Block Circulant Codes with Application to Decentralized Systems

Birenjith Sasidharan *Member, IEEE*, Emanuele Viterbo *Fellow, IEEE*, Son Hoang Dau *Member, IEEE*

Abstract—The structure of linear dependence relations between coded symbols of a linear code, irrespective of specific coefficients involved, is referred to as the *topology* of the code. The specification of coefficients in turn is referred to as an *instantiation* of the topology. In this paper, we first propose a new block circulant topology $T_{[\mu,\lambda,\omega]}(\rho)$ for linear codes parameterized by integers $\rho \geq 2, \omega \geq 1, \lambda \geq 2$, and μ a multiple of λ . In this topology, the code has μ local (punctured) codes with $ρ$ parity-check (p-c) constraints and a total of $μρ$ p-c equations fully define the code. The set of symbols of a local code overlap with that of another in a uniform pattern, determined by two parameters, the *overlap width* ω and the *overlap factor* λ .

Next, we construct a class of block circulant (BC) codes $C_{BC}[\mu, \lambda, \omega, \rho]$ with blocklength $n = \mu(\rho + \omega)$, dimension $k = \mu\omega$ that instantiate $T_{[\mu,\lambda,\omega]}(\rho)$. Every local code of $\mathcal{C}_{BC}[\mu,\lambda,\omega,\rho]$ is a $[\rho + \lambda \omega, \lambda \omega, \rho + 1]$ generalized Reed-Solomon (RS) code. The overlap pattern between local codes helps to enhance the minimum distance $\rho + 1$ to $2\rho + 1$, without compromising much on the rate. We also provide an efficient decoding algorithm to correct 2ρ erasures when $\lambda = 2$ and the algorithm is amenable to distributed execution. Finally, we illustrate with an example that the BC codes serve as a viable alternative to 2D RS codes in protocols designed to tackle blockchain networks' data availability (DA) problem. In these protocols, every node in a network of light (resource-limited) nodes randomly queries symbols from a codeword stored in full (resource-rich) nodes and verifies these symbols using a cryptographic commitment scheme. For the same target performance in tackling the DA problem, the BC code requires querying a smaller number of samples than the 2D RS code when both have the same dimension and a fixed high rate. Furthermore, the number of local codes in the BC code is typically smaller than that in the 2D RS code, yielding a proportionate reduction in the complexity of realizing the commitment scheme.

I. INTRODUCTION

IN many applications, the code design problem comes with
additional structural constraints, apart from meeting targets N many applications, the code design problem comes with on error-correction capability and rate. The linear dependence relations between symbols in a codeword are expected to conform to certain structures, as demanded by needs of the application. For example in codes with locality [\[1\]](#page-12-0), every symbol is part of a set of linear dependence relations involving a small number of symbols, much less than the dimension of the code. In a distributed storage system, this structure helps to repair a failed node by downloading data from only a small number of easily accessible live nodes. The constraint of locality does not set the coefficients of the linear dependence relations, but it specifies that the number of symbols involved in the relation must be small. Down this line, a new approach emerged in the realm of designing codes [\[2\]](#page-12-1). Desirable features of a code developed for an application are achieved in two logically separated steps, viz., first by determining the structure of linear dependence relations among code symbols, and second by specifying the coefficients involved in these relations. The first is referred to as the *topology* of the code, and the second as an *instantiation* of the chosen topology. This two-step process for designing linear codes is referred to as the *modular approach* [\[2\]](#page-12-1).

The modular approach in code design became prominent along with the development of locally repairable codes [\[1\]](#page-12-0). The notions of locality [\[1\]](#page-12-0), [\[3\]](#page-12-2), [\[4\]](#page-12-3), locality with global parities [\[3\]](#page-12-2), availability [\[5\]](#page-12-4), [\[6\]](#page-12-5), and hierarchical locality [\[7\]](#page-12-6) are examples of diverse topologies that received attention due to applications in distributed storage. Though it is formally articulated only recently in [\[2\]](#page-12-1), the modular approach has existed in coding theory since its early days. For instance, the product topology is quite well-known starting from its introduction by Elias in 1954 [\[8\]](#page-12-7) with the aim of reliable communication with reduced decoding complexity, and up to its rejuvenated interest owing to applications in solid-state drives [\[9\]](#page-12-8), [\[10\]](#page-12-9). Many product-like topologies are introduced later. The product topology with additional global constraints binding all code symbols is named as grid-like topology and is explored in [\[2\]](#page-12-1) in an attempt to characterize all correctable erasure patterns. The staircase codes [\[11\]](#page-12-10), [\[12\]](#page-12-11) and diamond codes [\[13\]](#page-12-12) with applications respectively in fibre optic communication and magnetic disk arrays are codes with product-like topology with controlled deviations from the product topology, as required by the type of error/erasure patterns to be corrected. Recently an extended product topology that is relevant in disk arrays is introduced and studied in [\[14\]](#page-12-13).

In this paper, we adopt the modular approach to design erasure codes suitable for a unique application in decentralized systems. Efforts to achieve scalability of blockchain networks by the introduction of resource-limited "light" nodes apart from resource-rich "full" nodes resulted in a security vulnerability known as the *data availability (DA) problem*[1](#page-0-0)

¹The data availability problem in a decentralized system $[15]$ is quite different from the problem of availability in a distributed storage system [\[5\]](#page-12-4).

[\[15\]](#page-12-14). The problem arises when a malicious full node hides a few data symbols and there is no way to determine if the unavailability of data is on purpose of malicious intentions or due to network delays. A protocol that involves random querying by light nodes of a small number of symbols of an $[n, k, d]$ 2D Reed-Solomon (RS) codeword stored in full nodes has been identified as a robust solution to tackle the DA problem. In this protocol, every light node queries s random symbols independent of other light nodes from the codeword that is stored in every full node. If more than $(d-1)$ symbols of the codeword are unavailable, then a majority of light nodes are expected to query at least one unavailable symbol. On the other hand, if at least $(n-d+1)$ symbols are available in full nodes, then light nodes are expected to query $(n-d+1)$ symbols collectively so that distributed decoding of unavailable symbols can be carried out. Reconstructed symbols are then broadcast among full nodes. The choice of 2D RS code for the above protocol owes to two important features of the product topology of the code:

- Parity-check (p-c) constraints of all local codes (a punctured code obtained by puncturing certain locations) completely determine the p-c constraints of the entire code. This helps to do distributed encoding and decoding of the $code^2$ $code^2$.
- The minimum distance of the code scales to larger values than that of a local code. Hence, the erasure-correcting capability of the code is strictly better than that of any local code.

In addition to features gifted by the topology, the 2D RS code has an additional advantage, coming from the way it instantiates the topology using RS codes:

• Every local code is a polynomial evaluation code, in particular the RS code. This helps in making use of a popular cryptographic commitment scheme called Kate-Zaverucha-Goldberg (KZG) scheme [\[16\]](#page-12-15) (whose optimized implementation is available in [\[17\]](#page-12-16)) to verify the legitimacy of data that is exchanged between untrusted nodes.

All this led protocol designers to converge to 2D RS code as their natural choice. Against the backdrop of the above application, we make the following contributions.

- 1) We propose a new block circulant topology $T_{[\mu,\lambda,\omega]}(\rho)$ for linear codes parameterized by integers $\rho \geq 1$, $\omega \geq 1$, $\lambda \geq 2$, and μ a multiple of λ . There are μ local codes in this topology. A key feature of the topology is the uniform pattern with which local codes overlap with one another. The pattern is determined by two parameters, the *overlap factor* λ and the *overlap width* ω . Every local code has $ρ$ parity-check constraints and a blocklength of $λω + ρ$. The collection of $\mu \rho$ p-c constraints associated with the local codes fully defines the topology.
- 2) We construct a class of block circulant codes $\mathcal{C}_{BC}[\mu, \lambda, \omega, \rho]$ with blocklength $n = \mu(\rho + \omega)$, dimension $k = \mu \omega$ that instantiate the topology $T_{[\mu,\lambda,\omega]}(\rho)$. Every local code of $C_{BC}[\mu, \lambda, \omega, \rho]$ is a $[n_0 = \rho + \lambda \omega, k_0 =$

 $\lambda \omega, d_0 = \rho + 1$ Reed-Solomon code. When $\lambda = 2$, we show that the code has a minimum distance $d = 2\rho + 1$, that scales by a factor of $\lambda = 2$ relative to the minimum distance d_0 of every local code. We also provide an efficient decoding algorithm to correct 2ρ erasures when $\lambda = 2$ and the algorithm is amenable to distributed execution. For a given rate, our code performs better than product codes in terms of fractional minimum distance d/n in the regime of high rate.

3) Block circulant codes offer a viable alternative to 2D RS codes to achieve a wider parameter regime in protocols designed to tackle the DA problem in blockchain networks. More importantly, they outperform 2D RS codes in the regime of low storage overhead (inverse of rate). For example, we compare a [1444, 1024, 49] 2D RS code with a [1416, 1024, 65] shortened BC code both having a storage overhead of about 1.4x. In a system consisting of 1000 light nodes, the 2D RS code requires to query 72 coded symbols per light node, while the BC code requires only 53 in order to achieve the same target performance in tackling the DA problem. Apart from attaining lower network traffic, the low number 12 of local codes in the BC code instead of 76 in the 2D RS code yields a proportionate reduction in both spaceand time-complexity of realizing the KZG commitment scheme.

In Sec. [II,](#page-1-1) we present the block circulant topology. In Sec. [III,](#page-4-0) we present a code construction that instantiates the topology for an overlap factor $\lambda = 2$, determine its minimum distance, and provide an efficient erasure-correcting decoding algorithm. The construction is generalized for every $\lambda \geq 2$ in Sec. [IV.](#page-8-0) Finally in Sec. [V,](#page-8-1) we discuss an application of the code in decentralized systems.

Notation: We define $[n] := \{1, 2, ..., n\}$ and $[a, b] :=$ ${a, a + 1, \ldots, b}$ for any integers n, a, b . For any vector $\mathbf{x} = (x_1 \ x_2, \ \ldots, \ x_n), \ \text{supp}(\mathbf{x}) = \{i \mid 1 \leq i \leq n, x_i \neq 0\}.$ Let $A = \{a_1, a_2, \ldots, a_{|A|}\} \subseteq [n]$ be a subset of $[n]$. Then we denote the vector $(x_{a_i}, i = 1, 2, ..., |A|)$ of length $|A|$ by \mathbf{x}_A . Let C be an $[n, k, d]$ linear code. Then we define a punctured code $C_A = \{c_A \mid c \in C\}$ and call A as the support of C_A . An $(a \times a)$ identity matrix is denoted by I_a . Occasionally, we write a matrix A of size $(m \times n)$ as $A_{m \times n}$ to enhance readability. A vector of evaluations of a polynomial $p(X)$ at points in an ordered set A is denoted by $p(A)$.

II. CODES WITH BLOCK CIRCULANT TOPOLOGY

In this section, we first describe two known topologies in order to motivate the need for block circulant topology. Subsequently, we formally define block circulant topology and discuss its features.

A. Codes with a Topology

The concept of a topology of a linear code was introduced in [\[2\]](#page-12-1) in conjunction with the development of locally recoverable codes (LRCs). In an LRC, a code symbol can be recovered by accessing r other symbols where r is much less than the

²Distributed encoding/decoding is also referred to as collaborative encoding/decoding in research blogs of Ethereum that describe the DA problem.

dimension k of the code. We formally define linear LRCs with information-symbol or all-symbol locality in the following.

