Abstract: We consider a Stackelberg game in which a principal (she) establishes a two-stage contract with a non-myopic agent (he) whose type is unknown. The contract takes the form of an incentive function mapping the agent's first-stage action to his second-stage incentive. While the first-stage action reveals the agent's type under truthful play, a non-myopic agent could benefit from portraying a false type in the first stage to obtain a larger incentive in the second stage. The challenge is thus for the principal to design the incentive function so as to induce truthful play. We show that this is only possible with a constant, non-reactive incentive functions when the type space is continuous, whereas it can be achieved with reactive functions for discrete types. Additionally, we show that introducing an adjustment mechanism that penalizes inconsistent behavior across both stages allows the principal to design more flexible incentive functions.

Keywords: Principal-agent problems, Stackelberg games, contract theory, strategic learning.

1. INTRODUCTION

The rise of digital technologies has turned human agents into active participants within complex sociotechnical systems such as transportation networks and power grids. Optimizing and controlling such systems require planners to design incentives that take into account the interactions among agents and their strategic behavior. For instance, Brown and Marden (2017) propose incentive mechanisms for routing drivers in a traffic network to reduce congestion, while Niazi et al. (2024) design incentives to promote eco-driving in urban transportation to reduce emissions. The incentive mechanism proposed by Satchidanandan and Dahleh (2022) efficiently integrates electric vehicles into power grids as mobile battery storage units. For a more in-depth exploration of incentive design applications in control, refer to Chremos and Malikopoulos (2024).

When the principal (she) and the agent (he) interact repeatedly, integrating learning algorithms with incentive mechanisms becomes key to optimizing system performance in strategic environments. The InsurTech industry (Holzapfel et al., 2023) is a good example of such interactions. During a monitoring phase, the principal (the insurer) collects data to learn the agent's behavioral patterns based on which the insurance plan is established for the deployment stage. For instance, through InsurTech, the principal can incentivize the agent to eco-drive during his

daily commute or devise an insurance policy based on the safety of the agent's driving behavior.

In this paper, we explore the challenges involved in learning when a principal interacts with a strategic, non-myopic agent in a two-stage contract modeled as a Stackelberg game. The principal makes decisions first, knowing that the agent will observe her decisions and respond strategically. Since a non-myopic agent anticipates his actions' consequences, the challenge is for the principal to predict and influence his behavior effectively under adverse selection.

Recent advancements in learning-based incentive mechanisms focus on how a principal can leverage learning algorithms to align agent behavior with desired outcomes through incentives. A key challenge lies in addressing information asymmetry, where the principal lacks complete knowledge of agent preferences. When the agent is myopic, Ratliff and Fiez (2020) propose an adaptive, model-based framework that integrates learning and control techniques. In a dynamic setting with an evolving system state, Lauffer et al. (2023) propose an online learning algorithm for the principal, enabling her to learn and adjust incentives with unknown agent preferences. Hutchinson et al. (2024) present a learning-based pricing mechanism for safety-critical networks, ensuring safety constraints while estimating user price responses over time. Another development involves Guruganesh et al. (2024) who extend algorithmic contract theory to such scenarios and propose dynamic contracts to optimize the principal's outcome,

even when the agent uses a no-regret learning algorithm in response.

The case of non-myopic agents has been comparatively less studied and is particularly challenging in learning-based incentive design. Indeed, such agents can manipulate the learning process by acting strategically, and sometimes deceptively. For example, a driver might adopt an uncharacteristically safe driving style during the monitoring phase to secure a lower insurance premium in the deployment stage of a usage-based insurance plan. Similarly, an agent might misrepresent himself as someone who prioritizes travel time, thus manipulating the principal into offering a higher reward for adopting eco-driving (Niazi et al., 2024).

Gerardi and Maestri (2020) focus on long-term contracts and examine strategies employed by the agent to broker increasingly favorable terms from the principal. Moreover, when the agent is sufficiently non-myopic, the screening mechanism proposed by Gerardi and Maestri (2020) becomes infeasible, leading to inefficiencies in the allocation of incentives and revealing challenges due to dynamic adverse selection. Birmpas et al. (2020) demonstrates this vulnerability and proposes methods for the principal to identify the best commitment strategy despite such manipulation.

