Utilizing singular value decomposition, our investigation focuses on the spectrum of the singular values within a sparse non-Hermitian Sachdev-Ye-Kitaev (SYK) model. Unlike the complex eigenvalues typical of non-Hermitian systems, singular values are inherently real and positive. Our findings reveal a congruence between the statistics of singular values and those of the analogous Hermitian Gaussian ensembles. An increase in sparsity results in the non-Hermitian SYK model deviating from its chaotic behavior, a phenomenon precisely captured by the singular value ratios. Our analysis of the singular form factor (σ FF), analogous to the spectral form factor (SFF) indicates the disappearance of the linear ramp with increased sparsity. Additionally, we define singular complexity, inspired by the spectral complexity in Hermitian systems, whose saturation provides a critical threshold of sparseness. Such disintegration is likely associated with the breakdown of the existing holographic dual for non-Hermitian systems.

Introduction: Spectral statistics serve as a critical tool for probing the energy levels in quantum systems, offering insights into the dynamics within quantum chaos and Random Matrix Theory (RMT) [1–9]. Short-range statistics, encompassing level statistics, and the ratio of consecutive level spacings reveal the symmetries and randomness in the system [10]. Long-range correlations are captured by the Spectral Form Factor (SFF) [11–14], which in quantum chaotic systems, displays a dip-rampplateau structure [15]. It indicates the level-repulsion among the eigenvalues, a characteristic feature of quantum chaos [16] and has also been understood from the semiclassical gravity [17]. Recent investigations have vielded precise measurements of SFF, marking a significant advancement in probing quantum chaos in quantum many-body systems through experiments [18, 19].

Analogously, the upsurge in research has been directed towards unraveling the quantum chaotic properties of open quantum systems, primarily through the Lindbladian dynamics in RMT [20, 21] and operator growth, see [22] for a comprehensive review. These systems, interacting with external environments, are often described by non-Hermitian Hamiltonians [23–27], leading to complex eigenvalues. This connotes a departure from conventional methods suited for Hermitian systems and necessitates new methods for spectral analysis. Advances include generalizing level spacing ratios to complex planes [28] and adapting SFF to dissipative systems, known as Dissipative Spectral Form Factor (DSFF) [29–31], showing a quadratic ramp-plateau pattern diverging from the *linear* ramp structure seen in Hermitian systems. Several other generalizations for SFF in non-Hermitian and open systems have also been proposed [32-34].

Recently, an alternative approach [35] considers the real and positive singular values of non-Hermitian Hamiltonians instead of the complex eigenvalues, obtained through Singular Value Decomposition (SVD) [36], as opposed to diagonalization. Aligning with the Hermitization process [37], this method facilitates a straightforward generalization of the frameworks used for Hermitian systems, bypassing the complexities associated with the complex plane. Such definitions have been fruitful in defining the singular spacing ratios [35] and singular form factor (σ FF) [38] in a much elegant manner that effectively captures the integrable to chaotic transitions, non-Hermitian many-body localization [38, 39] and non-Hermitian skin effect [40-42]. Outside this domain, SVD has also found applications in generalizing entanglement entropy for non-Hermitian transition matrices in AdS/CFT correspondence [43].

In this paper, we utilize the SVD framework to study the quantum chaotic properties and their transitions in the sparse, non-Hermitian version of the Sachdev-Ye-Kitaev (SYK) model [44, 45]. Standing as a quintessential archetype for quantum chaos and possessing a dual gravitational theory at low temperatures [46], the SYK model (see See [47, 48] for comprehensive reviews) can be adapted into sparse variants [49–53], maintaining its chaotic nature up to a critical sparsity threshold [54, 55]. This adaptation holds theoretical considerations in holography as well as the practical significance for the deployment of the SYK model on quantum processors [56, 57], where managing a sparse matrix is more viable. Our focus is particularly drawn to the influence that sparsity exerts on the average singular value spacing ratio,

^{*} Authors' names are listed in alphabetical order.

denoted by $\langle r_{\sigma} \rangle$, and the σ FF, which serves as an extension of the conventional *r*-value [10] and the SFF in Hermitian systems, respectively. Additionally, we introduce *singular complexity*, inspired by spectral complexity, a boundary dual to the volume of the Einstein-Rosen bridge in gravitational theories [58]. Our findings suggest that these metrics proficiently encapsulate the transition from chaos to integrability in the non-Hermitian SYK model, as we outline in the following sections.