Definition 1. An $[n, k, d]$ *systematic linear code* C *is an* (r, δ) *LRC with information-symbol locality if associated to every* $message symbol$ $u_i, 1 \leq i \leq k$, there is a set of $n_0 - 1$ other *code symbols* $(c_{i1}, c_{i2}, \ldots, c_{in_0-1})$ *such that the set of* n_0 *code* $symbols$ $(u_i, c_{i1}, c_{i2}, \ldots, c_{in_0-1})$ *forms a* $[n_0, k_0, d_0]$ *code* C_i *such that* $d_0 \geq \delta$, $n_0 \leq r + \delta - 1$ *and consequently* $k_0 \leq r$. We refer to the punctured code C_i *as a local code associated* to message symbol u_i . If the above condition is true for every *code symbol (irrespective of whether the code is systematic or not), then we call* C *as an LRC with all-symbol locality.*

Respectively in [\[3\]](#page-12-2) and [\[4\]](#page-12-3), forms of generator and paritycheck matrices are introduced that led to $[n, k, d]$ codes with (r, δ) information-symbol and all-symbol locality. The form of generator matrix given in [\(1\)](#page-2-0) can give rise to a $[n = 7, k = 4]$ code C with $(r = 2, \delta = 2)$ -information-symbol locality:

$$
G_{\text{lin}}^{(i)} = \begin{bmatrix} 1 & g_{13} & g_{17} \\ 1 & g_{23} & g_{27} \\ & 1 & g_{36} & g_{37} \\ & & 1 & g_{46} & g_{47} \end{bmatrix} . \tag{1}
$$

The code C that instantiates $G_{lin}^{(i)}$ has two $[n_0 = 3, k_0 = 2]$ local codes $\{(c_1, c_2, c_3) | (c_1, \ldots, c_7) \in C\}$ and $\{(c_4, c_5, c_6) |$ $(c_1, \ldots, c_7) \in C$. The last symbol c_7 is not part of either of the local codes and is linearly dependent on all the message symbols. For this reason, we call it as a global parity whereas c_i , $i = 3, 6$ are called local parities. In similar lines, an LRC C with $(r = 2, \delta = 3)$ all-symbol-locality can be obtained by a parity-check-matrix of the form:

$$
H_{\text{lin}}^{(a)} = \begin{bmatrix} 1 & h_{13} & h_{14} \\ & 1 & h_{23} & h_{24} \\ & & & 1 & h_{37} & h_{38} \\ & & & & 1 & h_{47} & h_{48} \\ h_{51} & h_{52} & h_{53} & h_{54} & h_{55} & h_{56} & h_{57} & h_{58} \end{bmatrix} .
$$
 (2)

Again, C that instantiates $H_{lin}^{(a)}$ is a $[n = 8, k = 3]$ code with two $[n_0 = 4, k_0 = 2]$ local codes $\{(c_1, c_2, c_3, c_4)$ $(c_1, \ldots, c_8) \in C$ and $\{(c_5, c_6, c_7, c_8) \mid (c_1, \ldots, c_8) \in C\}.$ The first local code is determined by the first two rows of $H_{lin}^{(a)}$ and the second by the third and fourth rows. There is an additional parity-check constraint that involves all the code symbols. Hence it is referred to as a global paritycheck constraint in contrast to local parity-check constraints appearing in the first four rows. The number of global pc constraints either in $G_{lin}^{(i)}$ or in $H_{lin}^{(a)}$ is denoted by h. In both examples [\(1\)](#page-2-0) and [\(2\)](#page-2-1), we have $h = 1$. We refer to the topology described by either $G_{lin}^{(i)}$ or $H_{lin}^{(a)}$ as the *linear topology*. Codes instantiating linear topology and attaining the maximum possible minimum distance are known in the literature by the name of pyramid codes [\[3\]](#page-12-2), [\[4\]](#page-12-3).

B. Grid-like Topology and 2D Reed-Solomon Codes

In [\[2\]](#page-12-1), Gopalan et al. introduced a grid-like topology for linear codes and formally defined it as given below. The gridlike topology is a generalized abstraction of the *product codes* introduced in [\[8\]](#page-12-7).

Definition 2. [\[2\]](#page-12-1) (Grid-like topology) Let $n_c \leq n_r$ be positive *integers. Consider an* $(n_c \times n_r)$ *array of symbols* x_{ij} , $1 \leq i \leq$ $n_c, 1 ≤ j ≤ n_r$ *from some field* **F***. Let* $0 ≤ a ≤ n_c - 1, 0 ≤$ $b \leq n_r - 1$ *and* $0 \leq h \leq (n_c - a)(n_r - b) - 1$ *be integers. Then we define* $T_{n_c \times n_r}(a, b, h)$ *as grid-like topology which constitute the following:*

1) There are a *parity check equations for each column* j ∈ $[n_r]$ *, i.e.,*

$$
\sum_{i=1}^{n_c} \alpha_i^{(u)} x_{ij} = 0, \ u \in [a]
$$

for some indeterminate coefficients $\{\alpha_i^{(u)}\}$.

2) There are b parity check equations for each row $i \in [n_c]$ *, i.e.,*

$$
\sum_{j=1}^{n_r} \beta_i^{(u)} x_{ij} = 0, \ u \in [b]
$$

for some indeterminate coefficients $\{\beta_i^{(u)}\}$.

3) There are h *global parity check equations involving symbols of the entire array, i.e.,*

$$
\sum_{i=1}^{n_c} \sum_{j=1}^{n_r} \gamma_{ij}^{(u)} x_{ij} = 0, \ u \in [h]
$$

for some indeterminate coefficients $\{\gamma_{ij}^{(u)}\}$.

When $n_c = n_r$ *and* $a = b$ *, we call it a square-grid topology. A linear code over a field* F *is said to instantiate the grid*like topology $T_{n_c \times n_r}(a, b, h)$ if it has a parity-check matrix H *that is completely determined by parity-check equations* of $T_{n_c \times n_r}(a, b, h)$ for some fixed assignment of values to $\{\alpha_i^{(u)}\}, \{\beta_i^{(u)}\}, \{\gamma_{ij}^{(u)}\}.$

In linear topology, a code symbol is associated to at most one local code. In grid-like topology in contrast, there are two local codes associated to every symbol, namely an $[n_c, n_c - a]$ code and an $[n_r, n_r - b]$ code, the former referred to as the column code and the latter as the row code. In addition to p-c constraints of local codes, every symbol is subjected to h additional global p-c constraints. When $h = 0$, the grid-like topology $T_{n_c \times n_r}(a, b, 0)$ is associated with a generator matrix G_{grid} that can be written as the tensor product of generator matrices of row and column codes. For example, when $n_c =$ $3, n_r = 4, a = 1, b = 2, h = 0, n = n_c n_r = 12, k = (n_c$ $a)(n_r - b) = 4$, G_{grid} takes the form:

$$
G_{\text{grid}} = \begin{bmatrix} 1 & g_{13}^{(r)} & g_{14}^{(r)} \\ 1 & g_{23}^{(r)} & g_{24}^{(r)} \end{bmatrix} \otimes \begin{bmatrix} 1 & g_{13}^{(c)} \\ 1 & g_{23}^{(c)} \end{bmatrix}
$$
 (3)

where ⊗ represents the tensor product of matrices. Though the grid-like topology is introduced and studied in [\[2\]](#page-12-1) with application to distributed storage systems, our motivation to revisit the topology stems from the use of 2D RS codes in blockchain protocols.

Let us consider a $[n = n_0^2, k = k_0^2, d = (n_0 - k_0 + 1)^2]$ 2D Reed-Solomon code C_{2DRS} where both row and column codes are $[n_0, k_0, d_0 = n_0 - k_0 + 1]$ RS codes. Clearly, C_{2DRS} instantiates square-grid topology $T_{n_0 \times n_0}(n_0 - k_0, n_0 - k_0, 0)$. The C_{2DRS} has the following key advantages, relevant in a decentralized system:

- 1) Both encoding and decoding can be executed in a distributed manner where each participant node carries out operations on a given row or column in the grid. Each node will be equipped with algorithms related to $[n_0, k_0]$ RS code.
- 2) It is possible to verify the correctness of a code symbol by processing only the row and column codes containing that symbol. This can be done by accessing only symbols from these local codes, rather than the entire code.

Moreover, the code C_{2DRS} is optimal in minimum distance among all codes instantiating the grid-like topology. For any [n, k, d] code instantiating grid-like topology $T_{n_c \times n_r}(a, b, h)$, it is known that

$$
d \le (a+1)(b+1) + h. \tag{4}
$$

With $h = 0$, C_{2DRS} achieves the upper bound in [\(4\)](#page-3-0).

C. Block Circulant Topology

Consider an $[n, k, d]$ code C_{lin} instantiating the linear topology and with local codes of uniform parameter sets $[n_0, k_0, d_0]$. Then C_{lin} either has a generator matrix as in [\(1\)](#page-2-0) or has a parity-check matrix as in [\(2\)](#page-2-1). The code has either (r, δ) information-symbol or (r, δ) all-symbol locality with $n_0 = r + \delta - 1$, $k_0 = r$ and $d_0 \ge \delta$. It can be shown that the rate $\frac{k}{n}$ of C_{lin} is upper bounded by the rate of the local code $\frac{k_0}{n_0}$ [\[18\]](#page-12-17). The bound is attained when $h = 0$ where h is the number of global p-c constraints of the linear topology. It is straightforward to argue that $d \leq d_0 + h$. So when $h = 0$, $d \leq d_0$ and the bound is attainable by choosing a good instance as the code. Thus, the rate and the minimum distance of C_{lin} are limited by those of its local codes when there are no global p-c constraints.

In contrast, consider a $[n = n_0^2, k = (n_0 - a)^2, d]$ code C_{sq} that instantiates square-grid topology $T_{n_0 \times n_0}(a, a, 0)$, again with $h = 0$, i.e., zero global p-c constraints. Every local code of C_{sq} is a $[n_0, k_0 = n_0 - a, d_0]$ code where $d_0 \le (a + 1)$. We already observed that when C_{sq} is picked as C_{2DRS} , $d =$ $(a + 1)^2$ thus achieving a value much larger than d_0 of the local code. However, the rate of the code $\frac{k}{n} = \frac{(n_0 - a)^2}{n_0^2}$ $rac{(-a)}{n_0^2}$ dips quite low compared to that of the local code, viz., $\frac{(n_0-a)}{n_0}$. Thus even when $h = 0$, the square-grid topology enables to increase the minimum distance beyond that of the local codes, at the cost of a significant loss in rate.

It is worthwhile to compare linear and square-grid topologies when both do not have any global p-c constraint. Both the rate and the minimum distance remain the same as those of local codes under the linear topology. On the other hand, the square-grid topology allows to tradeoff rate against minimum distance taking parameters of local codes as the benchmark. It is intriguing to search for other useful topologies that lie in a presumably broad spectrum between these two. Keeping this in mind, we pose the following question. Can we design topologies that (a) involve only local parity-check constraints, yet that (b) allow to scale minimum distance above that of local codes, and (c) resist a large reduction in rate compared to that of local codes?

The proposed block circulant topology defined below is an example of such a desired topology. Later in Sec. [V,](#page-8-1) we will describe how it becomes useful in decentralized systems.