When the agent also uses a learning method to tip the outcome in his favor, Lin and Chen (2024) show that the principal can achieve near-optimal payoffs when the agent uses a specific no-regret learning model, but that this performance can decline significantly against agents with no-swap-regret learning models. An important work by Haghtalab et al. (2022) addresses various aspects of learning in Stackelberg games with non-myopic agents that discount future utilities. They explore applications like security games and strategic classification, and propose a bandit algorithm that reacts to the agent’s past actions with a sufficiently large delay.

In this paper, we explore incentive mechanisms that induce truthful play, meaning that a non-myopic agent finds it most beneficial to play according to his true type in both stages of the game. Our analysis in Section 3 reveals that, when the mechanism ignores the agent’s second-stage action, only constant incentive functions (independent of the agent’s first-stage action in the first) can induce truthful behavior for a continuous type space. However, for a discrete type space, we show the existence of monotonic step functions as effective incentives. These functions reward the agent in proportion to his action or “effort” level, and induce truthful play when the jumps between reward levels are sufficiently small.

The fact that only constant functions induce truthful play for continuous types is due to the combination of two kinds of information asymmetry in the contract: adverse selection in the first stage (the principal does not know the agent’s type) and moral hazard in the second stage (the mechanism ignores the second-stage action). Even though the first-stage action fully reveals the agent’s type when he plays truthfully, the principal cannot use the learned type to verify that the second-stage action is consistent with it. This creates an uneven playing field which advantages the agent due to the lack of transparency in his actions.

To address these challenges, we introduce an additional adjustment mechanism in Section 4, which penalizes inconsistencies in the agent’s actions while also properly incentivizing truthful play when the agent is consistent, that is, when his second-stage action matches the type portrayed by the first-stage action. We prove that introducing such an adjustment mechanism can induce truthful play.

2. PROBLEM DEFINITION

We consider a contracting scenario between two players: the principal (referred to as *she*) and the agent (referred to as *he*). After establishing notation and preliminaries, this section defines the Stackelberg game that models a single-stage principal-agent contract. We then analyze the agent’s optimal response given the principal’s chosen incentive under complete information. Subsequently, we introduce the two-stage contract under incomplete information and define truthful play under this contract, assuming the agent is non-myopic and his private information (type) is unknown to the principal.

2.1 Notations and Preliminaries

We denote by $\overline{\mathbb{R}} = \mathbb{R} \cup \{-\infty, +\infty\}$ the extended real line, and for $A \subseteq \overline{\mathbb{R}}$, A_+ and A_+^* denote respectively the sets of non-negative and positive numbers in A .

Let $A \subseteq \mathbb{R}$ be an open set, then ϕ' denotes the derivative of the function $\phi : A \rightarrow \mathbb{R}$ (when it exists), $\partial\phi$ denotes its subdifferential, and $D_i\pi$ denotes the partial derivative of the function $\pi : A^2 \rightarrow \mathbb{R}$ with respect to the i th argument (when it exists).

For a function $\phi : A \rightarrow \overline{\mathbb{R}}$ defined over a subset $A \subseteq \mathbb{R}$, $\phi^* : \mathbb{R} \rightarrow \overline{\mathbb{R}}$ denotes its *convex conjugate* (a.k.a. Fenchel-Legendre transform):

$$\phi^*(u) := \sup_{a \in A} [ua - \phi(a)]. \quad (1)$$

An immediate consequence of the definition is the Fenchel–Young inequality:

$$\forall a \in A, \forall u \in U, \phi(a) + \phi^*(u) \geq au$$

with equality iff $u \in \partial\phi(a)$.

The *Bregman divergence* of a differentiable function $\phi : A \rightarrow \mathbb{R}$ is $D_\phi : A^2 \rightarrow \mathbb{R}$ defined for $(x, y) \in A^2$ by

$$D_\phi(x, y) = \phi(x) - \phi(y) - \phi'(y) \cdot (y - x).$$

Note that D_ϕ vanishes on the diagonal $y = x$ and if ϕ' is continuous (e.g. when ϕ is convex) then the same holds for D_ϕ ’s partial derivatives. Finally, D_ϕ is non-negative when ϕ is convex.

2.2 Single-stage Stackelberg Game

We denote by $U \subseteq \mathbb{R}$ and $A \subseteq \mathbb{R}$ the action sets of the principal and the agent, respectively. The principal’s utility function $v_p : U \times A \rightarrow \mathbb{R}$ is given by

$$v_p(u, a) = \rho(a) - ua \quad (2)$$

for some function $\rho : A \rightarrow \mathbb{R}$. The agent’s utility $v_a : U \times A \rightarrow \mathbb{R}$ is parametrized by his type θ taking values in a type space $\Theta \subseteq \mathbb{R}$ and is given by

$$v_a(u, a; \theta) = ua - \theta\phi(a) \quad (3)$$

for some function $\phi : A \rightarrow \mathbb{R}$.