non-Hermitian SYK model: The prototypical model we consider is the 4-body non-Hermitian SYK model (nSYK), given by the following Hamiltonian [59, 60]

$$H_{\text{nSYK}} = \sum_{1 \le a < b < c < d \le N} (J_{abcd} + iM_{abcd}) \psi_a \psi_b \psi_c \psi_d , \quad (1)$$

where J_{abcd} and M_{abcd} are the independent random couplings drawn from the Gaussian ensemble with zero mean and variance $\langle J_{abcd}^2 \rangle = \langle M_{abcd}^2 \rangle = 6/N^3$. The variables ψ_k are the Majorana fermions obeying Clifford algebra $\{\psi_a, \psi_b\} = \delta_{ab}$. For numerical purposes, we consider the 4-body interactions only. The couplings M_{abcd} explicitly break the Hermiticity of the Hamiltonian (1), which otherwise reduces to the usual Hamiltonian [44, 45] when M_{abcd} vanishes for all $\{a, b, c, d\}$. This model has been pivotal in exploring non-Hermitian quantum chaos [61, 62].

In the following, we also consider the sparse version of the Hamiltonian (1), given by

$$H_{nSYK}^{\text{sparse}} = \sum_{1 \le a < b < c < d \le N} x_{abcd} (J_{abcd} + iM_{abcd}) \psi_a \psi_b \psi_c \psi_d \,.$$

$$\tag{2}$$

In this sparse formulation, $x_{ijkl} \in [0, 1]$ are random variables that introduce an element of sparsity to the Hamiltonian. They follow a Gaussian distribution with zero mean and a variance of $\langle x_{abcd}^2 \rangle = 6/(pN^3)$ [49, 54]. The parameter p governs the probability of x_{abcd} being unity, thus determining the level of sparsity within the Hamiltonian. A fully *dense* model is characterized by $x_{abcd} = 1$ or p = 1 for all combinations of $\{a, b, c, d\}$, aligning with the original nSYK Hamiltonian (1). Conversely, a completely sparse model would have $x_{abcd} = 0$ or p = 0 for all combinations, representing the other extreme [49].

The probabilistic nature of x_{abcd} implies that the exact number of non-zero terms in H_{nSYK}^{sparse} is not fixed but rather determined by the probability p. It is worth noting that one can choose to fix the number of non-zero terms in the sparse Hamiltonian (2) for each realization. However, such distinctions become less significant when considering the average over a large number of ensembles [54, 55]. For our study, we follow [55] without fixing the total number of terms in the sparse Hamiltonian in each realization.

Singular value decomposition and singular value statistics: In Hermitian systems, the eigenspectrum of the Hamiltonian is a key indicator of chaotic dynamics. The eigenvalues E_n are real, allowing for the definition of consecutive level spacings $s_n = E_{n+1} - E_n$, as an ordered list. For large Hilbert spaces, the average consecutive level spacing ratio r_n is defined as $r_n = \min(s_n, s_{n+1}) / \max(s_n, s_{n+1})$ with $\langle r \rangle = \max(r_n)$ being the average r value [10]. Its usefulness lies in the simplification of the numerical analysis by bypassing the need to unfold the spectrum for level statistics. Typically, the *r*-ratio statistics is derived from the midspectrum, avoiding edge anomalies. For Gaussian Orthogonal Ensemble (GOE), Gaussian Unitary Ensemble (GUE), and Gaussian Symplectic Ensemble (GSE), the level statistics follow the Wigner-Dyson distribution with an average $\langle r\rangle_{\rm GOE}\approx 0.53590,\; \langle r\rangle_{\rm GUE}\approx 0.60266$ and $\langle r\rangle_{\rm GSE}\approx 0.67617$ respectively while the Poissonian distribution corresponds to $\langle r \rangle_{\rm P} \approx 0.386$ [10]. It is important to note that these values (except for $\langle r \rangle_{\rm P}$) are for three-dimensional matrices, and they decrease as the dimension increases. Numerically such values can obtained by fitting the data at appropriate matrix dimensions [10].

While $\langle r \rangle$ -value is well-defined for Hermitian systems, it falls short in applying for non-Hermitian systems where eigenvalues are complex, and thus an ordered sequence of level spacings is not feasible. In such scenarios, one must consider complex spacing ratios [28], which are defined in the two-dimensional complex plane. Consequently, the consecutive level spacings are generalized to the Euclidean distance between the eigenvalues in the complex plane, and the complex spacing ratio is then defined by taking the ratio of the distance from a given eigenvalue to its nearest neighbor, to the distance to its second nearest neighbor. However, this definition does not reduce to $\langle r \rangle$ -value for Hermitian systems. Rather it reduces to a different $\langle r \rangle$ -value formed by the closest and second closest neighbors from the ordered set [63].