Definition 3. *(Block Circulant Topology) Let* $\rho, \omega, \lambda \geq 2$ *be positive integers. Let* $\mu = \lambda \nu$ *with* $\nu \geq 1$ *be an integer multiple of* λ *. Consider a set of* $n := \mu(\rho + \omega)$ *symbols* ${x_0, x_1, ..., x_{n-1}}$ *of some field* **F***. Let* $A_i, i = 1, 2, ..., \mu$ *be (non-disjoint) subsets of* $[0, n-1]$ *each of size* $\rho + \lambda \omega$ *and let each* A_i *be a union of* $(\lambda + 1)$ *pairwise disjoint subsets* $B_{i0}, B_{i1}, \ldots, B_{i,\lambda}$ *. These sets are defined as below:*

$$
B_{i0} = \{ i\omega + (i-1)\rho, i\omega + (i-1)\rho + 1, ..., i(\rho + \omega) - 1 \}, i \in [\mu], B_{ij} = \{ (i + j - 2)(\rho + \omega), (i + j - 2)(\rho + \omega) + 1, ..., (i + j - 2)(\rho + \omega) + \omega - 1 \}, i \in [\mu], j \in [\lambda], A_i = \bigcup_{j=0}^{\lambda} B_{ij}, i \in [\mu],
$$

where every element of B_{ij} , $j = 0, 1, \ldots, \lambda$ *is computed modulo* $\mu(\rho + \omega)$ *. The set of symbols* $\{x_0, x_1, \ldots, x_{n-1}\}$ *is identified as a union of* µ *subsets*

$$
X_i = \{x_j \mid j \in A_i\}, \ i \in [\mu],
$$

each of size $\rho + \lambda \omega$ *. We index the elements of* X_i *alternatively as* $X_i = \{x_{i0}, x_{i1}, \ldots, x_{i,\rho+\lambda\omega-1}\}$ *for every* $i \in [\mu]$ *. Then we define* $T_{[\mu,\lambda,\omega]}(\rho, h)$ *as block circulant topology which constitute the following:*

1) There are ρ *parity check equations for every* $i \in [\mu]$ *, i.e.,*

$$
\sum_{j=0}^{\rho+\lambda\omega-1} \alpha_{ij}^{(u)} x_{ij} = 0, \ u \in [\rho], \ i \in [\mu]
$$

for some indeterminate coefficients $\{\alpha_{ij}^{(u)}\}$.

2) There are $0 \le h \le \mu\omega - 1$ *global parity check equations involving all* n *symbols, i.e.,*

$$
\sum_{i=0}^{n-1} \gamma_i^{(u)} x_i = 0, \ u \in [h]
$$

for some indeterminate coefficients $\{\gamma_i^{(u)}\}$.

The block circulant topology with $h = 0$ *, i.e., with no global parities, is denoted by* $T_{[\mu,\lambda,\omega]}(\rho)$ *and we shall consider only* $T_{[\mu,\lambda,\omega]}(\rho)$ *throughout this paper. A linear code over a field* F *is said to instantiate the block circulant topology* $T_{[\mu,\lambda,\omega]}(\rho)$ *if it has a parity-check matrix H that is completely determined by parity-check equations of* $T_{[\mu,\lambda,\omega]}(\rho)$ *for some fixed assignment of values from* \mathbb{F} *to* $\{\alpha_{ij}^{(u)}\}, \{\gamma_i^{(u)}\}.$

The structure of the parity-check matrix of a code instantiating $T_{[\mu,\lambda,\omega]}(\rho)$ is given in [\(5\)](#page-4-1) taking an example with $\mu = 6, \lambda = 3, \omega = 3, \rho = 2$. It can be observed that the submatrix of H_{bc-top} formed by columns associated to ${H_{ij} | j$ is even} can be made full-rank by appropriate choice of coefficients. In that case, all the rows of the H_{bc-top} become linearly independent and thus H_{bc-top} becomes a full-rank matrix. We shall restrict our discussion to only such codes instantiating $T_{[\mu,\lambda,\omega]}(\rho)$.

$$
H_{bc-top} = \begin{bmatrix} H_{11} & H_{12} & H_{13} & H_{15} \\ & H_{23} & H_{24} & H_{25} & H_{27} \\ & & H_{35} & H_{36} & H_{37} & H_{39} \\ & & & H_{47} & H_{48} & H_{49} & H_{4,11} \\ & & & H_{59} & H_{5,10} & H_{5,11} \\ & & & H_{6,11} & H_{6,12} \end{bmatrix}_{\mu\rho\times\mu(\rho+\omega)},
$$
\n
$$
H_{ij} = \begin{cases} \begin{bmatrix} h_{2i-1,(5j/2)-1} & h_{2i-1,(5j/2)} \\ h_{2i,(5j/2)-1} & h_{2i,(5j/2)} \end{bmatrix}_{\rho\times\rho}, & i \in [6], j = 2i, \\ \begin{bmatrix} h_{2i-1,((5j-1)/2)-1} & h_{2i-1,(5j-1)/2} & h_{2i-1,((5j-1)/2)+1} \\ h_{2i,((5j-1)/2)-1} & h_{2i,(5j-1)/2} & h_{2i,((5j-1)/2)+1} \end{bmatrix}_{\rho\times\omega}, & i \in [6], j = 2i - 1, 2i + 1, 2i + 3 \text{ mod } 12. \end{bmatrix} \end{cases}
$$
\n(6)

Fig. 1: The structure of parity-check matrix in block circulant topology $T_{[\mu,\lambda,\omega]}(\rho)$ when we pick $\mu = 6, \lambda = 3, \omega = 3, \rho = 2$.

Consider an $[n, k, d]$ code C instantiating $T_{[\mu, \lambda, \omega]}(\rho)$. It is clear that blocklength $n = \mu(\rho + \omega)$ and dimension $k = \mu\omega$. All the local codes in C are of parameters $[\rho + \lambda \omega, \lambda \omega]$ with a rate of $\frac{\lambda \omega}{\rho + \lambda \omega}$. A prominent feature of H_{bc-top} is the regular overlap pattern between the supports of different local codes. If $\mu > \lambda$, then every local code overlaps with $2(\lambda - 1)$ other local codes, each on a subset of ω symbols. If $\mu = \lambda$, every local code overlaps with $(\lambda - 1)$ other local codes. For this reason, we call the parameters λ, ω in $T_{[\mu,\lambda,\omega]}(\rho)$ respectively as the *overlap factor* and the *overlap width*. In [\(5\)](#page-4-1), as $\lambda = 3$ and $\mu > \lambda$, every local code overlaps with 4 other local codes in their support. The code C has a rate

$$
R_{bc} = \frac{\omega}{\rho + \omega}, \tag{7}
$$

that is less than the rate of local codes. However, it is possible to achieve high rates by a suitable choice of ρ, ω . The maximum achievable minimum distance of every local code is $\rho + 1$. The relevant question is to determine how much can the minimum distance d be scaled above $\rho + 1$. In the coming two sections, we provide a code construction $\mathcal{C}_{BC}[\mu, \lambda, \omega, \rho]$ instantiating $T_{[\mu,\lambda,\omega]}(\rho)$. The code has $d = 2\rho+1$ when $\lambda = 2$, establishing that $T_{[\mu,\lambda,\omega]}(\rho)$ allows to scale d by a factor of about $\lambda = 2$ over that of the local code.

III. A CONSTRUCTION FOR AN OVERLAP FACTOR $\lambda = 2$

In this section, we present a code construction $\mathcal{C}_{\text{BC}}[\mu, 2, \omega, \rho]$ that instantiates $T_{[\mu, \lambda, \omega]}(\rho)$ with $\lambda = 2$. We begin with a review of generalized Reed-Solomon (GRS) codes as they form an important building block for the construction.

A. A Review of Generalized Reed-Solomon Codes

Let \mathbb{F}_q be a finite field of $q > n$ elements. Let Λ = $\{\alpha_0, \alpha_1, \ldots, \alpha_{n-1}\}\$ be a set of n non-zero elements in \mathbb{F}_q . Let

$$
V_r(\Lambda) := \begin{bmatrix} 1 & 1 & \cdots & 1 \\ \alpha_0 & \alpha_1 & \cdots & \alpha_{n-1} \\ \vdots & \vdots & & \vdots \\ \alpha_0^{r-1} & \alpha_1^{r-1} & \cdots & \alpha_{n-1}^{r-1} \end{bmatrix}
$$
 (8)

denote an $(r \times n)$ Vandermonde matrix. When it is required to make explicit reference to elements, we may as well write $V_r(\Lambda)$ as $V_r(\alpha_0, \alpha_1, \ldots, \alpha_{n-1})$. For some non-zero constants $a_0, a_1, \ldots, a_{n-1} \in \mathbb{F}_q$, we construct an $(n \times n)$ diagonal matrix M and define a parity-check matrix H_{GRS} as follows:

$$
M = \text{diag}(a_0, a_1, \dots, a_{n-1}) \tag{9}
$$

$$
H_{\text{GRS}} = V_r(\Lambda) \cdot M. \tag{10}
$$

A GRS code over \mathbb{F}_q is defined as

$$
\mathcal{C}_{\text{GRS}} = \{ \mathbf{c} \in \mathbb{F}_q^n \mid H_{\text{GRS}} \mathbf{c}^T = \mathbf{0} \}. \tag{11}
$$

It is well-known that C_{GRS} is an $[n, k = n - r, d = r + 1]$ linear code and it can alternatively be defined as an evaluation code:

$$
\mathcal{C}_{\text{GRS}} = \{ \mathbf{c} = (a'_0 f(\alpha_0), a'_1 f(\alpha_1), \dots, a'_{n-1} f(\alpha_{n-1})) \mid \nf(X) \in \mathbb{F}_q[X], \ \deg(f(X)) \leq k - 1 \} \tag{12}
$$

where $a'_0, a'_1, \ldots, a'_{n-1} \in \mathbb{F}_q$ are constants given by

$$
(a'_i)^{-1} = a_i \prod_{\substack{j=0 \ j \neq i}}^{n-1} (\alpha_i - \alpha_j), \ i = 0, 1, \dots, n-1. \tag{13}
$$

We refer to α_j, a_j, a'_j respectively as code locator, paritycheck column multiplier, and generator column multiplier all associated to the code symbol c_j for every $j = 0, 1, \ldots, n-1$ in a codeword $\mathbf{c} = (c_0, c_1, \dots, c_{n-1})$. The polynomial $f(X)$ that defines a codeword $c \in C_{GRS}$ as given in [\(12\)](#page-4-2) is referred to as the message polynomial of c. As can be observed from [\(13\)](#page-4-3), it is possible to fix $a'_i = 1$ for all i by suitably choosing $a_i, i = 0, 1, \dots, n-1$ as a function of code locators. We refer to such a GRS code as *basic Reed-Solomon* (BRS) code and is given by

$$
\mathcal{C}_{\text{BRS}} = \{ \mathbf{c} = (f(\alpha_0), f(\alpha_1), \dots, f(\alpha_{n-1})) \mid (14)
$$

$$
f(X) \in \mathbb{F}_q[X], \deg(f(X)) \le k - 1 \}.
$$

A BRS code is completely determined by a set of code locators. Every codeword $c \in \mathcal{C}_{BRS}$ is mapped to a message polynomial $f(X)$ by an 1-1 correspondence. We denote this bijection by $\Phi_{\mathcal{C}_{BRS}}$ and write $\Phi_{\mathcal{C}_{BRS}}(f) = \mathbf{c}$. When the code is clear from the context, we may omit the subscript and write $\Phi(f) = \mathbf{c}.$

$$
H_{BC,2} = \begin{bmatrix} W_{11} & W_{12} & W_{13} & W_{24} & W_{21} & & & & & \\ & W_{23} & W_{24} & W_{21} & W_{12} & W_{13} & & & \\ & & & \ddots & & & \ddots & & \\ & & & & W_{11} & W_{12} & W_{13} & \\ & & & & & W_{23} & W_{24} \end{bmatrix}_{2\nu\rho \times 2\nu(\rho+\omega)}
$$
(15)

Fig. 2: The parity-check marix of $C_{BC}[\mu, 2, \omega, \rho]$ that instantiates block circulant topology $T_{[\mu,2,\omega]}(\rho)$. We have $\mu = \lambda \nu = 2\nu$. The submatrix $W_{ij} = V_j M_{ij}$ where V_j 's are Vandermonde matrices and M_{ij} 's are diagonal matrices.