We interpret the agent's action a as an "effort" level (broadly conceived) and the principal's action u as a (marginal) monetary incentive for the agent to exert a desired level of effort. With this interpretation, $\phi(a)$ can be thought of as the cost incurred by the agent for adopting the effort level a , while $\rho(a)$ is the corresponding benefit to the principal. We assume that the principal moves first by announcing the incentive $u \in U$, and letting the agent adapt his effort level accordingly.

Example 1. The agent's action a can be interpreted as his eco-driving level. This reflects the strategies he chooses to minimize emissions or fuel consumption. For instance, smoother acceleration and maintaining a consistent speed could be high eco-driving levels. The travel time for the agent, denoted by the function $\phi(a)$, depends on his eco-driving level and traffic conditions. Generally, more eco-friendly driving might lead to slightly longer travel times. To incentivize eco-driving, the principal offers a reward, ua , based on the agent's chosen level, a . Finally, the function $\rho(a)$ represents the reduction in emissions achieved by the agent's eco-driving level, a . \diamond

Throughout the paper, we make the following assumptions.

Assumption 2. $\Theta \subseteq \mathbb{R}_+^*$, $U \in \{\mathbb{R}, \mathbb{R}_+^*\}$, and ϕ is differentiable and strictly convex with $\phi'(A) = U$. \diamond

Assumption 2 guarantees that the agent's best-response to an incentive u is well-defined as stated below.

Lemma 3. For all $\theta \in \Theta$ and $u \in U$, the agent has a unique best-response in A :

$$a_\theta(u) := (\phi')^{-1}\left(\frac{u}{\theta}\right). \quad (4)$$

For all $\theta \in \Theta$, the function $a_\theta : U \rightarrow A$ is a homeomorphism with inverse $a \mapsto \theta\phi'(a)$. Finally, the agent's utility when best-responding is given by

$$v_a(u, a_\theta(u); \theta) = \theta\phi^*\left(\frac{u}{\theta}\right) \quad (5)$$

where ϕ^* is the convex conjugate of ϕ . \diamond

If the agent's type θ is known by the principal, the natural solution concept is a Stackelberg equilibrium: the principal chooses $u \in U$ so as to maximize her utility after the agent best-responds. In other words, the principal wants to solve

$$\sup_{u \in U} [\rho(a_\theta(u)) - ua_\theta(u)]. \quad (6)$$

Lemma 4. For all $\theta \in \Theta$, the single stage game has a complete information Stackelberg equilibrium iff

$$\sup_{a \in A} [\rho(a) - \theta a\phi'(a)]. \quad (7)$$

is attained. When this condition is satisfied, $(u_e, a_e) \in U \times A$ is a Stackelberg equilibrium iff a_e is a solution to (7) and $u_e = \theta\phi'(a_e)$. \diamond

Lemma 4 reveals an important feature of the principal's decision problem that will be useful in the subsequent sections. Instead of thinking of the principal's action as choosing an incentive, we can equivalently think of it as choosing which action the agent should take. Then, the principal can "reverse-engineer" the incentive that would induce this action with the help of the inverse best response function a_θ^{-1} .

Remark 5. Observe that the supremum in (7) is reached under rather mild assumptions. For example, it is easy to

check that it suffices to have ρ continuous with $a \mapsto \rho(a)/a$ bounded. \diamond

Remark 6. When the principal does not know the agent's type θ but has a prior distribution with density p_θ over Θ , the best she can do is to choose u so as to maximize her expected utility:

$$\sup_{u \in U} \mathbb{E}[\rho(a_\theta(u)) - ua_\theta(u)] \quad (8)$$

where the expectation is over p_θ . \diamond

2.3 Two-stage Contract with Unknown Type

We now extend the single-stage Stackelberg game studied in the previous section to a two-stage contract under incomplete information, where the agent's type is unknown to the principal. The timing of the contract is as follows.