In a recent work [35], an alternate proposal was suggested. Instead of focusing on complex eigenvalues, the analysis is based on singular values derived from the singular value decomposition (SVD) of the Hamiltonian. SVD is expressed as $H = U\Sigma V^{\dagger}$, where U and V are $N \times N$ unitary matrices satisfying $U^{\dagger}U = V^{\dagger}V = 1$, and $\Sigma = \operatorname{diag}(\sigma_1, \cdots, \sigma_N)$ is a diagonal matrix containing the singular values σ_i . Singular values are always positive and applicable to both Hermitian and non-Hermitian matrices. For Hermitian matrices, singular values reduce to the absolute values of the eigenvalues, but for non-Hermitian matrices, the singular values and eigenvalues are not straightforwardly related [64]. Importantly, the techniques of SVD are advantageous over other methods such as bi-orthogonalization, where the Hamiltonian can be diagonalized by a bi-orthogonal transformation such that $H = P \Lambda Q^{\dagger}$, where $\Lambda = \text{diag}(E_1, \cdots E_n)$ is a diagonal matrix containing the complex eigenvalues of the non-Hermitian Hamiltonian [65]. The matrices P and Q are not individually unitary, but they are bi-unitary

System	N = 20	N = 22	N = 24	N = 26	N = 28	N = 30
$\langle r \rangle_{\rm RMT}$	0.6744	0.5996	0.5307	0.5996	0.6744	0.5996
$\langle r_{\sigma} \rangle_{\rm nSYK}$	0.6744	0.5997	0.5307	0.5996	0.6745	0.5995

TABLE I. The Table shows the $\langle r_{\sigma} \rangle$ -values for the non-Hermitian SYK model (1) for different system sizes N = 20 (10000), N = 22 (6000), N = 24 (2000), N = 26 (1000), N = 28 (100), and N = 30 (50), where the parenthesis includes the number of samples taken. Here $N \mod 8 = 0$ (GOE), 2, 6 (GUE), and 4 (GSE) [68]. The values are in precise agreement (with numerical accuracy) with the $\langle r \rangle_{\rm RMT}$ values for large N results given in [10].

satisfying $P^{\dagger}Q = Q^{\dagger}P = 1$.

SVD is a fundamental matrix factorization technique in linear algebra [36]. Curiously, the singular values of a non-Hermitian matrix H can be computed without directly performing SVD. This method, known as *Hermitization* [37], involves constructing a new matrix H, twice the dimension of H. This larger matrix incorporates both H and its Hermitian conjugate H^{\dagger} in a block structure. The matrix H is defined as [37]

$$\mathsf{H} = \begin{pmatrix} \mathbb{0} & H \\ H^{\dagger} & \mathbb{0} \end{pmatrix} \quad \Rightarrow \quad \mathsf{H}^2 = \begin{pmatrix} HH^{\dagger} & \mathbb{0} \\ \mathbb{0} & H^{\dagger}H \end{pmatrix} . \tag{3}$$

The eigenvalues of H are $\{\pm \sigma_n\}$, precisely containing the singular values of H. This is because the non-zero blocks in H are off-diagonal, leading to a characteristic polynomial that yields the squares of the singular values of H as eigenvalues. This is equivalent to constructing an effective Hamiltonian H_{eff} , by taking the square root of the product H and H^{\dagger} such that $H_{\text{eff}} = \sqrt{H^{\dagger}H}$ or $H_{\text{eff}} = \sqrt{HH^{\dagger}}$. The eigenvalues of H_{eff} represent the singular values of H [37]. Such construction of a Hermitized matrix resembles the formulation of the Wishart SYK model and its supersymmetric version, comprised of non-Hermitian conserved charges or supercharges [66, 67].

Given the singular values $\{\sigma_i\}$ of the corresponding non-Hermitian Hamiltonian H, one analogously defines $\lambda_i = \sigma_{i+1} - \sigma_i$ as the singular value spacings. Consequently, the singular-value-spacing ratio r_{σ} is defined analogous to the r-ratio as [35]

$$r_{\sigma,n} = \frac{\min(\lambda_i, \lambda_{i+1})}{\max(\lambda_i, \lambda_{i+1})}, \qquad \langle r_{\sigma} \rangle = \operatorname{mean}(r_{\sigma,n}).$$
(4)

Referred to as the average r_{σ} value, these values adhere to statistical distributions akin to those observed for non-Hermitian Hamiltonians, similar to the $\langle r \rangle$ -value distributions for Hermitian matrices. This framework has been instrumental in the 38-fold symmetry classification in non-Hermitian systems [35].

