental control parameters. Notably, droplets transition from undeformed binding to flat droplet interfaces at a characteristic DNA coverage. These equilibrium predictions agree quantitatively with experiments on droplet-substrate and droplet-droplet binding, revealing a weak effective binding strength of $3.7 \pm 0.3 K_{\rm B}$ T owing to entropic costs. Our results open the path to rich design strategies for making colloidal architectures.

Biological cells are a prime example of a system in which membrane deformation and molecular adhesion dictate cellular self-assembly into large-scale structures, such as tissues [1]. Their shape distribution and adhesion strength are crucial to biological func-Analogously, droplets [3], vesicles [4, 5], tion [2]. and colloids [6–8] coated with ligands are known to self-assemble into programmable architectures, such as chains [9], foldamers [10], clusters [11, 12], soft gels [13], and biomimetic tissues [14]. These systems offer avenues for biomimicry in simplified model systems to help understand mechanisms underlying biological processes [11, 15-17]. Moreover, they open the path to tunability in materials with novel mechanical and optical properties [18–20]. On the molecular scale, the binder strength, flexibil-

On the molecular scale, the binder strength, nexibility, and specificity of interactions have been shown to influence the structure of self-assembled particulate networks [12, 21]. On the scale of the particles, increasing the concentration of binders at the interface leads to more connected networks with a higher valence [22] and larger deformations away from spherical [16]. Further, decreasing the stiffness of the particles or the surface tension of emulsion droplets allows for the formation of cohesive packings that mimic tissues [14].

To gain greater control over these systems, it is necessary to construct a theoretical model that relates molecular binder properties to the self-assembly of the constituent particles. The literature spans from microscopic models of protein-mediated cell adhesion [23-26] and cellular recognition [27], to DNA-binding of vesicles [5], and biomimetic droplets [9, 16]. These models balance ligand binding strength with particle elasticity to reach mechanical equilibrium, which is distinct from adhering solid particles, where the ligands are immobile and the binding region is limited by the spherical geometry of the interfaces [7, 8, 28, 29]. In the case of droplet-droplet binding, low concentrations of DNA result in adhesions with extended linkers between spherical interfaces [9]. Adding more DNA binders to the droplet surfaces leads to progressively larger and denser adhesion patches, which can deform into flat interfaces if the binders overcome the surface tension cost.

Here we combine experiments and theory to develop a thermodynamic model for the deformed droplet regime, as shown in the schematics of fig. 1. The cost of the energy of deformation, governed by surface tension γ , balances with the configurational entropy gain of the binders to give the equilibrium patch DNA density and size as a function of the total numbers of DNA N and N' on the droplet surfaces. Comparing the free energies of the undeformed [9] and deformed bound droplets allows us to identify the DNA coverage that favors the deformed state. By varying surfactant concentration, we show that emulsions with a lower surface tension require less DNA to deform into flat patches, consistent with model predictions. Once deformed, the area of adhesion A grows approximately with the square root of the number of DNAs n inside the adhesion patch, in good agreement with theory. While the nominal DNA binding strength ϵ plays an important role in determining the fraction of DNA recruited from the droplet surface into the patch, it does not significantly affect patch size. Thus, our statistical mechanics approach describes equilibrium droplet adhesion spanning spherical and deformed regimes, allowing one to tune macroscopic adhesion shape and strength from the bottom up.

The free energy functional of the deformed system consists of the energy gain of DNA hybridization, the energy costs of binder stretching, crowding, and surface deformation, and the configurational entropy changes due to binder recruitment from the surface into the adhesion patch,

$$\mathcal{F}_{\mathbf{D}} = \mathcal{F}_b + \mathcal{F}_s + \mathcal{F}_r + \mathcal{F}_\gamma - \kappa_{\mathrm{B}} \mathrm{T} \ln \Omega_C.$$
(1)

At high droplet coverage and significant deformation, the theory assumes that the DNA linkers stand perpendicular to the bound interfaces, implying that the steric repulsion between the strands \mathcal{F}_r is negligible. Additionally, the Debye length in our system is on the order of 1 nm, such that electrostatic repulsion can be ignored.