B. The Construction of $\mathcal{C}_{BC}[\mu, 2, \omega, \rho]$

Let $\mu, \lambda, \omega, \rho$ be positive integers as defined in $T_{[\mu,\lambda,\omega]}(\rho)$ and we fix $\lambda = 2$. Since $\lambda \mid \mu$, we write $\mu = 2\nu$ where $\nu \ge 1$ is a positive integer. We describe the code construction in a step-by-step manner as follows.

1) Let \mathbb{F}_q be such that $q > 2(\rho + \omega)$. We pick a subset of non-zero elements $\Lambda = {\alpha_0, \alpha_1, \ldots, \alpha_{2(\rho+\omega)-1}}$ of \mathbb{F}_q . Recall the definition of sets $\{A_i\}, \{B_{ij}\}\$ from Defi-nition [3.](#page-3-1) We partition Λ into four ordered sets as below:

$$
\Lambda_{\ell} := \left\{ \begin{array}{l} \{\alpha_j \mid j \in B_{(\ell+1)/2,1}\}, & \ell = 1,3 \\ \{\alpha_j \mid j \in B_{(\ell/2),0}\}, & \ell = 2,4 \end{array} \right. . \tag{16}
$$

Observe that $|\Lambda_{\ell}| = \omega$ when ℓ is odd and $|\Lambda_{\ell}| = \rho$ when ℓ is even.

2) In association to each Λ_{ℓ} , we define a Vandermonde matrix (by slight abuse of notation) as:

$$
V_{\ell} = V_{\rho}(\Lambda_{\ell}), \ \ell = 1, 2, 3, 4. \tag{17}
$$

3) Construct six diagonal matrices $M_{11}, M_{12}, M_{13}, M_{23}, M_{24}, M_{21}$ in such a manner that the matrices W_1, W_2 as defined below

$$
W_1 = [W_{11} \ W_{12} \ W_{13}] := [V_1 M_{11} \ V_2 M_{12} \ V_3 M_{13}] (18)
$$

$$
W_2 = [W_{23} \ W_{24} \ W_{21}] := [V_3 M_{23} \ V_4 M_{24} \ V_1 M_{21}] (19)
$$

form parity-check matrices of two $[\rho + 2\omega, 2\omega, \rho + 1]$ basic RS codes. The GRS codes defined by W_1, W_2 as parity-check matrices are denoted by $\mathcal{D}_1[2], \mathcal{D}_2[2]$ respectively. From the discussion in Sec. [III-A,](#page-4-4) it may be observed that diagonal entries of M_{11} , M_{12} , M_{13} are determined by $\Lambda_1 \cup \Lambda_2 \cup \Lambda_3$. Similarly, diagonal entries of M_{23} , M_{24} , M_{21} are determined by $\Lambda_3 \cup \Lambda_4 \cup \Lambda_1$. It will be evident in the next step that these two basic RS codes $\mathcal{D}_1[2], \mathcal{D}_2[2]$ form the local codes in the code $C_{BC}[\mu, 2, \omega, \rho]$. Observe that in the notation M_{ij} , the first index i indicates the local code and the second index i indicates the associated Vandermonde matrix.

- 4) Next, we construct a $(\mu \rho \times \mu (\rho + \omega))$ parity-check matrix $H_{BC,2}$ as given in [\(15\)](#page-5-0).
- 5) Finally, the code is defined as

$$
\mathcal{C}_{\text{BC}}[\mu, 2, \omega, \rho] = \{ \mathbf{c} \in \mathbb{F}_q^n \mid H_{\text{BC}, 2} \mathbf{c}^T = \mathbf{0} \}. (20)
$$

In $H_{BC,2}$, the submatrix formed by columns associated to ${W_{ij}, j$ is even} is of full rank. Therefore, the dimension of $C_{BC}[\mu, 2, \omega, \rho]$ is equal to $k = \mu\omega$ and thus $C_{BC}[\mu, 2, \omega, \rho]$ is a $[n = \mu(\rho + \omega), k = \mu\omega]$ code instantiating $T_{[\mu,2,\omega]}(\rho)$. There are μ local codes $C_{BC,j}[2]$ in $C_{BC}[2]$ defined by

$$
\mathcal{C}_{\mathrm{BC},j}[2] \quad = \quad \{\mathbf{c}|_{A_j} \quad | \quad \mathbf{c} \in \mathcal{C}_{\mathrm{BC}}[2] \}
$$

where A_i is as defined in Definition [3.](#page-3-1) Observe that each of these local codes is one of either $\mathcal{D}_1[2]$ or $\mathcal{D}_2[2]$.

In the coming subsections, we describe a systematic encoding procedure, an efficient erasure-correction decoder. As a corollary, we also characterize the minimum distance of the code.

C. Systematic Encoding of $\mathcal{C}_{BC}[\mu, 2, \omega, \rho]$

By construction of $H_{BC,2}$, its square submatrix

$$
\tilde{H}_{BC,2} = \text{diag}[W_{12}, W_{24}, \dots, W_{12}, W_{24}]
$$

is invertible because both W_{12} and W_{24} are invertible matrices. Multiplying $H_{BC,2}$ on the left by $\tilde{H}_{BC,2}^{-1}$ followed by necessary column permutations, we convert $H_{BC,2}$ into its systematic form. In turn, we obtain a systematic generator matrix $G_{BC,2}$ (upto column permutations) for $C_{BC}[\mu, 2, \omega, \rho]$ given by:

$$
G_{BC,2} = [I_{\mu\omega} | -P_{BC,2}], \text{ where } (21)
$$

\n
$$
P_{BC,2} = \begin{bmatrix} (W_{12}^{-1}W_{11})^T & (W_{24}^{-1}W_{23})^T & \cdots & (W_{24}^{-1}W_{21})^T \\ (W_{12}^{-1}W_{13})^T & (W_{24}^{-1}W_{21})^T & \vdots \\ & & (W_{24}^{-1}W_{23})^T \end{bmatrix}.
$$

\n
$$
(W_{24}^{-1}W_{23})^T
$$

\n(22)

D. An Erasure Correcting Decoder for $C_{BC}[\mu, 2, \omega, \rho]$

We use the letter E to denote an erasure. For any vector $\mathbf{x} = (x_i, i \in A)$ of arbitrary length |A| where A is an ordered set, we define

$$
S_E(\mathbf{x}) = \{i \mid x_i = \mathbf{E}\} \subseteq A,\tag{23}
$$

$$
n_E(\mathbf{x}) = |S_E(\mathbf{x})|.
$$
 (24)

For an $[n, k, d = n - k + 1]$ GRS code C_{GRS} over any field, there is an efficient decoder of time-complexity $O(n \log^2 n \log \log n)$ [\[19\]](#page-12-18) that can recover from any set of $(d - 1)$ erasures. We use DEC_{CGRS} to denote the erasure correcting decoder of the code C_{GRS} . It takes as input a vector y that is obtained by subjecting a codeword $c \in C_{GRS}$ to erasures, and outputs the correct codeword c if $n_E(\mathbf{y}) \leq n-k$. If $n_E(y) > n - k$, it returns y itself as the output. We consider C_{GRS} up to column permutations and therefore the same algorithm $DEC_{C_{GRS}}$ works even if the input vector is permuted with a known permutation. In this subsection, We make use of C_{GRS} as a building block to construct an erasurecorrecting decoder for $C_{BC}[\mu, 2, \omega, \rho]$, denoted by DEC_{CBC[2]}. Let $\mathbf{c} = (c_0, c_1, \dots, c_{n-1}) \in C_{BC}[\mu, 2, \omega, \rho]$ be an arbitrary codeword. Let $\mathbf{r} = (r_0, r_1, \dots, r_{n-1}) \in (\mathbb{F}_q \cup \{\mathbb{E}\})^n$ be a vector obtained as

 $r_i = \begin{cases} c_i & \text{if } i\text{-th location is not erased} \\ E & \text{if } i\text{-th location is erased} \end{cases}$.

The decoder takes r as input and outputs the codeword c if $n_E(y) \le 2\rho$. If $n_E(y) > 2\rho$, it returns y itself as the output. The decoder $DEC_{\mathcal{C}_{GRS}}$ when $\mathcal{C}_{GRS} = \mathcal{D}_1[2]$ is denoted by DEC $_{\mathcal{D}_1[2]}$ and similarly when $\mathcal{C}_{GRS} = \mathcal{D}_2[2]$, by DEC $_{\mathcal{D}_2[2]}$. Let us define another $[n = 2(\rho + \omega), k = 2\omega, d = 2\rho + 1]$ basic RS code given by

$$
\mathcal{D}_{1\oplus 2}[2] = \{ (f(\alpha_i), i \in \bigcup_{\ell=1}^4 \Lambda_\ell) \mid f(X) \in \mathbb{F}_q[X],
$$

$$
\deg(f(X)) \le 2\omega - 1 \} \qquad (25)
$$

that is relevant for the decoding algorithm. In the following, we describe $DEC_{C_{BC}[2]}$ in a step-by-step manner and its correctness will be proved in a subsequent theorem.

- (1) Compute $e = n_E(\mathbf{r})$. If $e > 2\rho$, return r.
- (2) Set $\ell \leftarrow 0$. Set $\hat{\mathbf{r}}_{\ell} \leftarrow \mathbf{r}$. Compute $\hat{\mathbf{r}}_{\ell j} \leftarrow \hat{\mathbf{r}}_{\ell} |_{A_j}, j \in [\mu]$ and index the entries of the vector as $\hat{\mathbf{r}}_{\ell j} = (\hat{r}_{\ell j}[i], i \in$ (A_j) . Compute $J_1 \leftarrow \{j \mid n_E(\hat{\mathbf{r}}_{\ell j}) \leq \rho\}$. Repeat Steps 3 – 4 until $J_1 = \phi$. If $J_1 = \phi$, move to Step 5.
- (3) For every $j \in [\mu]$, compute

$$
\hat{\mathbf{r}}_{\ell+1,j} \leftarrow \left\{ \begin{array}{ll} \text{DEC}_{\mathcal{D}_1[2]}(\hat{\mathbf{r}}_{\ell j}) & \text{if } j \text{ is odd} \\ \text{DEC}_{\mathcal{D}_2[2]}(\hat{\mathbf{r}}_{\ell j}) & \text{if } j \text{ is even} \end{array} \right. \tag{26}
$$

(4) Compute $\hat{\mathbf{r}}_{\ell+1} = (\hat{r}_{\ell+1,0}, \hat{r}_{\ell+1,1}, \dots, \hat{r}_{\ell+1,n-1})$ as

$$
\hat{r}_{\ell+1,i} \leftarrow \begin{cases} \hat{r}_{\ell+1,j}[i] & \text{if } \exists j \in [\mu] \text{ such that } \hat{r}_{\ell+1,j}[i] \neq \text{E} \\ \text{E} & \text{otherwise} \end{cases} \tag{27}
$$

Compute $\hat{\mathbf{r}}_{\ell+1,j} \leftarrow \hat{\mathbf{r}}_{\ell+1} |_{A_j}, j \in [\mu]$ and update $J_1 \leftarrow$ $\{j \mid n_E(\hat{\mathbf{r}}_{\ell+1,j}) \leq \rho\}$. Increment $\ell \leftarrow \ell+1$.