Table I showcases the $\langle r_{\sigma} \rangle$ -value for the dense non-Hermitian SYK model (1) for varying system sizes N, representing the total number of fermions. The data is juxtaposed with corresponding Hermitian Gaussian

FIG. 1. The consecutive singular level-spacing distribution in the non-Hermitian dense SYK model (1) for N = 24 (2000)(GOE), 26 (1000) (GUE) and 28 (100) (GSE) with the corresponding realizations shown in the brackets. The solid lines represent distribution for GOE, GUE, and GSE respectively taking matrices of size $10^4 \times 10^4$ with averaging over 1000 realizations.

ensembles, revealing a striking correlation that underscores the utility of the $\langle r_{\sigma} \rangle$ -value in understanding non-Hermitian systems. Figure 1 correspondingly shows the consecutive singular level-spacing distribution $p_{\sigma}(\lambda)$ for N = 24 (GOE), N = 26 (GUE) and N = 28 (GSE) respectively, which are approximated by the Wigner-Dyson distribution [1]

$$p(\lambda) = \begin{cases} \frac{\pi\lambda}{2} e^{-\frac{\pi\lambda^2}{4}} & \text{GOE}, \\ \frac{32\lambda^2}{\pi^2} e^{-\frac{4\lambda^2}{\pi}} & \text{GUE}, \\ \left(\frac{64}{9\pi}\right)^3 e^{-\frac{64\lambda^2}{9\pi}} & \text{GSE}. \end{cases}$$
(5)

with the normalization $\int_0^\infty p(\lambda) d\lambda = \int_0^\infty \lambda p(\lambda) d\lambda = 1.$

SVD in sparse non-Hermitian SYK model: In the preceding discussion, we delved into the behavior of the r_{σ} ratio for the non-Hermitian SYK model, given by equation (1), across various system sizes. We now turn our attention to the sparse variant of this model, which is governed by the sparsity parameter p. Our aim is to elucidate the impact of sparsity on the $\langle r_{\sigma} \rangle$ -ratio during the transition from a densely connected to a sparsely connected regime.

Figure 2 illustrates how the average $\langle r_{\sigma} \rangle$ -value varies with the sparsity parameter p for different system sizes. Each system size, representing a distinct ensemble, is depicted in a unique color. The dotted lines mark the expected values for Poisson statistics and the Hermitian ensemble, as specified in Table I. It is observed that the Hamiltonian (2) retains its chaotic nature up to a critical level of sparsity denoted by $p_{\rm crit}$. This chaotic behavior is also corroborated by the $\langle r \rangle$ -ratio presented in Table I. Consequently, we define a transition point $p_{\rm crit}$ beyond which the Hamiltonian (2) ceases to exhibit chaotic dynamics. Such transition point is obtained by considering approximately 99% of the corresponding $\langle r_{\sigma} \rangle$ value at p = 1 [55]. Notably, as the system size increases, this

FIG. 2. (Top) Variation of $\langle r_{\sigma} \rangle$ -value with various level of sparsity p. The size of the circle varies with N i.e., the largest N corresponds to the leftmost plot for each color. At low sparsity, the $\langle r_{\sigma} \rangle$ matches with the corresponding random matrix ensemble until a threshold $p_{\rm crit}$ is reached, after which $\langle r_{\sigma} \rangle$ drops to the Poissonian value, indicating a hint of integrability. The estimated errors for the values obtained is smaller than the markers in the plot. (Bottom) The finite-size dependence of the threshold or the critical value $p_{\rm crit}$. It decreases as the system size increases. The decrease is $1/N^3$ with a large system size, as given in (6).

transition point migrates towards lower sparsity levels. When the sparsity is sufficiently low, the $\langle r_{\sigma} \rangle$ -value aligns with the Poisson limit, signifying the Hamiltonian's transition to integrability.

In conjunction with the above, we also present the relationship between the critical sparsity $p_{\rm crit}$ and the system size N. Intriguingly, the critical value diminishes as the system size increases. This reduction follows a power-law trend, best described by fitting the data to the curve [55]

$$p = kN \binom{N}{4}^{-1} \approx \frac{24k}{N^3}, \qquad (6)$$

in the large N limit. where the decrease is proportional to $1/N^3$ and the constant k is approximately 1.68, as determined by the fitting process. This scaling behavior is consistent with that observed for the sparse Hermitian SYK model, as reported in [54, 55].