FIG. 1. Schematics of undeformed (top) and deformed (bottom) droplet adhesion via DNA linkers in the dropletsubstrate (a) and droplet-droplet (c) experiments. Fluorescence microscopy images of droplet-substrate (b) and dropletdroplet (d) binding show a distribution of adhesion patches. Zooms show ring and disk adhesion morphologies on the substrate, while dimer droplets exhibit both perimeter and patch fluorescence. Scale bars are 5 µm.

The total hybridization energy $\mathcal{F}_b = -\epsilon n$ is reduced by a uniform molecular stretching penalty $\mathcal{F}_s = s_0 n$, where n is the number of DNAs in a patch. The resulting effective binding energy is balanced against the cost of droplet deformation, modeled as

$$\mathcal{F}_{\gamma} = \nu \gamma \frac{A^2}{A_0} \tag{2}$$

where ν is the number of deforming surfaces, γ is the surface tension and A and A_0 are the areas of the deformed patch and the undeformed droplet surface, respectively [30]. Equation (2) is accurate if $A \ll A_0$. Finally, configurational entropy is modeled by counting the number of microstates Ω_C that N and N' DNA binders on the two surfaces can assemble into

$$\Omega_C = \binom{N}{n} \binom{N'}{n} n! A^n a^n (A_0 - A)^{N-n} (A_0 - A)^{N'-n} \quad (3)$$

where $a = \frac{1}{4} \left(c_0^{-\frac{1}{2}} + c'_0^{-\frac{1}{2}} \right)^2$ is the linker area that characterizes the closeness needed by a DNA binder to find a partner in the patch, for initial DNA concentrations $c_0 = N/A_0, c'_0 = N'/A_0$ [31]. Minimizing the free energy with respect to A and n respectively gives

$$\frac{\partial \mathcal{F}_{\mathbf{D}}}{\partial A} = 0 = 2\nu\gamma \frac{A}{A_0} - \frac{n}{A}\kappa_{\mathrm{B}}\mathrm{T} + \frac{(N+N'-2n)}{A_0 - A}\kappa_{\mathrm{B}}\mathrm{T} \quad (4)$$

and

$$\frac{\partial \mathcal{F}_{\mathbf{D}}}{\partial n} = 0 = -\epsilon_{\text{eff}} + \kappa_{\text{B}} T \ln \left(\frac{\frac{n}{AA_{0}}}{1 - \frac{n}{N}} \frac{\left(\frac{A_{0} - A}{\sqrt{N}}\right)^{2}}{1 - \frac{n}{N'}} \right), \quad (5)$$

with $\epsilon_{\text{eff}} = \epsilon - s_0$ and the mean $\overline{N} = \left(\left(N^{\frac{1}{2}} + N'^{\frac{1}{2}} \right) / 2 \right)^2$. Simultaneously solving equations (4) and (5) predicts A and n as a function of experimental control parameters, N, N', and γ . Note that when the density of DNA outside the patch is low, eq. (4) simplifies to a square root law for the growth of A with n,

$$A \approx \sqrt{\frac{A_0 \kappa_B T}{2\nu\gamma}} \sqrt{n}.$$
 (6)

Interestingly, the patch area does not depend on the DNA binding energy in this limit.

To test the model, DNA-coated silane droplets stabilized with SDS surfactant are bound to a substrate surface coated with mobile complementary DNA of concentration c_s (fig. 1(a)). In this case, the theory remains quantitatively valid when setting $\nu = 1$ and $N' = c_s A_0$. High-intensity fluorescent adhesions are observed under the microscope (fig. 1(b)), resolving the patch size A and radial distribution of DNA, whose integral gives n. These data reveal the onset of droplet deformation by the change in morphology from ring-shaped to diskshaped adhesions, as shown by the examples in the zoom in fig. 1(b). Given that the droplets are above the focal plane, it is not possible to measure their perimeter intensity, from which N could be inferred. Therefore, a second set of experiments is performed using droplet-droplet dimers ($\nu = 2$, fig. 1(c)) functionalized with complementary DNA with distinct fluorescent labels (fig. 1(d)). Here the intensities of both the patches and the droplet perimeters are simultaneously quantified, determining N, N' as well as n.