(5) Set $\hat{\mathbf{r}} \leftarrow \hat{\mathbf{r}}_{\ell}$. Compute $\hat{\mathbf{r}}_j \leftarrow \hat{\mathbf{r}} \mid_{A_j}, j \in [\mu]$. If $n_E(\hat{\mathbf{r}}) = 0$, then the decoding is completed and return $\hat{\mathbf{r}}$. If $n_E(\hat{\mathbf{r}}) \neq$ 0, then assign $J_2 \leftarrow \{j \mid n_E(\hat{\mathbf{r}}_j) > \rho\}$. Identify unique $j_1 \in [\mu]$ such that $J_2 = \{j_1, j_2\}$ and

$$
j_2 = \begin{cases} j_1 + 1 & \text{if } j_1 < \mu \\ 1 & \text{if } j_1 = \mu \end{cases} . \tag{28}
$$

(6) Generate the vector $\hat{\mathbf{s}} \in (\mathbb{F}_q \cup \{\mathbf{E}\})^{(\rho+2\omega)}$ with its entries indexed as $\hat{\mathbf{s}} = (\hat{s}_i, i \in A_{j_1})$. Set $\hat{\mathbf{s}} \leftarrow \mathbf{0}$ if $\mu = 2$, or else set it as given in [\(29\)](#page-6-0):

$$
\hat{s}_i \leftarrow \begin{cases} \hat{r}_i - \hat{r}_{2(\rho+\omega)+i \mod n} & i \in B_{j_1,1} \\ \mathbf{E} & i \in B_{j_1,0} \\ 0 & i \in B_{j_1,2} \end{cases} . (29)
$$

(7) If $\mu > 2$, update $\hat{\mathbf{s}}$ as:

$$
\hat{\mathbf{s}} \leftarrow \left\{ \begin{array}{ll} \text{DEC}_{\mathcal{D}_1[2]}(\hat{\mathbf{s}}) & \text{if } j_1 \text{ is odd} \\ \text{DEC}_{\mathcal{D}_2[2]}(\hat{\mathbf{s}}) & \text{if } j_1 \text{ is even} \end{array} \right. \tag{30}
$$

Compute $s(X) \leftarrow \Phi^{-1}(\hat{\mathbf{s}}).$

(8) Generate two vectors $\hat{\mathbf{u}}_1, \hat{\mathbf{u}}_2 \in (\mathbb{F}_q \cup \{\mathbb{E}\})^{2(\rho+\omega)}$ as in [\(31\)](#page-6-1) and [\(32\)](#page-6-1) when their entries are indexed as \hat{u}_1 = $(\hat{u}_{1i}, i \in A_{j_1} \cup B_{j_2,0}), \hat{\mathbf{u}}_2 = (\hat{u}_{2i}, i \in B_{j_1,0} \cup A_{j_2});$

$$
\hat{u}_{1i} \leftarrow \begin{cases} \hat{r}_i & i \in A_{j_1} \\ \hat{r}_i + s(\alpha_i) & i \in B_{j_2,0} \text{ and } \hat{r}_i \neq \text{E} \end{cases} (31)
$$
\n
$$
\hat{u}_{2i} \leftarrow \begin{cases} \hat{r}_i & i \in A_{j_2} \\ \hat{r}_i - s(\alpha_i) & i \in B_{j_1,0} \text{ and } \hat{r}_i \neq \text{E} \end{cases} (32)
$$
\n
$$
\hat{u}_{2i} \leftarrow \begin{cases} \hat{r}_i & i \in A_{j_2} \\ \hat{r}_i - s(\alpha_i) & i \in B_{j_1,0} \text{ and } \hat{r}_i \neq \text{E} \end{cases} (32)
$$

(9) Update $\hat{\mathbf{u}}_1$, $\hat{\mathbf{u}}_2$ as:

$$
\hat{\mathbf{u}}_1 \leftarrow \text{DEC}_{\mathcal{D}_{1\oplus 2}[2]}(\hat{\mathbf{u}}_1) \tag{33}
$$

$$
\hat{\mathbf{u}}_2 \leftarrow \text{DEC}_{\mathcal{D}_{1\oplus 2}[2]}(\hat{\mathbf{u}}_2) \tag{34}
$$

 (10) Update $\hat{\bf{r}}$ as:

$$
\hat{r}_i \leftarrow \begin{cases} \hat{u}_{\ell i} & i \in A_{j_1} \cup A_{j_2} \text{ and } \ell \in \{1, 2\} \\ \hat{r}_i & i \notin A_{j_1} \cup A_{j_2} \end{cases} \tag{35}
$$

Return \hat{r} .

In the following theorem, we establish the correctness of the decoder.

Theorem III.1. Let $\mathbf{c} \in \mathcal{C}_{BC}[\mu, 2, \omega, \rho]$ and **r** be a vector *obtained by subjecting* **c** *to erasures.* If $n_E(\mathbf{r}) \leq 2\rho$, then the *algorithm* DEC^C*BC*[2] *outputs* c *when it is executed with* r *as its input.*

Proof. The Step 1 of $DEC_{\mathcal{C}_{BC}[2]}$ ensures that the input r to the algorithm satisfies $n_E(\mathbf{r}) \leq 2\rho$. Recall that $\mathcal{C}_{BC}[2]$ consists of μ local codes indexed by $j = 1, 2, \dots, \mu$ and for every j it is denoted by $C_{BC,j}[2]$. Each $C_{BC,j}[2]$ is a $[\rho + 2\omega, 2\omega, \rho +$ 1] GRS code and can correct any set of up to ρ erasures. In Steps 3, 4, erasures are corrected exploiting the erasurecorrecting-capability of only these local codes. Suppose that there are up to ρ erasures in the support of one local code, say $C_{BC,j}[2]$, whereas more than ρ erasures in the support of another local code, say $C_{BC,j'}[2]$. For favourable j, j', it is possible that the number of erasures within the support of $C_{BC, j'}[2]$ can go below $\rho + 1$ after correcting erasures in the support of $C_{BC, j}[2]$. For this reason, Steps 3, 4 are repeated for multiple rounds until no more erasures can be corrected with the help of local codes. The set J_1 that is initialized in Step 2 and updated in every iteration of Step 4 counts the number of local codes whose support contains up to ρ erasures. When $J_1 = \phi$, the loop iterating Steps 3,4 terminates. The vector after correcting all possible erasures until $J_1 = \phi$ is given by ˆr.

In Step 5, if $n_E(\hat{r}) = 0$ then clearly $\hat{r} = c$ because both the GRS decoders $DEC_{\mathcal{D}_1[2]}$ and $DEC_{\mathcal{D}_1[2]}$ are correct. Let us assume that $n_E(\hat{\bf r}) \neq 0$. It is straightforward to observe that every local code whose support includes erasures must include more than ρ erasures. The non-empty set J_2 enlists all such local codes. Next we show that $|J_2| = 2$ and there exists unique $j_1 \in [\mu]$ such that $J_2 = \{j_1, j_2\}$ and j_2 satisfies [\(28\)](#page-6-2). In the first place, we argue that J_2 can not be a singleton. Suppose $J_2 = \{j'_1\}$ on the contrary, then either of the following two events must happen. The first event is $S_E(\hat{\mathbf{r}}) \subset B_{j'_1,0}$.

In the second event, either $0 < |S_E(\hat{\mathbf{r}}) \cap B_{j_2',1}| \le \rho$ or $0 < |S_E(\hat{\mathbf{r}}) \cap B_{j'_3,2}| \le \rho$ where $j'_2, j'_3 \in [\mu]$ are such that $A_{j'_2}$ and $A_{j'_3}$ have non-trivial intersections with $A_{j'_1}$. The first event implies $n_E(\hat{\bf r}) \leq \rho$ contradicting our assumption. The second event implies $J_1 \neq \emptyset$, again contradicting to the fact that the algorithm proceeded to Step 5. Thus $|J_2| > 1$. If $\mu = 2$, then $A_1 \cup A_2 = [0, n-1]$ and therefore J_2 must be $\{1,2\}$ clearly satisfying [\(28\)](#page-6-2). Let us consider $\mu \geq 4$. And, let us assume on the contrary that either $|J_2| \geq 3$ or $J_2 = \{j_1, j_2\}$ such that j_2 violates [\(28\)](#page-6-2). Then there must be at least two elements j'_1, j'_2 in J_2 such that $Aj'_1 \cap Aj'_2 = \phi$. Since $n_E(\hat{\mathbf{r}}|_{A_{j'_1}}) > \rho$ and $n_E(\hat{\mathbf{r}}|_{A_{j'_2}}) > \rho$ by definition of J_2 , it follows that $n_E(\hat{\mathbf{r}}|_{A_{j'_1} \cup A_{j'_2}}) > 2\rho$. This is a contradiction to the fact that $n_E(\hat{\mathbf{r}}) \leq n_E(\mathbf{r}) \leq 2\rho$. Thus we have proved that j_1 will be identified uniquely in Step 5 and hence the algorithm proceeds to Step 6.

After the execution of Step 5, the set of erased locations $S_E(\hat{\mathbf{r}})$ is confined as $S_E(\hat{\mathbf{r}}) \subset A_{j_1} \cup A_{j_2}$ and $n_E(\hat{\mathbf{r}}) \leq 2\rho$. In Steps 6-10, all erasures at $S_E(\hat{\bf r})$ will be decoded with the help of a combination of $\mathcal{D}_1[2], \mathcal{D}_2[2]$ and $\mathcal{D}_{1\oplus 2}[2]$. Since both $C_{BC,j_1}[2]$ and $C_{BC,j_2}[2]$ are BRS codes of dimensions 2ω , there exist unique polynomials $m_1(X), m_2(X)$ of degree at most $2\omega - 1$ such that

$$
\begin{array}{rcl}\n\mathbf{c}|_{A_{j_1}} & = & \Phi_{\mathcal{C}_{BC,j_1}[2]}(m_1) \\
\mathbf{c}|_{A_{j_1}} & = & \Phi_{\mathcal{C}_{BC,j_2}[2]}(m_2)\n\end{array}
$$

where Φ is as defined in Sec. [III-A.](#page-4-4) In order to prove that the decoder is correct, it is sufficient to reconstruct m_1 and m_2 correctly.