Spectral and Singular form factor: In the realm of quantum chaos, the Spectral Form Factor (SFF) serves as

a pivotal tool for probing the full spectrum of eigenvalue correlations, encompassing both short and long-range interactions. The SFF is defined as the Fourier transform of two-point eigenvalue correlation pairs [12–14]

$$SFF(t) = \frac{1}{L^2} \left\langle |Z_E(it)|^2 \right\rangle = \frac{1}{L^2} \left\langle \left| \sum_n e^{-iE_n t} \right|^2 \right\rangle, \quad (7)$$

where $Z_E(it) = \sum_n e^{-iE_nt}$ is the infinite-temperature partition function for the energy eigenvalues, and L is the dimension of the Hilbert space. Here the angle brackets indicate an ensemble average, which is particularly relevant in the context of a disordered system since SFF is not self-averaging [69]. Throughout our discussion, we consider the quenched disorder, instead of annealed one, which is less physical in this scenario. Interestingly, in the context of a disorder-free SYK model [70], the SFF reveals indications of integrability, marking a departure from the chaotic behavior [71].

For systems exhibiting quantum chaos, the SFF displays a characteristic dip-ramp-plateau pattern. The initial dip, evident in the early-time regime, is a nonuniversal trait influenced by the detailed nature of the energy spectrum [11]. This dip extends until a timescale known as the Thouless time $(t_{\rm Th})$ [72, 73] or ramp time [16] beyond which the energy difference surpasses the inverse of $(t_{\rm Th})$, referred to as the *Thouless energy* [74]. Subsequently, a ramp emerges at $t_{\rm Th}$, indicative of eigenvalue repulsion, a phenomenon that mirrors the SFF behavior predicted by RMT [14, 16] and underscores the chaotic dynamics of the Hamiltonian. Moreover, this ramp hints at the presence of a holographic dual to the corresponding theory. Beyond the Heisenberg time [69, 75], which scales inversely to the mean level spacing, the SFF reaches a plateau that depends on the system size. In contrast, integrable systems typically bypass the ramp stage and saturate directly from the dip to the plateau regime. SFF in sparse SYK models has been thoroughly investigated in the literature [50, 51, 54, 55].

Analogous to the SFF, the singular form factor (σ FF) is defined as [38]

$$\sigma FF(t) = \frac{1}{L^2} \left\langle |Z_{\sigma}(it)|^2 \right\rangle = \frac{1}{L^2} \left\langle \left| \sum_n e^{-i\sigma_n t} \right|^2 \right\rangle, \quad (8)$$

where $Z_{\sigma}(it) = \sum_{n} e^{-i\sigma_{n}t}$ is the infinite-temperature partition function of singular values, which can be further expressed as the overlap between the time-evolved right or left singular vectors governed by the effective Hamiltonian $\sqrt{H^{\dagger}H}$ or $\sqrt{HH^{\dagger}}$ respectively [38].

Figure 3 shows the distinct dip-ramp-plateau pattern exhibited by σ FF for the non-Hermitian model (2), across varying degrees of sparsity. In this study, we consider a system size of N = 26 and analyze the outcomes from 1000 independent realizations of the Hamiltonian to ensure robust statistical analysis. To reduce the oscillations

FIG. 3. Behavior singular form factor $\sigma FF(t)$ for various sparsity parameter p. The linear ramp ceases to exist as the sparsity increases. The system parameters are N = 26 (GUE) with 1000 Hamiltonian realizations. Here we choose the Gaussian filter (10) with $\alpha = 3.27$, which lies within the prescribed range in [55].

in the dip region, we use the filter function $Y_{\sigma}(\alpha, t)$ [72] such that

$$\sigma FF(t) = \left\langle \frac{|Y_{\sigma}(\alpha, t)|^2}{|Y_{\sigma}(\alpha, 0)|^2} \right\rangle, \tag{9}$$

Here the filter function for the singular values is chosen to be Gaussian, which we refer to as the Gaussian *singular* filter function. It is defined as

$$|Y_{\sigma}(\alpha,t)|^{2} = \left|\sum_{n} e^{-\alpha\sigma_{n}^{2}} e^{-i\sigma_{n}t}\right|^{2}.$$
 (10)

As shown for Hermitian systems, given the energy spectrum is centered around E = 0, such a filter function modifies the density of states $\rho(E) \rightarrow e^{-\alpha E^2}\rho(E)$ such that the σ FF receives the dominant contribution from the bulk of the energy spectrum [72, 73]. Here α is a free parameter and controls the Gaussianity of the spectrum. This filtering avoids the unfolding which can otherwise be studied using the *connected unfolded* SFF [73]. For our computation, we employ the filter function on the singular values by choosing $\alpha = 3.27$, which lies inside the range given in [55] (dependent on N). Filter functions for SFF have also recently been shown to be associated with quantum channels [76].