We use the droplet-substrate data to test the effect of surface tension on the transition from undeformed to deformed binding and subsequent patch growth. In fig. 2(a) we plot A versus n for droplets with varying amounts of TMN co-surfactant. All data collapses onto a curve with a limiting patch area $A_{\rm lim} = 0.9\mu {\rm m}^2$ at low n, consistent with the geometric undeformed area $A_{\rm lim} = 2\pi R_0 L$, where $R_0 = 3.0 \pm 0.3\mu {\rm m}$ is the droplet radius and $L = 46 {\rm nm}$ is the theoretical linker contour length, cf. [9]. The behavior changes qualitatively for higher n, showing continuous growth above $A_{\rm lim}$. This growth is well

FIG. 2. (a) Growth of droplet-substrate adhesion patch area A with n exhibits a fast rise up to the undeformed droplet limit plateau (dot-dashed line), followed by a gradual increase in the deformed regime, in good agreement with theory and eq. (6). Data is shown for 1, 2, and 3 mM TMN cosurfactant concentrations in green, red, and blue, respectively. The transition n_C is predicted to increase with surface tension (inset black line and grey shaded region). (b) Ring probability P(Ring) sharply decreases with n, giving experimental estimates for n_C (inset in panel (a)). Panels (c) and (d) show the radial DNA profiles in ring and disk morphologies (indicated by arrows in panel (a)). Scale bars are 1 µm.

fit by eq. (6) using increasing surface tensions with decreasing TMN concentration, consistent with measured values [33]. Patches with $A > A_{\rm lim}$ show a decreased likelihood of ring morphology P(Ring)(fig. 2(b)), consistent with the transition from a spherical droplet to one with a flat interface. Sigmoidal fits show that P(Ring) = 0.5 is crossed at higher *n* with increasing surface tension, as shown in the inset in fig. 2(a). The error bars correspond to the gap in data around the transition point, which may be due to hysteretic effects. Figure 2 Panels (c) and (d) show typical radial profiles of DNA before and after this transition, at points indicated on the graph in fig. 2(a).

Droplet-droplet binding data reveals a similar growth in the area versus patch DNA curve (fig. 3(a)) as the droplet-substrate case, in good agreement with the square root law in eq. (6) (dashed lines) for two emulsion batches. Lines of best fit correspond to surface tensions $\gamma = 2.8$ and $4.4 \pm 0.2 \,\mathrm{mN}\,\mathrm{m}^{-1}$. These droplets appear softer than those in the droplet-substrate case because of differences in surfactants [31]. Due to a lower spatial resolution of patches, signatures of the morphology transition are not apparent. On the other hand, the total number of DNA at the interface N is readily measured, such that the full model solving Eqs. (4) and (5)can be tested using both n and N. Fitting the data in fig. 3(a),(b) with the full model (solid lines) gives lower surface tensions $\gamma = 1.6$ and $2.4 \pm 0.2 \,\mathrm{mN \, m^{-1}}$ than eq. (6) (dashed lines), as well as an effective binding energy $\epsilon_{\text{eff}} = 3.7 \kappa_{\text{B}} T \pm 0.3 \kappa_{\text{B}} T$. This discrepancy is because the full model additionally takes into account DNA recruitment and crowding effects inside the patch. Indeed, the DNA spacing, obtained from the triangular lattice spacing per molecule $(2A/\sqrt{3}n)^{\frac{1}{2}}$ inside the patch, asymptotically reaches the crystalline limit of 4.7 nm [32] in fig. 3(c). This packing density limit fixes the maximum patch size possible with a given DNA binder. Growing larger patches would require a decrease in surface tension or lateral attractive interactions [14].