Two-stage contract

- (1) At stage $t = 1$:
 - The principal plays $u_1 \in U$ and commits to an incentive function $u_2 : A \rightarrow U$ for the second stage.
 - The agent plays $a_1 \in A$, which is observed by the principal.
- (2) At stage $t = 2$:
 - The incentive $u_2(a_1) \in U$ is realized according to the principal's commitment in the first stage.
 - The agent plays $a_2 \in A$, which may not be observed by the principal.

We interpret the first stage as a *learning phase*, in which the principal attempts to learn the type of the agent by observing his action a_1 and the second stage as a *deployment stage*, which exploits the knowledge gathered in the first stage. The agent is non-myopic and plays in a way that maximizes his *cumulative utility*:

$$v_a(u_1, a_1; \theta) + v_a(u_2(a_1), a_2; \theta) = u_1 a_1 - \theta\phi(a_1) + u_2(a_1)a_2 - \theta\phi(a_2).$$

The crucial feature of this game is that the second stage incentive, $u_2(a_1)$, only depends on the first stage action. This models situations in which the second stage action cannot be observed by the principal, or where, for practical reasons, the incentive must be fixed at the beginning of the second stage. The principal thus faces *moral hazard*: the agent is not accountable at the second stage and will always choose the action a_2 that maximizes his second stage utility. In other words, the agent plays $a_2 = a_\theta(u_2(a_1))$, and using (5), his cumulative utility becomes

$$V_a(a_1) := u_1 a_1 - \theta\phi(a_1) + \theta\phi^*\left(\frac{u_2(a_1)}{\theta}\right). \quad (9)$$

Moreover, the principal announces and commits to the incentive function u_2 at the beginning of the game. In other words, even though the principal reacts to what is observed in the first stage, the functional form of this reaction is known by the agent and can thus be anticipated.

When the agent plays myopically in the first stage, $a_1 = a_\theta(u_1)$, he reveals his type to the principal whenever $\phi'(a_\theta(u_1)) \neq 0$. Indeed, by (4), we have $\theta = u_1/\phi'(a_\theta(u_1))$

in this case. However, the agent might prefer to deviate from the myopic best response in the first stage, in order not to fully reveal his type to the principal—or equivalently, pretend to be of a different type—and secure himself a larger incentive at the second stage. In other words, the principal faces *adverse selection* in the first stage.

It is natural to ask whether it is possible for the principal to design u_2 so as to counteract the agent’s adverse selection. This leads to the following definition.

Definition 7. We say that the incentive function $u_2 : A \rightarrow U$ induces *truthful* play if for every type $\theta \in \Theta$,

$$V_a(a_\theta(u_1)) \geq V_a(\hat{a}_1), \quad \text{for every } \hat{a}_1 \in A. \quad \diamond \quad (10)$$

Truthful play means that it is in the agent’s best interest to play a best-response (4) at the first stage. This is useful because it allows the principal to learn the agent’s type θ from his action a_1 . If the agent always play truthfully, ($a_1 = a_\theta(u_1)$), then the principal would naturally designs the incentive function u_2 such that, for all $\theta \in \Theta$, $u_2(a_\theta(u_1))$ solves (6). However, if the agent does not play truthfully, he can exploit the incentive function u_2 by causing the principal to learn a false type $\hat{\theta}$. Therefore, the principal needs a more careful approach beyond just solving (6). In fact, she must seek a functional form of the incentive u_2 that induces truthful play while maximizing her expected utility as in (8).

Example 8. Consider a usage-based or pay-as-you-drive insurance. In this system, an agent’s driving behavior during a monitoring phase (action denoted by a_1) determines their safety level. Safer driving (higher a_1) translates to a lower insurance premium in the following phase. The incentive for safe driving is essentially the reduced insurance cost, represented by $u_2(a_1)$. However, there can be inconveniences associated with driving more cautiously, such as increased travel time. This inconvenience is captured by the function $\phi : A \rightarrow \mathbb{R}$. Additionally, some factors, like poor training or physical limitations, can make safe driving more challenging for an agent. These challenges are represented by the parameter θ . A higher θ indicates greater difficulty in driving safely.