A notable observation is a parallelism between the behavior of σFF in non-Hermitian systems and the SFF in Hermitian systems. This similarity underscores the efficacy of σFF as a robust indicator for quantum chaos in non-Hermitian frameworks. In regimes of lower sparsity, the presence of the ramp is clearly evident, signifying the retention of chaotic dynamics within this parameter space. It remains pronounced until a critical sparsity threshold is reached. Beyond this juncture, the linear ramp—a signature trait of non-integrable systems—ceases to manifest, indicating a shift towards regularity and a departure from chaotic behavior.

Figure 4 shows the variation of Thouless time $(t_{\rm Th})$, for N = 26, with sparseness parameter p. The $t_{\rm Th}$ is calculated by considering the time at which the σFF of the system considered first intersects the SFF of the GUE random matrices [16]. To determine the intersection point precisely we consider the the following fractional error function [72]

$$\epsilon(t) := \left| \frac{\sigma FF(t) - \sigma_{ramp}(t)}{\sigma_{ramp}(t)} \right|, \qquad (11)$$

indicating the deviation of the computed σFF to the linear-fitted function for the ramp $\sigma_{ramp}(t)$ for p = 1(dense SYK model (1)). We consider the value t as the Thouless time or ramp time t_{Th} , where the fractional error $\epsilon(t)$ reaches 20%. The red line shows the fitting $t_{Th} \approx a/p^b + c$ with a = 1.923, b = 0.8767 and c = 0.007. Curiously, this fitting follows closely to the 1/p scaling in contrast to the $1/p^2$ scaling in Hermitian systems [55]. Such distinction is possible since the singular values and the eigenvalues are inherently different. Yet, we do not rule out the possibility of the scaling of the exponent bwith the system size.

In Hermitian systems, a key observation is that the singular values correspond to the absolute values of the eigenvalues. This distinction is crucial, as it implies that the SFF and σ FF, exhibit fundamentally different behaviors. This difference is illustrated in the inset of Fig. 4, which depicts the dynamics of SFF and σ FF for the dense Hermitian SYK₄ model. The model is derived by setting $M_{abcd} = 0$ for all $\{a, b, c, d\}$ in its non-Hermitian counterpart (Eq. (1)). Replacing σ_n by eigenvalues E_n in (9), we get the analogous definition of filtered SFF.

Notably, the singular values offer a *weaker* effect compared to the eigenvalues, considering the ramp. However, to reduce the SFF from σ FF, we consider the following prescription. From SVD, we obtain two sets of vectors, the left and right singular vectors. They are related by

$$H |u_n\rangle = \sigma_n |v_n\rangle$$
, $H^{\dagger} |v_n\rangle = \sigma_n |u_n\rangle$, (12)

where $\{\sigma_n\}$ are the singular values. For Hermitian systems, the eigenvalues are real, and the left $(|u_n\rangle)$ and the

FIG. 4. (Main plot) Thouless time (ramp time) with respect to sparsity parameter. The red line is the fit $t_{\rm Th} \approx a/p^b + c$ with a = 1.923, b = 0.8767 and c = 0.007. (Inset) The behavior of SFF and the σ FF for the Hermitian dense SYK₄ model. The system parameters are N = 26 with 1000 random Hamiltonian realizations taken. The σ FF (green line) is computed considering all the positive singular values. It reduces to the SFF after taking the appropriate rescaling of the singular vectors and singular values, which otherwise equals the eigenvalues (with appropriate signs).

System	$\langle r_{\sigma} \rangle$	$\langle r \rangle$	$\langle r_+ \rangle$	$\langle r_{-} \rangle$	$\langle r \rangle$ (2 blocks)

TABLE II. The Table shows the comparison between the singular value $\langle r_{\sigma} \rangle$ -value and the $\langle r \rangle$ -values for the *dense* Hermitian SYK model for different system sizes N = 20 (GSE), N = 22 (GUE), N = 24 (GOE). We take 1000 Hamiltonian realizations for each case. The Hermitian model is obtained by setting $M_{abcd} = 0$ for all $\{a, b, c, d\}$ in (1). Here the $\langle r_+ \rangle$ -value includes the positive eigenvalues while $\langle r_- \rangle$ -value includes the negative eigenvalues only. They are to be matched with the $\langle r \rangle_{\rm RMT}$ values in Table I and [10]. The $\langle r_{\sigma} \rangle$ -values are compared with the $\langle r \rangle$ -value of 2 blocks (marked in blue) [55]. Explanation is given in the text.

right $(|v_n\rangle)$ singular vectors are related with a factor of ± 1 . If the left and right singular vectors are equal, i.e., $|u_n\rangle = |v_n\rangle$ for some n, then the corresponding singular value exactly equals the eigenvalue i.e., $\sigma_n = E_n$. However, if they differ by a negative sign i.e., $|u_n\rangle = -|v_n\rangle$ for some n, then the corresponding singular value and the eigenvalue differs by a negative sign i.e., $\sigma_n = -E_n$. It is thus straightforward to identify such vectors such that the singular values can be directly mapped with the eigenvalues, and correspondingly compute the σ FF. In this case, the σ FF exactly equals the SFF as shown by the red line in the inset of Fig. 4.