Commonly, an effective binding energy per molecule is obtained from the logarithmic ratio of concentrations inside and outside the patch, shown in fig. 3(d). Both in experiments and theory, this ratio decreases at large N. This is because the further growth of a patch becomes less favorable due to increased crowding. The obtained values are in the range of a few $\kappa_{\rm B}T$, consistent with those reported for the same DNA binders in the undeformed regime in [9] where droplet-droplet binding was shown to be reversible. While this ratio varies with N, the quantity $\epsilon_{\rm eff}$ is a property of the individual DNA molecules as modeled in eq. (1). Its fitted value of $3.7 \kappa_{\rm B} T$ is much lower than the expected $-\Delta G \approx 48 \kappa_{\rm B} T$ [34, 35] for the DNA sequence used in this study because it includes the conformational entropy loss of DNA molecules confined in the binding patch, as well as the stretch energy per molecule s_0 . For large N, the logarithmic concentration ratio inferred from our theory with this value of ϵ_{eff} is in good agreement with experiment (fig. 3(d)).

Given the fact that we use the same DNA in both sets of experiments, we can use the estimated value for ϵ_{eff} in the full model for droplet-substrate binding. The solid lines in fig. 2(a) show that the model successfully predicts A for large n. In order to estimate the patch coverage where the droplet first deforms, we now compare the free energies $\mathcal{F}_{\mathbf{D}}$ of the present formalism with those of the undeformed droplet theory $\mathcal{F}_{\mathbf{U}}$ [9]. The latter differs from eq. (1) in two respects: the microstate count Ω_C is evaluated in the limit of small n, and the molecular contributions $\mathcal{F}_s, \mathcal{F}_r$ vary with position in the patch. This is because the spacing h between interfaces varies with the position for undeformed droplets, resulting in non-uniform concentration profiles (cf. fig. 2(c)).

FIG. 3. Droplet-droplet adhesion patch area A grows with the amount of DNA in the patch (a) and the total droplet DNA (b) for two emulsion batches. Experimental data are fit with the theory to give estimates for the surface tension and the effective binding strength. Fits with the simplified approach Eq. eq. (6) are also shown for comparison. Note that the geometric limit (dot-dash line) is at the resolution of the microscope in this case. (c) DNA spacing in the adhesion patches (inferred from n, A assuming a triangular lattice) approaches the close-packing limit of DNA (dashed line) with increasing DNA coverage [32]. (d) The natural logarithm of the concentration ratio inside and outside the patch shows an increase at large N due to crowding in both experiments and theory.

The functional form of the nonlinear molecular spring energy s and the exclusion interaction between molecules are kept the same in the deformed case. Note that we do not neglect \mathcal{F}_r in either $\mathcal{F}_{\mathbf{U}}$ or $\mathcal{F}_{\mathbf{D}}$ here, as the patch coverage n at the undeformed/deformed transition is relatively small. The uniform equilibrium distance h_0 between droplet and substrate in the deformed case is obtained by minimizing $\mathcal{F}_{\mathbf{D}}$ with respect to h, from which the equilibrium spring energy per molecule $s_0 = s(h_0)$ is deduced.

Figure 4 plots the free energies per molecule $\mathcal{F}_{\mathbf{U}}/n$ and $\mathcal{F}_{\mathbf{D}}/n$ for the three surface tensions of fig. 2(a). This identifies the γ -dependent transition patch coverage n_C (gray shading, also shown in fig. 2(a),(b)). The functional dependence $n_C(\gamma)$ predicted from theory is shown as the solid line in the inset of fig. 2(a), in good agreement with the empirical transition values obtained from experimental patch morphology data.

If we consider \mathcal{F}/n to control the melting temperature of a patch, then fig. 4 predicts that melting temperature is maximized for sparsely covered undeformed patches. On the other hand, the total free energy of the patch, i.e. the binding strength, is significantly higher in the deformed regime with large n. The kinetics of the transition between the two states upon changes in N remains an open question. However, the fact that \mathcal{F}/n is on the order of a few K_BT implies that the system is reconfigurable and will evolve towards the equilibria described here. Therefore, tuning the microscopic properties of the binders and the mechanical properties of the particles then allows for flexible control over the shape, size, and strength of adhesion of particles with mobile linkers. For instance, the spring energies could be replaced with Hookean springs or catch bonds [36] in the case of protein-protein adhesion, or additional lat-