Here’s the key issue: according to (4), when θ is high, truthful safe driving, $a_1 = a_\theta(u_1)$, results in a lower safety level and a higher premium. A strategic non-myopic agent might exploit this by pretending to be extra safe (i.e., he chooses $a_1 \gg a_\theta(u_1)$) during monitoring phase to get a lower premium. However, there’s no guarantee this safe behavior will continue in the actual insurance phase. Therefore, the insurance provider (principal) needs to design the incentive function $u_2 : A \rightarrow U$ to encourage truthful safe driving in the monitoring phase so that an appropriate premium can be set for the agent in the deployment stage. This ensures fair pricing regardless of the agent’s attempts to manipulate the system. \diamond

3. TWO-STAGE CONTRACT WITH MORAL HAZARD IN THE SECOND STAGE

In this section, we investigate the question of existence of non-trivial incentive functions $u_2 : A \rightarrow U$ that induce truthful play $a_1 = a_\theta(u_1)$. By non-trivial we mean that the incentive $u_2(a_1)$ varies with $a_1 \in A$. We obtain very

contrasted answers depending on whether the type space is continuous or discrete.

3.1 Inducing Truthful Play under Continuous Types

When the type space Θ is continuous, the only incentive function u_2 that induces truthful play is trivial.

Proposition 9. Assume $\Theta = \mathbb{R}_+^*$ and $U = \mathbb{R}_+^*$. Then, the incentive function $u_2 : A \rightarrow U$ induces truthful play iff it is constant. \diamond

In other words, the incentive function u_2 is completely non-reactive to the agent’s action a_1 in the first stage. By being non-reactive, the principal guarantees the agent that she will not learn his type θ , or at least not choose the incentive of the second stage based on his type. As a result, the agent does not gain anything by misrepresenting his type in the first stage. But as a result, the principal loses the ability to adjust the agent’s incentive in the second stage based on the first-stage action and thus cannot exploit the type revealed by truthful play.

Therein lies the dilemma: to incentivize truthfulness, the principal is forced to commit to a non-reactive incentive function, which makes the two-stage contract trivial. On the other hand, if the incentive function u_2 varies with the agent’s first-stage action a_1 , then it is always in the best interest of a non-myopic agent to play untruthfully.

Proof. [Proof of Proposition 9] Consider $\theta \in \Theta$ and $a = a_\theta(u_1)$. Using (9), inducing truthful play is equivalent to requiring that for all $\hat{a} \in A$

$$u_1 a - \theta \phi(a) + \theta \phi^* \left(\frac{u_2(a)}{\theta} \right) \geq u_1 \hat{a} - \theta \phi(\hat{a}) + \theta \phi^* \left(\frac{u_2(\hat{a})}{\theta} \right).$$

Dividing by θ and rearranging

$$\phi^* \left(\frac{u_2(\hat{a})}{\theta} \right) - \phi^* \left(\frac{u_2(a)}{\theta} \right) \leq \phi(\hat{a}) - \phi(a) - \frac{u_1}{\theta} (\hat{a} - a).$$

Finally, we eliminate θ using that $\phi'(a) = \frac{u_1}{\theta}$ due to (4) and recognize a Bregman divergence on the right-hand side:

$$\phi^* \left(\frac{u_2(\hat{a}) \phi'(a)}{u_1} \right) - \phi^* \left(\frac{u_2(a) \phi'(a)}{u_1} \right) \leq D_\phi(\hat{a}, a). \quad (11)$$

In other words, inducing truthful play is equivalent to (11) for $a = a_\theta(u_1)$ and all $\hat{a} \in A$, where $a_\theta(u_1)$ is given in (4). But as θ ranges over Θ , $\frac{u_1}{\theta}$ ranges over U (due to $\Theta = U = \mathbb{R}_+^*$), hence

$$\{a_\theta(u_1) \mid \theta \in \Theta\} = (\phi')^{-1}(U) = A$$

where the last equality follows from Assumption 2. Therefore, inducing truthful play with respect to every $\theta \in \Theta$ is equivalent to (11) for every $(a, \hat{a}) \in A^2$, where $a = a_\theta(u_1)$.

Sufficiency. If u_2 is constant, then the left-hand side in (11) is 0, and by convexity of ϕ , the divergence D_ϕ is non-negative hence truthfulness is satisfied.

Necessity [proof sketch]. Assume that u_2 induces truthful play, equivalently that (11) holds for all $(a, \hat{a}) \in A^2$. First, we establish that u_2 is continuous over A . This can be shown by rearranging (11) and writing in terms of $u_2(\hat{a})$. Then, by letting $\hat{a} \rightarrow a$, one has that u_2 is continuous at

a by the continuity of ϕ , ϕ' , and ϕ^* . Finally, by using the convexity of ϕ^* , we consider a such that $u_2(a) \neq 0$ and show that u_2 is differentiable at a with $u_2'(a) = 0$. \square

3.2 Inducing Truthful Play under Discrete Types

We saw that when the type space Θ is continuous, the only incentive function u_2 that induces truthful play is a trivial, constant function. However, when the type space is discrete, there are non-trivial incentive functions that induce truthful play. These incentive functions can be characterized as step functions with a sufficiently small step size.