We will prove that the vector \hat{s} computed by the algorithm in Steps 6-7 is equal to $(p(\alpha_i), i \in A_{j_0})$ where $p(X) \triangleq m_1(X)$ $m_2(X)$. Therefore, the polynomial $s(X)$ is indeed equal to $p(X)$. Observe first that $p(X)$ is of degree at most $2\omega - 1$. We first prove the assertion when $\mu = 2$. When $\mu = 2$, $j_1 = 1$ and $j_2 = 2$. Furthermore,

$$
(m_1(\alpha), \alpha \in \Lambda_1) = (m_2(\alpha), \alpha \in \Lambda_1) \tag{36}
$$

$$
(m_1(\alpha), \alpha \in \Lambda_3) = (m_2(\alpha), \alpha \in \Lambda_3) \tag{37}
$$

because $c|_{B_{j_1,1}} = c|_{B_{j_2,2}}$ and $c|_{B_{j_1,3}} = c|_{B_{j_2,1}}$. This implies that $m_1(X)$ and $m_2(X)$ are the same, as they evaluate the same on 2ω distinct points. Therefore $p(X)$ is a zero polynomial and its evaluation on any set is a zero vector exactly matching the value of \hat{s} after executing Step 7. Next let us consider that $\mu \geq 4$. We proceed to argue that the vector \hat{s} after executing Step 6 is obtained by subjecting $(p(\alpha_i), i \in A_{j_1})$ to exactly ρ erasures. The set of code locators associated to $c|_{B_{j_1,1}}$ in the BRS codeword $c|_{A_{j_1}}$ is the same as that associated to $c|_{B_{j_2,2}}$ in the BRS codeword $c|_{A_{j_2}}$. To be precise, it is given by Λ_1 if j_1 is odd and Λ_3 if j_1 is even. In other words, it is $\Lambda_{2(i_2 \mod 2)+1}$ for every j_1 . As a consequence,

$$
\mathbf{c}|_{B_{j_1,1}} = (m_1(\alpha), \alpha \in \Lambda_{2(j_2 \mod 2)+1}) \quad (38)
$$

$$
\mathbf{c}|_{B_{j_2,2}} = (m_2(\alpha), \alpha \in \Lambda_{2(j_2 \text{ mod } 2)+1}) \quad (39)
$$

$$
(n(\alpha), \alpha \in \Lambda_{2(j_2 \text{ mod } 2)+1}) = \mathbf{c}|_{\mathbf{c}} = \mathbf{c}|_{\mathbf{c}} \quad (40)
$$

$$
\Rightarrow (p(\alpha), \alpha \in \Lambda_{2(j_2 \text{ mod } 2)+1}) = \mathbf{c}|_{B_{j_1,1}} - \mathbf{c}|_{B_{j_2,2}} \qquad (40)
$$

$$
= \hat{\mathbf{r}}|_{B_{j_1,1}} - \hat{\mathbf{r}}|_{B_{j_2,2}}.\qquad(41)
$$

The last equality [\(41\)](#page-7-0) follows because $S_E(\hat{\mathbf{r}}) \subset B_{i_1,0} \cup B_{i_2,0} \cup$ $B_{j_1,2}$ for $\mu \geq 4$ since $J_1 = \phi$. In similar lines, the set of code locators associated to $c|_{B_{j_1,2}}$ in the BRS codeword $c|_{A_{j_1}}$ is exactly the same as that associated to $c|_{B_{j_2,1}}$ in the BRS codeword $c|_{A_{j_2}}$. It is given by $\Lambda_{2(j_1 \text{ mod } 2)+1}$ for every j_1 and therefore

$$
\mathbf{c}|_{B_{j_1,2}} = (m_1(\alpha), \alpha \in \Lambda_{2(j_1 \mod 2)+1})
$$

\n
$$
\mathbf{c}|_{B_{j_2,1}} = (m_2(\alpha), \alpha \in \Lambda_{2(j_1 \mod 2)+1}).
$$

But $B_{j_1,2} = B_{j_2,1}$ as j_2 satisfies [\(28\)](#page-6-2), and hence $c|_{B_{j_1,2}} =$ $c|_{B_{j_2,1}}$. Therefore

$$
(p(\alpha), \alpha \in \Lambda_{2(j_1 \bmod 2)+1}) = \mathbf{0}_{(1 \times \omega)}.
$$
 (42)

It follows from (41) , (42) that \hat{s} generated in Step 6 is a vector obtained by subjecting $(p(\alpha_i), i \in A_{j_1})$ to exactly ρ erasures. Since the both $DEC_{\mathcal{D}_1[2]}(\hat{s})$ and $DEC_{\mathcal{D}_2[2]}(\hat{s})$ can correct up to ρ erasures, the decoding in [\(30\)](#page-6-3) is correct. Hence $\hat{\mathbf{s}}$ and $s(X)$ after executing Step 7 are respectively $(p(\alpha_i), i \in A_{j_1})$ and $p(X)$ as claimed.

Next, we will show that vectors $\hat{\mathbf{u}}_1, \hat{\mathbf{u}}_2$ computed in Steps 8-9 are respectively equal to $(m_1(\alpha_i), i \in A_{j_1} \cup B_{j_2,0})$ and $(m_2(\alpha_i), i \in A_{j_2} \cup B_{j_1,0})$. We will first argue that $\hat{\mathbf{u}}_1$ and $\hat{\mathbf{u}}_2$ after executing Step 8 are obtained by subjecting respectively $(m_1(\alpha_i), i \in A_{j_1} \cup B_{j_2,0})$ and $(m_2(\alpha_i), i \in A_{j_2} \cup B_{j_1,0})$ to at most 2ρ erasures. By definition of m_1, m_2 , $\hat{\mathbf{r}}|_{A_{j_1}}$, $\hat{\mathbf{r}}|_{A_{j_2}}$ are respectively obtained by subjecting $(m_1(\alpha_i), i \in A_{j_1})$ and $(m_2(\alpha_i), i \in A_{j_2})$ to erasures. We also have $m_1(X) =$ $m_2(X) + p(X)$ and $m_2(X) = m_1(X) - p(X)$. As a consequence, the vectors $\hat{\mathbf{u}}_1$, $\hat{\mathbf{u}}_2$ as computed in [\(31\)](#page-6-1) and [\(32\)](#page-6-1) are respectively $(m_1(\alpha_i), i \in A_{j_1} \cup B_{j_2,0})$ and $(m_2(\alpha_i), i \in$ $A_{j_2} \cup B_{j_1,0}$ subjected to erasures as claimed. Furthermore, since $n_E(\hat{\mathbf{r}}) \le 2\rho$, it follows that $n_E(\hat{\mathbf{u}}_i) \le 2\rho$, $i = 1, 2$. In Step 9, $\hat{\mathbf{u}}_1$, $\hat{\mathbf{u}}_2$ are passed to a decoder for the code $\mathcal{D}_{1\oplus 2}[2]$ defined in [\(25\)](#page-6-4). Since $\mathcal{D}_{1\oplus 2}[2]$ can correct up to 2ρ erasures, the vectors $\hat{\mathbf{u}}_1$, $\hat{\mathbf{u}}_2$ at the end of execution of Step 9 are exactly as claimed.

By replacing every erasure in $\hat{\mathbf{r}}|_{A_{j_1}\cup A_{j_2}}$ with $m_1(\alpha_i)$ or $m_2(\alpha_i)$ with appropriate choice of $\alpha_i, i \in A_{j_1} \cup A_{j_2}$, vector $c|_{A_{j_1}\cup A_{j_2}}$ can be correctly generated. In Step 10, $\hat{\mathbf{r}}|_{A_{j_1}\cup A_{j_2}}$ is updated in this manner while $\hat{\mathbf{r}}|_{[0,n-1]\setminus A_{j_1}\cup A_{j_2}}$ is retained as it is. Therefore $\hat{\bf r}$ after the execution of Step 10 is equal to the correct codeword c. This completes the proof. \Box

If the decoding of erased symbols in a codeword is carried out by a network of nodes with every node in parallel with others executing an algorithm with a input consisting of only a small number of code symbols much less than the dimension of the code, then we call it *distributed decoding*. In similar lines, we define *distributed encoding* as well. If a code is determined solely by parity-check equations of a set of local codes then it is amenable for distributed encoding/decoding. The exact protocol of how to divide the code symbols, the need of a controller node, or any sequential procedure involved in certain parts of decoding can vary based on the code and is not considered. For example, a product code can be encoded/decoded in a distributed manner with every node operating on symbols associated to either a row code or a column code. It is straightforward to check that both the systematic encoding in Sec. [III-C](#page-5-1) and the decoding algorithm above for the BC code are suitable for distributed execution. This property of the BC code becomes relevant in its application to blockchain networks as described in Sec. [V.](#page-8-1)

E. The Minimum Distance of $C_{BC}[\mu, 2, \omega, \rho]$

We characterize the minimum distance of the code $\mathcal{C}_{BC}[\mu, 2, \omega, \rho]$ in the following theorem.

Theorem III.2. Let $\mathcal{C}_{BC}[\mu, 2, \omega, \rho]$ as defined in Sec. [III-B](#page-5-2) be *an* $[n = \mu(\rho + \omega), k = \mu\omega, d]$ *linear code. Then*

$$
d = 2\rho + 1. \tag{43}
$$

Proof. Since $C_{BC}[\mu, 2, \omega, \rho]$ is a linear code,

$$
d = \min_{\substack{\mathbf{c} \in \mathcal{C}_{\text{BC}}(\mu, 2, \omega, \rho], \\ \mathbf{c} \neq 0}} w_H(\mathbf{c}).
$$

Let $\mathbf{u}^T = [1, 0, 0, \dots, 0]$ be a $(1 \times \mu\omega)$ vector containing all zeros except for a 1 at the first location. Let $\mathbf{c} \in \mathbb{F}_q^n$ be the codeword of $C_{BC}[\mu, 2, \omega, \rho]$ obtained by encoding u using the systematic generator matrix $G_{BC,2}$ in [\(21\)](#page-5-3). Every non-zero block matrix of $G_{BC,2}$ apart from I_{ω} is a Cauchy matrix and hence all its entries are non-zero. Therefore $w_H(c) = 2\rho + 1$ showing that $d \leq 2\rho+1$. By Theorem [III.1,](#page-6-5) any erasure pattern of at most 2 ρ erasures can be corrected and therefore $d \geq$ $2\rho + 1$. This completes the proof. \Box

IV. CONSTRUCTION FOR EVERY OVERLAP FACTOR

In this section, we generalize the construction described in Sec. [III](#page-4-0) for every $\lambda \geq 2$.

Let $\rho, \omega, \lambda, \mu = \lambda \nu$ be positive integers as given in Defini-tion [3](#page-3-1) of $T_{[\mu,\lambda,\omega]}(\rho)$. We describe the code construction in a step-by-step manner as follows.

1) Let \mathbb{F}_q be such that $q > \lambda(\rho + \omega)$. We pick a subset of non-zero elements $\Lambda = {\alpha_0, \alpha_1, \ldots, \alpha_{\lambda(\rho+\omega)-1}}$ of \mathbb{F}_q . Recall the definition of sets A_i, B_{ij} from Definition [3.](#page-3-1) We partition Λ into 2λ ordered sets as given below:

$$
\Lambda_{\ell} = \begin{cases} \{\alpha_j \mid j \in B_{(\ell+1)/2,1}\}, \ell=1,3,\ldots,2\lambda-1\\ \{\alpha_j \mid j \in B_{(\ell/2),0}\}, \ell=2,4,\ldots,2\lambda \end{cases} (44)
$$

Observe that $|\Lambda_{\ell}| = \omega$ when ℓ is odd and $|\Lambda_{\ell}| = \rho$ when ℓ is even.