FIG. 4. Free energy per molecule as a function of patch DNA n in the undeformed $\mathcal{F}_{\mathbf{U}}$ and the deformed $\mathcal{F}_{\mathbf{D}}$ cases, calculated using experimentally deduced values of ϵ_{eff} and γ in the droplet-substrate case. The grey shaded region denotes the predicted transition where $\mathcal{F}_{\mathbf{U}}/n = \mathcal{F}_{\mathbf{D}}/n$, also shaded in fig. 2(a). $\mathcal{F}_{\mathbf{D}}$ colors correspond to droplet surface tensions shown in fig. 2.

eral interactions could be present, as in the case of DNAcondensation [37] or *cis*-bound cadherins [38]. Alternatively, droplets could be exchanged for soft particles with Hertzian contact mechanics [39] or liposomes [40] with membrane bending elasticity. These changes to the free energy functional open the path to designing an even broader variety of adhesive particles. Extending the theory to higher coordination numbers will give rise to novel particulate networks (e.g. colloidal gels) with well-defined tunable architectures.

Appendix

Droplet synthesis

Following the procedure outlined in [42], the droplets were prepared with an amount ranging from 1 to 20% vol/vol monomer and 20% vol/vol ammonia was dissolved in deinoized(DI) water. The monomer portion was comprised of diethoxydimethylsilane (Sigma Aldrich) for droplet-substrate binding and of a mixture of dimethoxydimethylsilane (Sigma Aldrich) and 3-Chloropropylmethyldimethoxysilane (Gelest), in 4:1 proportion, for droplet-droplet binding. The additional monomer in the droplet-droplet case is to ensure that these droplets sink to the bottom of their flow cells for observation. The droplets were washed of ammonia and reaction byproducts by centrifugation or dialysis with 5 mM SDS.

Functionalizing droplets with DNA

The DNA-functionalized droplets were prepared following the methods in [9, 42]. Briefly, the azide-labeled DNA, purchased from Integrated DNA Technologies, and 1,2-distearoyl-sn-glycero-3-phosphoethanolamine-N-[dibenzocyclooctyl (polyethylene glycol)-2000](ammonium salt)(DSPE-PEG-DBCO, Avanti Polar Lipids) are prepared as mobile binders to functionalize the droplets as described in [9, 42].

The mobile binders are diluted to known concentrations with a dilute droplet sample in 50 mM NaCl TE buffer, (50 mM NaCl, 10 mM Tris 1 mM ethylenediaminetetraacetic acid (EDTA)), to functionalize a known quantity of droplets. After incubating, the droplets are washed in 50 µL NaCl TE buffer with 0.1% Triton-165 to remove loosely attached DNA and then washed several times in 50 mM NaCl TE buffer to remove the Triton-165 solution before being stored in stored in 50 mM NaCl TE buffer.

Microscopy

The droplets were observed using the 100x oil lens on a Nikon Ti-E epifluorescence microscope. The A DNA carries Cy5 fluorescent dye while the A' DNA carries Cy3 fluorescent dye, allowing for their imaging in separate channels.

Custom built flow cell

To prepare the flow cell for the binding experiments, glass slides and coverslips are first cleaned in a $\sim 2\%$ solution of Helmanex (Sigma Aldrich) then plasma cleaned in an O₂ plasma bath for 30 min. After cleaning, the slides and coverslips are hydrophobized with hexamethyldisilazane (Sigma Aldrich). For droplet-substrate experiments, two coverslips are secured to a hydrophobized slide with UV glue to produce a chamber. A third coverslip is place over the chamber and secured with UV glue as well. For droplet-droplet experiments, a piece of parafilm is placed on a hydrophobized glass slide upon which chambers approximately 1 mm wide are cut out. A coverslip is placed over the chambers and secured by heating the slide and parafilm.