Intriguingly, the Hermitian system exhibits a unique characteristic in its $\langle r_{\sigma} \rangle$ -value as well. As depicted in Table II, there is a notable distinction when comparing the $\langle r_{\sigma} \rangle$ -value to the $\langle r \rangle$ -values within the identical Hermitian SYK₄ model. Additionally, the $\langle r_{+} \rangle$ -value and

FIG. 5. Behaviour of the singular complexity with time for dense (p = 1) non-Hermitian SYK model (1). The system parameter is N = 26 with 1000 random Hamiltonian realizations taken. Inset shows the early time behavior of the complexity, which increases quadratically followed by linear growth and saturation.

 $\langle r_{-} \rangle$ -value were computed separately, considering only the positive and negative eigenvalues of the Hamiltonian, respectively. These ratios align with the overall $\langle r \rangle$ -value, which is anticipated since it solely accounts for the spacing between consecutive eigenvalues. Nonetheless, these individual ratios as well as the overall $\langle r \rangle$ -value do not correspond to the $\langle r_{\sigma} \rangle$ -value, which is identified as the $\langle r \rangle$ -value for two separate blocks before symmetry resolution. This discrepancy arises because, in Hermitian systems, the singular values are determined by the absolute magnitudes of the eigenvalues, leading to the computation of the $\langle r_{\sigma} \rangle$ -value mirroring the $\langle r \rangle$ -value for bifurcated blocks [35, 55, 77]. We anticipate such bifurcation has a similar effect of having the presence of conserved charges [66, 67]. Curiously, this phenomenon is exclusive to Hermitian and anti-Hermitian (with $J_{abcd} = 0$, $M_{abcd} \neq 0$) systems and echoes the discrepancy between the σ FF and SFF as shown in the inset of Fig. 4.

It is imperative to differentiate the behavior of σFF from the dissipative spectral form factor (DSFF), especially since DSFF has been instrumental in deciphering chaos in non-Hermitian and open systems [29–31]. The σFF is characterized by its reliance on real singular values, whereas the DSFF encompasses the complex eigenspectrum, establishing a fundamental difference between the two. The DSFF reveals a unique quadratic ramp-plateau structure in non-Hermitian systems [29, 30]. Meanwhile, the σ FF, while also mirroring the SFF exactly for Hermitian systems upon the appropriate identification of the singular vectors, preserves the linear ramp-plateau configuration. It, thus, serves as an effective marker for the transition between integrable and chaotic phases. Therefore, despite their inherent differences, both metrics are apt for exploring the nuances of non-Hermitian and open quantum systems.

Spectral complexity for singular values - Singular complexity: A related quantity, capturing the long-range

FIG. 6. Behaviour of the saturation of the singular complexity with different sparseness for N = 26 with 1000 random Hamiltonian realizations.

spectral correlation is motivated by considering the spectral complexity [58]. Within the framework of the AdS/CFT duality [78, 79], spectral complexity finds its counterpart in the volumetric measure of the Einstein-Rosen bridge, serving as an analog for the computational and circuit complexity [80]. In a similar spirit, we define singular complexity at finite temperature $T = 1/\beta$ as

$$C_{\sigma}(t) = \frac{1}{Z_{2\sigma}(\beta)L} \sum_{\sigma_i \neq \sigma_j} \left[\frac{\sin(t(\sigma_i - \sigma_j)/2)}{(\sigma_i - \sigma_j)/2} \right]^2 e^{-\beta(\sigma_i + \sigma_j)},$$
(13)

designed to be suitable for non-Hermitian systems. Here $Z_{\sigma}(\beta) = \sum_{n} e^{-\beta\sigma_{n}}$ is the thermal *singular partition* function, constructed from the singular values of the corresponding non-Hermitian Hamiltonian. Assuming no degeneracy in the singular value spectrum, the derivative of the singular complexity is related to the σ FF as

$$\frac{d^2}{dt^2}C_{\sigma}(t) = \frac{2}{L}\frac{Z_{\sigma}(\beta)^2}{Z_{\sigma}(2\beta)}\sigma FF(t) - \frac{2}{L}, \qquad (14)$$

in a similar spirit to spectral complexity [58, 81] which can be checked directly using (8). Focusing on the infinite temperature $\beta = 0$ limit, (13) takes a simpler form

$$C_{\sigma}(t) = \frac{1}{L^2} \sum_{\sigma_i \neq \sigma_j} \left[\frac{\sin(t(\sigma_i - \sigma_j)/2)}{(\sigma_i - \sigma_j)/2} \right]^2.$$
(15)