2) In association to each Λ_{ℓ} , we define a Vandermonde matrix (by slight abuse of notation) as:

$$
V_{\ell} = V_{\rho}(\Lambda_{\ell}), \ \ell = 1, 2, \dots, 2\lambda. \tag{45}
$$

3) For $i = 1, 2, \ldots, \lambda$, we are interested in constructing W_i of size $(\rho \times (\lambda \omega + \rho))$. These are built by making use of $V_{\ell}, \ell \in [2\lambda]$ and $(\lambda^2 + \lambda)$ diagonal matrices $\{M_{ij}$ | $i = 1, 2, \dots, \lambda$, j is odd number between 1 and $2\lambda - 1$ or j is 2i. If j is odd, then M_{ij} is of size $(\omega \times \omega)$ and otherwise, of size $(\rho \times \rho)$. Given these diagonal matrices, we first define $W_{ij} = V_i M_{ij}$ and then W_i , $i \in [\lambda]$ as:

$$
W_i = [W_{i,2i-1} W_{i,2i} W_{i,2i+1} \cdots
$$

$$
W_{i,2\lambda-1} W_{i,1} \cdots W_{i,2i-5} W_{i,2i-3}].
$$
 (46)

The diagonal matrices $\{M_{ij}\}\$ are constructed in such a manner that each W_i , $i \in [\lambda]$ forms a parity-check matrix of a $[\rho+\lambda\omega, \lambda\omega, \rho+1]$ basic RS code. The codes defined by W_i , $i = 1, 2, ..., \lambda$ as parity-check matrices are denoted respectively by $C_{BC,1}, C_{BC,2}, \ldots, C_{BC,\lambda}$. From the discussion in Sec. [III-A,](#page-4-4) it may be observed that diagonal entries of $M_{i1}, M_{i3}, \ldots, M_{i,2\lambda-1}, M_{i,2i}$ are determined by $\Lambda_1 \cup \Lambda_3 \cup \cdots \cup \Lambda_{2\lambda-1} \cup \Lambda_{2i}$ for every *i*. It will be evident in the next step that these λ basic RS codes form the local codes in the code $\mathcal{C}_{BC}[\mu, \lambda, \omega, \rho]$ that we will define in [\(50\)](#page-8-2).

4) Next, we construct a $(\mu \rho \times \mu (\rho + \omega))$ parity-check matrix H_{BC} . We first view H_{BC} in a block-matrix-form as in [\(47\)](#page-8-3)

$$
H_{BC} = \begin{bmatrix} H_{11} & H_{12} & \cdots & H_{1,2\mu} \\ H_{21} & H_{22} & \cdots & H_{2,2\mu} \\ \vdots & \vdots & \ddots & \vdots \\ H_{\mu,1} & H_{\mu,2} & \cdots & H_{\mu,2\mu} \end{bmatrix}_{\mu\rho\times\mu(\rho+\omega)}
$$
(47)

where H_{ij} is of size $(\rho \times \omega)$ if j is odd and of size $(\rho \times \rho)$ if j is even. Then, we proceed to define each submatrix H_{ij} , $i \in [\mu], j \in [2\mu]$. Out of a total of $2\mu^2$ submatrices in [\(47\)](#page-8-3), only $\mu(\lambda + 1)$ submatrices are non-zero. For each $i = 1, 2, \dots, \mu$, H_{ij} is a non-zero matrix for $(\lambda + 1)$ values of j and these $(\lambda + 1)$ nonzero submatrices are defined jointly in [\(48\)](#page-8-4) and [\(49\)](#page-8-5). Let $i = s\lambda + t$ for $s \in \{0, 1, \ldots, \nu - 1\}, t \in \{1, 2, \ldots, \lambda\}.$ If $s < \nu - 1$ or $(s = \nu - 1, t = 1)$, then

$$
[H_{i,2i-1} \ H_{i,2i} \ H_{i,2i+1} \ H_{i,2i+3} \ \cdots \ H_{i,2(i+\lambda)-3}] := W_t.
$$
\n(48)

Or else, if $s = \nu - 1$ and $t > 1$, then

$$
[H_{i,2i-1} H_{i,2i} H_{i,2i+1} H_{i,2i+3} \cdots
$$

$$
H_{i,2\mu-1} H_{i1} H_{i3} \cdots H_{i,2t-3} = W_t.
$$
 (49)

The remaining $2\mu^2 - \mu(\lambda + 1)$ submatrices are matrices with all zeros. This completes the definition of H_{BC} .

5) Finally, the code is defined as

$$
\mathcal{C}_{\text{BC}}[\mu,\lambda,\omega,\rho] = \{ \mathbf{c} \in \mathbb{F}_q^n \mid H_{\text{BC}} \mathbf{c}^T = \mathbf{0} \}. \tag{50}
$$

When the parameters are clear in the context, we shall write \mathcal{C}_{BC} in place of $\mathcal{C}_{BC}[\mu, \lambda, \omega, \rho]$. In H_{BC} , the submatrix formed by columns associated to $\{W_{ij}, j \text{ is even}\}\$ is of full rank. Therefore, the dimension of $C_{BC}[\mu, \lambda, \omega, \rho]$ is equal to $k = \mu\omega$ and thus $C_{BC}[\mu, \lambda, \omega, \rho]$ is a $[n = \mu(\rho + \omega), k = \mu\omega]$ code instantiating $T_{[\mu,\lambda,\omega]}(\rho)$. There are μ local codes $\mathcal{C}_{BC,j}$ in \mathcal{C}_{BC} defined by

$$
\mathcal{C}_{\mathrm{BC},j} = \{ \mathbf{c} |_{A_j} \mid \mathbf{c} \in \mathcal{C}_{\mathrm{BC}} \}
$$

where A_i is as defined in Definition [3.](#page-3-1) Observe that each of these local codes is one of λ local codes \mathcal{D}_i , $i = 1, 2, \dots, \lambda$ where

$$
\mathcal{D}_i = \{ \mathbf{c} \mid W_i \mathbf{c}^T = 0 \}. \tag{51}
$$

V. AN APPLICATION IN DECENTRALIZED SYSTEMS

Erasure codes have recently found a distinctive application in decentralized systems consisting of untrusted nodes. The 2D RS codes that are endowed with the features of squaregrid topology are used in protocols aimed at tackling an important problem called the data availability problem [\[15\]](#page-12-14). In this section, we describe the DA problem, why 2D RS codes become suitable for protocols addressing the DA problem, and finally how BC codes serve as viable, and sometimes better, alternatives to 2D RS codes in these protocols.

A. The Data Availability Problem

In a blockchain network, new blocks favoured by a consensus algorithm are appended to a chain starting from the first block known as the genesis block. A block producer creates a block containing transactions picked up from a public pool and proposes it as the next block. Based on a consensus algorithm, the block is validated for correctness of transactions and also finalized to be part of the chain. The consensus protocol ensures that a single chain is finalized among many forks. Since every node has to keep a local copy of the entire blockchain and for other reasons, initial architecture of blockchain turned out to be non-scalable later. In response, a new type of nodes referred to as *light nodes* (in contrast to *full nodes* that are resource-rich) is introduced in an effort to achieve scalability. Light nodes store only a chain of smallsized block headers, instead of entire blocks.

Light nodes verify transaction inclusion with the help of a cryptographic primitive called *vector commitment* (VC) scheme. Suppose that $\mathbf{tx} = (tx_1, tx_2, tx_3, tx_4)$ is a vector of transactions in a block. Then com(tx), which is a *commitment* or *digest* of tx, is included in the block header. The number of bits in $com(tx)$ is much less than that of tx . When a light node receives tx_1 from another node, the node supplies a small-sized proof $\pi(tx_1)$ along with tx_1 . Given the proof and the digest com(tx) that it already has, the light node can verify if tx_1 is a legitimate part of tx. Though both com(\cdot) and $\pi(\cdot)$ are manyto-one functions, it is computationally hard to determine two different pre-images of a fixed value for both the functions. This forms the basis of security of a VC scheme.

Though a light node can verify transaction inclusion in the above manner, it has to rely on an honest full node to validate the correctness of the transaction. If there is a fraud transaction data, an honest full node will broadcast it with its proof. If a correct fraud proof is received within a fixed amount of time, the majority of honest light nodes will reject the block header, reaching a consensus. The strategy works if light nodes are connected to at least one honest full node. However, if a malicious block producer publishes the block header but withholds a part of the transaction data, then the honest full node can not generate the fraud proof. This is known as the data availability (DA) problem. A full node can not reject a block with incomplete data because it is impossible to distinguish whether the block producer is malicious or the challenger who detects the incompleteness of the block is malicious. A robust solution to the DA problem (see [\[20\]](#page-12-19) for details.) is that the light nodes ensure data availability in full nodes by themselves before accepting a block header. In [\[15\]](#page-12-14), Al Bassam et al. study the DA problem in depth and propose protocols based on random sampling and erasure code as its solution.

B. Data Availability Sampling with Erasure Codes and Performance Criteria

It defeats the purpose if a light node queries for the entire transaction data. Instead, it randomly samples a sufficiently small part of transaction data and this process is referred to as *data availability sampling* (DAS). The transaction data is split into k chunks, encoded using an $[n, k, d]$ erasure code and the coded chunks are stored in full nodes. Because $(d-1)$ erasures can be recovered, a malicious node is forced to hide at least d coded chunks. This enhances the probability that a light node queries for an unavailable chunk. The block header will be accepted by the light node only if the queried chunks are returned with correct proofs. In the following, we describe the performance metrics used to evaluate the light node protocol as presented in [\[15\]](#page-12-14).

Suppose that every block producer splits the entire transaction data into k chunks, encodes it using an $[n, k, d]$ code, and includes these n coded chunks into the block. Digests and proofs are also generated and included as part of coded data. Since each chunk of data is mapped to a symbol in a finite field, we use both chunk and symbol interchangeably. If there are $(n - d + 1)$ chunks available, then the entire data is recoverable, and therefore we want to accept the block header after the missing data is recovered and verified. If a block producer hides more than $(d - 1)$ chunks, then we want to reject the block header.

Assume that exactly d chunks are hidden. Suppose a light node makes a DAS query of $0 < s < n - d + 1$ distinct random chunks. Let X denote the number of chunks that are unavailable among these s chunks. Then the probability that the block header is rejected by the light node is the same as that of querying at least one unavailable chunk. It is given by:

$$
p_1(s) := \Pr(X \ge 1) = 1 - \prod_{i=0}^{s-1} \left(1 - \frac{d}{n-i} \right). \tag{52}
$$

Suppose there are c light nodes operating independently in the system, and let Y denote the number of light nodes sampling at least one unavailable chunk. Then the probability that more than c_0 light nodes query for a missing chunk is given by

$$
p_c(c_0, s) := \Pr(Y > c_0) = 1 - \sum_{j=0}^{c_0} {c \choose j} [p_1(s)]^j [1 - p_1(s)]^{c-j}.
$$
\n(53)

Let us define $\hat{c}(c, s, \gamma)$ as

$$
\hat{c}(c, s, \gamma) = \max_{1 \le c_0 \le c} \{c_0 \mid p_c(c_0, s) \ge \gamma\}.
$$
 (54)

for a threshold probability γ . When $\gamma = 0.99, \ \hat{c}(c, s, 0.99)$ is the maximum c_0 such that the probability $p_c(c_1, s)$ dips below 0.99 for any $c_1 > c_0$. If $p_c(c_0, s) < \gamma$ for every $1 \leq$ $c_0 \leq c$, then (s, γ) is not achievable in this system and we have to either increase s or decrease γ to define $\hat{c}(c, s, \gamma)$ meaningfully.