Droplet-Substrate experiment

The droplet-substrate data was collected following the procedure from [9]. Briefly, a custom-built flow chamber is loaded with the fluorescent lipid-DNA complex, which forms a mobile substrate on the surface of the chamber, while the remainder is washed out. The chamber is then filled with droplets in a buffer containing $20 \,\mathrm{mM} \,\mathrm{MgCL}_2$, 0.1% wt/vol Brij-35 surfactant, and 5 mM Tris. Patches are found using fluorescent and brightfield images obtained from a 100x oil immersion lens using a Hough transform. The average intensity of the patch is found by summing the intensities of the patch pixels and then dividing by the number of patch pixels. The radial profiles are found by drawing a ray from the center of the patch to a distance 3 times the patch radius around the patch in 15° increments. These measures are averaged to arrive at the final radial profiles.

The n value and DNA concentration are estimated by considering that droplets with the highest concentration of DNA considered, i.e. those with similar coverage to the substrate, have all the DNA inside the patches and none at the perimeter. Multiplying out the patch area gives a n/Average Intensity scaling to arrive at a value of n for the measured droplet-substrate patches.

Droplet-Droplet experiment

The droplet-droplet data was collected following the procedure from [9]. Functionalized droplets of the A and A' species are both brought into a custom built flow cell. The species A droplets varied in DNA concentration while the A' species of droplets were prepared to have the same amount of DNA in all conditions. The droplets were immersed in a buffer containing $20 \,\mathrm{mM} \,\mathrm{MgCl}_2$ and 0.5% wt/vol F38 pluronic surfactant and 5 mM Tris at pH 8. Microscopic images are analyzed using custom MATLAB software. First droplets are located within the image using a circular Hough transform on the brightfield image augmented through histogram stretching and Gaussian filtering to reduce noise. After obtaining the positions of the droplets, the fluorescent images of the A species DNA are used to measure the distribution of DNA around the perimeter of the droplets by finding the maximum intensity pixels in a radial scan around the center of the droplet. A patch on a droplet is then found by differentiating the pixel intensity along the droplet perimeter to locate sharp changes in intensity, which in turn identify the edges of the patch. The patch size is extracted from the length of the patch region under the implicit assumption that the patch is symmetrical.

The N and N' = 200,000 estimate is made by integrating the total intensity on a droplet, both inside and outside the patch, for each droplet, and interpolating between the average of the total intensity of the droplets at a given bulk DNA concentration and the average number of DNA per droplet calculated for that concentration, under the assumption that all DNA was adsorbed onto the droplet. This assumption is consistent with the fluorometry measures from [9].

Energy functional contributions from molecular mechanics

The DNA binders used in the present study are identical to those described in [9], i.e., a dsDNA oligomer connected to two PEG molecules anchored in the surfaces of droplets or substrate. Each bound linker thus represents a series of springs whose total energy s(h) depends on the distance h between the surfaces bound together. The DNA spring nonlinearity is taken from [41]; see [9] for details. The interaction energy per molecule is likewise given by a function g(h), evaluating the Onsager excluded-volume energy of two DNA molecules (as fixed-length rods) dependent on h. For the undeformed droplets of [9] this function decreases linearly with h. For deformed droplets with flat patches, h is universal for all binder molecules and the two contributions dependent on h are

$$\mathcal{F}_s + \mathcal{F}_r = ns(h)\mathbf{K}_{\rm B}\mathbf{T} + \frac{n^2}{c_m A}g(h)\mathbf{K}_{\rm B}\mathbf{T},\qquad(7)$$

for a patch of size A containing n binders, and $c_m = 1/(Ld)$ is a normalization concentration given by the length L and width d of the binders. No other free energy contribution depends explicitly on h, so that the minimization of (7) with respect to h yields an equilibrium surface-to-surface distance h_0 and corresponding values $s_0 = s(h_0)$ and $g_0 = g(h_0)$. Together with \mathcal{F}_b and \mathcal{F}_{γ} described in the main text, these are the free energy contributions from patch properties only.