At early times, it grows quadratically as $C_{\sigma}(t) \approx (1 - \frac{1}{L})t^2$, followed by a linear growth and plateau regime. The plateau value can be obtained analytically by taking the long-time average

$$\bar{C}_{\sigma} = \lim_{t_{\rm f} \to \infty} \frac{1}{t_{\rm f}} \int_0^{t_{\rm f}} C_{\sigma}(t) \, dt = \frac{2}{L^2} \sum_{\sigma_i \neq \sigma_j} \frac{1}{(\sigma_i - \sigma_j)^2} \,, \ (16)$$

which only depends on the difference between the singular values. For the eigenvalues, such saturation values have been studied for quantum billiards [82] and mixed-field Ising model [83], capturing the *spectral rigidity*. Integrable systems tend to saturate at higher values compared to the chaotic ones due to the presence of level-repulsion which directly affects the equivalent eigenspectrum of (16). At early times, the relation between spectral complexity and spread complexity [84] based on Krylov space approach [85] in the Hermitian settings has also been proposed [81]; see [22] for a detailed discussion.

Figure 5 shows the time evolution of the infinitetemperature singular complexity (15) for the dense Hamiltonian (1) with N = 26 and 1000 realizations. The complexity grows quadratically, followed by linear growth (inset) and saturation. Correspondingly, Fig. 6 depicts how the singular complexity approaches saturation at varying levels of sparsity, maintaining a magnitude order of $O(10^4)$ until it encounters a critical threshold. Beyond this threshold, there is a marked escalation at lower sparsity levels signaling an analogous level-repulsion between the singular values. This critical value is dependent on the system size N, and for N = 26, it occurs within the sparsity regime $0.003 \leq p_{\rm crit} \leq 0.004$. This value resembles the expected $\langle r_{\sigma} \rangle$ -ratio shown in Fig. 2.

Exhibiting chaotic dynamics is considered to be a crucial constraint that possesses a holographic dual geometry. While this discussion does not explore the specifics of such geometry, some proposals exist in the literature [59, 86, 87]. The breakdown of chaotic nature suggests that such dual geometry corresponding to a non-Hermitian system may be compromised at low sparsity.

Conclusion and Outlook: Drawing on the foundational work [35] on the applicability of SVD in non-Hermitian systems, our study delves into the quantum chaotic attributes of the sparse SYK model across varying levels of sparsity. The complex eigenvalues inherent to non-Hermitian Hamiltonians pose challenges to the generalization of traditional eigenvalue statistics. This complexity persists despite strides made with complex spacing ratios [28] and the DSFF [29, 30]. Nonetheless, recent advancements propose a novel perspective by focusing on singular values as opposed to eigenvalues within the non-Hermitian framework. Unlike their complex counterparts, singular values are inherently real and positive, aligning with the real eigenvalues in Hermitian systems upon appropriate alignment with singular vectors, as detailed in the main text.

Our investigation underscores that the statistical analysis of singular values, which elucidates short-range correlations, coupled with the σ FF and singular complexity, illuminating long-range correlations among singular values, serve as potent indicators of the chaos within non-Hermitian systems. As such, exploring the holographic bulk dual of singular complexity may offer insights into a potential holographic counterpart for non-Hermitian systems, especially the effective range of k in (6) in relation to 2d de Sitter (dS₂) gravity [86], which we leave for future work. Moreover, these tools adeptly reflect the shift towards integrability as sparsity intensifies. Notably, such transition is different than other chaoticintegrable transitions by two-point interactions observed in the SYK model [88]. We envision that these features will be exhibited in other correlation measures such as higher spacing ratios [63, 89] and the number variance [32, 72, 90, 91].

Parallel research avenues have explored the efficacy of sparse Hamiltonians [49, 50] within quantum processors [56, 57], maintaining chaotic dynamics to a substantial degree of sparsity. Notably, the SYK model retains its holographic duality even at minimal sparsity levels [54, 55]. Our study contributes to the burgeoning field of non-Hermitian systems and open-system dynamics, proposing a framework for the extrapolation of quantum chaotic properties within these systems. This might serve as the benchmark results for the simulation of sparse non-Hermitian systems on quantum processors.