Next assume that there are at least $(n - d + 1)$ chunks available. Then it is possible to do distributed decoding of every unavailable chunk if $(n-d+1)$ chunks are collectively sampled during DAS. The reconstructed samples are broadcast in the network of full nodes. Within some amount of time, all

the honest full nodes will have the entire data available. In turn, every query of the light node will be returned. Let Z denote the total number of distinct chunks out of n chunks that are sampled. Then we can compute

$$
q_c(s) := \Pr(Z \ge n - d + 1) = \n\begin{cases}\n1 - \sum_{i=1}^{n-d+1-s} (-1)^i \binom{d+i-2}{d-1} \binom{n}{d+i-1} \left[\frac{\binom{n-d+1-i}{s}}{\binom{n}{s}} \right]^c\n\end{cases}
$$

by invoking results from the theory of coupon collector's problem [\[21\]](#page-12-20). We would like to have $q_c(s) \geq \eta$ where η is approximately close to 1 (say, $\eta = 0.99$). Let us define

$$
\tilde{c}(c, s, \eta) = \min_{1 \le c_0 \le c} \{c_0 \mid q_{c_0}(s) \ge \eta\},\
$$

for a given probability η . If $q_{c_0}(s) < \eta$ for every $1 \leq c_0 \leq c$, then (s, η) is not achievable in this system, and we need to either decrease η or increase s to define $\tilde{c}(c, s, \eta)$ meaningfully.

For a given value of s, we would like to have $\hat{c}(c, s, 0.99)$ to be a large fraction of c and $\tilde{c}(c, s, 0.99)$ to be a small fraction of c. Turning it around, we can set performance targets on $\hat{c}(c, s, 0.99)$ and $\tilde{c}(c, s, 0.99)$, and ask for the minimum s that achieves the targets. Given a performance target (\hat{c}_T, \tilde{c}_T) , we define

$$
s_{\min} = \min\{s \mid \hat{c}(c, s, \gamma) \ge \hat{c}_T, \ \tilde{c}(c, s, \eta) \le \tilde{c}_T\}. \tag{56}
$$

In summary, the protocol as illustrated in Fig. [3](#page-10-0) works as follows:

- 1) Upon receiving a block header, every light node samples $s \geq s_{\text{min}}$ chunks independently of any other, accepts the header if the samples are returned with correct proof within a fixed amount of time, and rejects otherwise.
- 2) If $c > \tilde{c}_T$, they will successfully query $n d + 1$ chunks collectively with a high probability of at least η . Distributed decoding of unavailable chunks if any is carried out, and the reconstructed chunks are gossiped among all full nodes. All the chunks will be available within a fixed amount of time and hence queries of light nodes will be successfully returned with high probability in that time. Eventually, this leads to a consensus of accepting the block header if there are sufficiently many honest light nodes in the system.
- 3) On the other hand, if more than d chunks are hidden in an adversarial manner, the distributed decoding algorithm fails to recover unavailable chunks. Hence, queries of more than \hat{c}_T light nodes will fail with a high probability of at least γ . If sufficiently many among these \hat{c}_T light nodes are honest, then the consensus will be in favor of rejecting the block header.

C. The Choice of 2D Reed-Solomon Codes

There are two light node protocols considered in practice. The first [\[15\]](#page-12-14) is realizable with any VC scheme, but usually implemented [\[22\]](#page-12-21) with the Merkle-tree-based scheme. The second that is being pushed into practice by Ethereum [\[23\]](#page-12-22) is realized with a VC scheme called Kate-Zaverucha-Goldberg (KZG) polynomial commitment scheme [\[16\]](#page-12-15). We denote them respectively as $P_{2DRS,M}$ and $P_{2DRS,KZG}$ and in both, 2D RS

Fig. 3: Light node protocol based on 2D RS code, KZG commitment scheme, and data availability sampling. The protocol with Merkle-tree commitment has an additional mechanism for CFP's that is not shown in this diagram.

code is chosen as the erasure code. Since there are no global p-c constraints, any code instantiating $T_{n_0 \times n_0}(n_0 - k_0, 0)$ like an $[n_0^2, k_0^2]$ 2D RS code supports distributed decoding and encoding. There is no need of any "super-node" with a lot of resources dedicated for decoding and encoding [\[24\]](#page-12-23). This motivates the use of 2D RS code in both protocols. While $k_0 = (n_0/2)$ is chosen in initial proposals [\[15\]](#page-12-14), larger values of k_0 are considered in [\[25\]](#page-12-24) with a follow-up analysis on s_{min} .

Another security attack on these protocols is realized by generating the coded symbols incorrectly. This is referred to as the *incorrect coding (IC) attack*. To tackle the IC attack in $\mathcal{P}_{2DRS,M}$, digests associated to every local row- and columncodewords are also generated and added in the header, in addition to the Merkle-tree digest corresponding to the entire codeword. An honest full node can detect an incorrectly coded chunk by detecting that a p-c constraint associated to at least one $[n_0, k_0, d_0]$ row- or column-code C_{cfp} fails. Then it broadcasts a fraud proof, referred to as *codec fraud proof (CFP)*, to the network. The CFP consists of: (a) an index of C_{cfp} , (b) k_0 chunks belonging to C_{cfp} , (c) proofs for these chunks. Upon receiving a block header, every light node, in addition to making queries for s random samples, will also wait for a fixed amount of time T_{cfp} for the arrival of any CFP. A CFP can be validated using digest corresponding to C_{cfp} . The block header will be accepted only if no correct CFPs are received in addition to meeting earlier conditions. It is evident that the 2D RS code with topology $T_{n_0 \times n_0}(n_0 - k_0, 0)$ helps to reduce the size and operational complexity of CFPs's. Later, a framework called coded Merkle tree (CMT) [\[26\]](#page-12-25) based on LDPC codes was introduced with the aim of reducing CFP size to an optimal minimum. Optimizations on LDPC code used for CMT were later carried out in [\[27\]](#page-12-26). In [\[28\]](#page-12-27), a coded interleaving tree (CIT) was proposed to avoid the need for

Fig. 4: Performance of data availability sampling with $[1444, 1024, 49]$ 2D RS and $[1416, 1024, 65]$ BC codes. We set $c =$ $1000, \gamma = \eta = 0.99.$

TABLE I: A comparison of 2D RS and BC codes for light node protocols when full-node storage overhead is low. We set $c = 1000$, $\gamma = \eta = 0.99$ and choose codes so that both have a storage overhead of 1.4x approximately. The target performance for the protocols is set as $\hat{c}_T = 900$ and $\tilde{c}_T = 100$ in order to determine s_{min} .

anonymous communication channels required in CMT. We do not elaborate on these frameworks as our goal is not centered around CFPs.

Let us next consider $P_{2DRS,KZG}$ that differs from $P_{2DRS,M}$ only in the use of KZG VC scheme. The KZG VC scheme proposed in [\[16\]](#page-12-15) is specifically intended for vectors whose entries are evaluations of a fixed polynomial. Given the digest of a vector $\mathbf{c} = (c_i, i = 1, \dots, n_0)$ and proof for c_i , the KZG scheme can verify if c_i is part of c and if c_i is an evaluation of a fixed polynomial associated to c. Since every local code of 2D RS code is a polynomial evaluation code, the use KZG scheme in $\mathcal{P}_{2DRS,KZG}$ fully avoids the need for CFPs and handles the IC attack most efficiently.

D. BC Codes as an Alternative to 2D RS Codes

We observe that the BC codes possess both the features that led to choosing 2D RS codes in light node protocols, viz.,

- 1) It is fully determined by local p-c constraints with every local code having a uniform parameter set;
- 2) Every local code is a polynomial evaluation code.

So it is possible to replace 2D RS code with BC code in both $P_{2DRS,M}$ and $P_{2DRS,KZG}$ and thereby achieve wider parameter regimes. As illustrated below, BC codes even outperform 2D RS codes in a regime of low full-node storage overhead.

To make a fair comparison, we pick a 2D RS and BC code both with the same dimension k and approximately the same storage overhead n/k . We fix $k = 1024$ so that for size of a data chunk remains fixed in both the codes. The 2D RS code has parameters [1444, 1024, 49]. As an alternative, we first pick a BC code $C_{BC}[12, 2, 32, 86]$ having parameters [$n =$ $\mu(\rho + \omega) = 1416, k = \mu\omega = 1032, d = 2\rho + 1 = 65$ and then shorten it by 8 symbols to obtain a [1416, 1024, 65] code.

We denote the code as $\mathcal{C}_{BC}^{(8)}[12, 2, 32, 86]$. In this way both the codes have storage overhead of about 1.4x. Though both codes are realizable over the field \mathbb{F}_{256} , typically much larger prime fields are chosen for implementing KZG scheme.

Let us consider a set of $c = 1000$ light nodes and set $\gamma = \eta = 0.99$. Suppose we aim to achieve a target of $\hat{c}(1000, s, 0.99) = 900$ (i.e., 90% of all light nodes) and $\tilde{c}(1000, s, 0.99) = 100$ (i.e., 10% of all light nodes). In Fig. [4a,](#page-11-0) $p_1(s)$ is plotted under both codes and clearly BC code performs better thanks to its larger d/n value. In Fig. [4b,](#page-11-1) the minimum s to achieve $\hat{c}(1000, s, 0.99) = 900$ is determined under both codes. We obtain $s_{\text{min}} = 72$ for C_{2DRS} and $s_{\text{min}} = 53$ for $\mathcal{C}_{\text{BC}}^{(8)}[12, 2, 32, 86]$, yielding a reduction in network traffic for the BC code. In Fig. [4c,](#page-11-2) it is validated that the above s_{min} is sufficient to achieve the second target $\tilde{c}(1000, s, 0.99) = 100.$

The dimension of the local code is $k_0 = 32$ in C_{2DRS} as opposed to $k_0 = 172$ for $C_{BC}^{(8)}[12, 2, 32, 86]$. At the same time, the number of local codes L decreases from 76 in $2D$ RS to 12 in BC code. These two factors jointly have the following implications in $P_{2DRS,M}$ and $P_{2DRS,KZG}$ if we replace 2D RS code with BC code: (a) The time-complexity of a single node participating in the distributed decoding increases for BC code in both $P_{2DRS,M}$ and $P_{2DRS,KZG}$. However, the overall complexity is balanced by the reduction in total number of local codes. (b) The CFP size in $\mathcal{P}_{2DRS,M}$ increases from 32 to 172. (c) The size of block header (one digest each for every local code, and a digest for the entire code) significantly reduces from 77 to 13 for $P_{2DRS,M}$. In $P_{2DRS,KZG}$, a header size of 65 is attainable by exploiting the homomorphic property of KZG digest [\[29\]](#page-12-28), but still much larger than 13 of the BC code. (d) The time-complexity of computing a single KZG digest or proof is linear in k_0 . Accounting in the changes to k_0 and L, the overall complexity spent on KZG computations reduces in effect with BC code by a constant factor. All the important metrics are summarized in Table [I.](#page-11-3)

VI. CONCLUSION

In this paper, we proposed block circulant codes $C_{BC}[\mu, \lambda, \rho, \omega]$ that are fully defined by local p-c constraints quite like product codes, but outperforms product codes in fractional minimum distance for a given high rate. The code has an efficient, parallelizable erasure-decoding algorithm when the overlap factor $\lambda = 2$. A similar algorithm for $\lambda \geq 3$ is explored in the ongoing work. The block circulant topology of the code makes it suitable for light node protocols in blockchain networks. Analysis suggests that BC codes with $\lambda = 2$ work better than currently proposed 2D RS codes of the same storage overhead in tackling the DA problem in blockchain networks. A prototype implementation to validate the same and further fine-tuning by exploiting larger values of λ will be taken up as a future work.