Entropy terms for molecules in and outside the binding patch

Entropic cost of a configuration of molecules depends on the *n* molecules in the patch as well as the N - nand N' - n molecules outside the droplets (in the case of droplet-droplet binding), or the concentration c_s of molecules on the substrate (in the droplet-substrate case). Exact microstate counts for arbitrary configurations are elaborate, but can be simplified using the following assumptions appropriate for moderate to large coverage N, N' of droplets (resulting in relatively large patch populations n), and contrasting with the limit of small N (and n) employed in [9]: (i) The crowded patches do not leave much room for unbound linkers, so we assume all n patch linkers in the patch area A to be bound, leaving N - n unbound linkers outside, on an area $A_0 - A$; (ii) Onsager interaction of unbound linkers is negligible; (iii) the area a that a single linker in the patch has to be confined to in order to bind with a linker on the other surface is not given by a constant of molecular geometry a_{mol} , as it was in [9]. This is because the larger coverage densities in the present work translate to areas per molecule $\langle a_{mol},$ providing a stronger constraint.

Taking the initial densities (upon the beginning of patch formation) to be $c_0 = N/A_0$ and $c'_0 = N'/A_0$ for the two droplets, the limit explored here is that of $c_0, c'_0, c_s > c_{mol} \equiv 1/a_{mol}$. For the types of linkers and droplet sizes used, this translates to $N, N', N_S \gtrsim 17,000$, comfortably fulfilled over the range of interest of deformed droplets in the present work. In this limit, the areas covered per molecule then have characteristic linear extent $c_0^{-1/2}$, $(c'_0)^{-1/2}$. Overlap, and thus binding, occurs when an area given by the mean linear extent is covered by the linker, i.e., an effective area of

$$a = \frac{1}{4} \left(c_0^{-\frac{1}{2}} + c'_0^{-\frac{1}{2}} \right)^2 \,, \tag{8}$$

as given in the main text. Equation (3) of the main text is then the microstate count of n molecules binding into a patch of size A (and confined to a upon binding), with N-n and N'-n distributed outside the patch.

An analogous computation for droplet-substrate binding results in equivalent formulae (up to an irrelevant constant contribution to energy), if the coverage of the partner droplet is taken to be $N' = c_s A_0$, and c'_0 is replaced by c_s .

Transition from undeformed to deformed at moderate N

Although we neglect \mathcal{F}_r for simplicity for large N, N', for accurate comparison of the undeformed and deformed energy functionals we do take the interaction energies into account. The minimization of (7) yields a value of h_0 very insensitive to *n* (or the control parameters), resulting in a spring energy $s_0 \approx 2.6 k_B T$. In comparing $\mathcal{F}_{\mathbf{D}}$ with $\mathcal{F}_{\mathbf{U}}$, the former (from the present formalism) represents a limit of large N, N', while the latter (taken directly from [9]) represents a limit of $n \ll N, N'$. As we find that n grows consistently with the droplet coverages, the two approaches are expected to be comparable for intermediate values. As an indicator for when the deformed state becomes preferable, we compute $\mathcal{F}_{\mathbf{U}}/n$ and $\mathcal{F}_{\mathbf{D}}/n$, the energy changes upon adding another binder to the patch. While these stay negative over the range explored (the patch population n grows as the droplet population(s) increase), there is a critical value n_C beyond which growing a deformed patch is favorable over growth of the undeformed patch (see Figs. 2a and 4 of the main text).

Equilibrium states for large N

In contrast to [9], we are not simply comparing free energies at a fixed patch coverage n in the present work. Instead, we find equilibrium values of n using N, N', ϵ, γ (for the droplet-droplet case) or N, c_s, ϵ, γ (for the droplet-substrate case) as the experimentally relevant control parameters. Thus, the theory curves of plots like Fig. 2(a) of the main text are parametric plots: For a given substrate coverage c_s and binder species, N is varied and the equilibrium formulae (4) and (5) of the main text are used to quantify both n and A.

Full model fitting procedure

The full model was fit using data where N > 50,000 to ensure that only data from the deformed regime was considered. The data was binned so that a measure of uncertainty for the values could be considered across the range of N values in the deformed regime. The full model was fit by minimizing the logarithm of the sum of the squared quotients of all residuals over a bin's standard deviation of observed values of n and A, $\left(\frac{n-\hat{n}}{\sigma_n}\right)^2 + \left(\frac{A-\hat{A}}{\sigma_A}\right)^2$, where \hat{n}, \hat{A} are the model predicted values and σ_n, σ_A are the standard deviations of n and A of the bin.