Proposition 10. Assume that $\Theta = \{\theta_L, \theta_H\}$ with $\theta_L < \theta_H$ and consider the incentive function

$$u_2(a_1) = \begin{cases} u_L & \text{if } a_1 \geq t \\ u_H & \text{otherwise} \end{cases}$$

with

$$\frac{u_1}{\theta_H} \leq \phi'(t) \leq \frac{u_1}{\theta_L}.$$

Then, when $u_L > u_H$, the mechanism is truthful iff

$$\phi^*\left(\frac{u_L}{\theta_H}\right) - \phi^*\left(\frac{u_H}{\theta_H}\right) \leq \phi(t) + \phi^*\left(\frac{u_1}{\theta_H}\right) - \frac{u_1 t}{\theta_H}. \quad (12)$$

Otherwise, when $u_H > u_L$, the mechanism is truthful iff

$$\phi^*\left(\frac{u_H}{\theta_L}\right) - \phi^*\left(\frac{u_L}{\theta_L}\right) \leq \phi(t) + \phi^*\left(\frac{u_1}{\theta_L}\right) - \frac{u_1 t}{\theta_L}. \quad (13)$$

Proof. We give a proof for the case $u_L > u_H$. The case $u_H > u_L$ is exactly identical after swapping L for H .

Observe that, if an agent of type θ_L plays truthfully in the first stage (that is, $\phi'(a_1) = u_1/\theta_L$) then he gets the highest possible incentive u_L in the second stage and thus have no incentive to deviate. Hence, only an agent of type θ_H could benefit from playing untruthfully in the first stage in order to secure the incentive u_L in the second stage.

It is easy to see that for an agent of type θ_H , the choice of action a_1 which maximizes his first stage utility while guaranteeing incentive u_L at the second stage is precisely t . In order for this deviation not to be beneficial, we need

$$u_1 t - \theta_H \phi(t) + \theta_H \phi^*\left(\frac{u_L}{\theta_H}\right) \leq \theta_H \phi^*\left(\frac{u_1}{\theta_H}\right) + \theta_H \phi^*\left(\frac{u_H}{\theta_H}\right).$$

We obtained the desired condition after dividing the previous inequality by θ_H and rearranging. \square

Remark 11. Note that by the Fenchel–Young inequality (cf. Section 2.1) the upper-bounds in (12) and (13) are non-negative, and even positive as long as $\phi'(t) > u_1/\theta_H$ for (12) and $\phi'(t) < u_1/\theta_L$ for (13). In other words, the characterization of truthfulness in Proposition 10 is nontrivial in that it allows for a range of values for u_L and u_H with $u_L \neq u_H$. Furthermore, the most permissive setting of t (that is, the one making the set of truthful mechanisms the largest) is achieved when $\phi'(t) = u_1/\theta_L$ for (12) and $\phi'(t) = u_1/\theta_H$ for (13). \diamond

4. TWO-STAGE CONTRACT WITH ADJUSTMENT MECHANISM

When the principal cannot observe the agent's second-stage action, we saw in Section 3 that for a continuous type

space, the only incentive functions that induce truthful play are the constant ones. Because the principal does not know the type θ of the agent, she faces adverse selection in the first stage. When she cannot observe the action of the agent in the second stage, she also faces moral hazard. As a result, she cannot validate the agent's type she learned in the first stage. This gives the agent an unfair advantage over the principal as it is impossible for her to observe any discrepancies between the agent's actions in both stages.

In this section, we aim to mitigate moral hazard by relaxing the assumption that the principal cannot observe the second stage action. Specifically, in addition to the second stage incentive function $u_2 : A \rightarrow U$, we introduce an *adjustment* function $\pi : A^2 \rightarrow \overline{\mathbb{R}}$ which depends on both actions and can be thought of as an additional reward or penalty (depending on the sign of π) collected at the end of the second stage. The principal commits to π along with u_2 at the beginning of the game, and the timing of the modified two-stage contract is as follows.

Two-stage contract with adjustment

- (1) At stage $t = 1$:
 - The principal plays $u_1 \in U$ and commits to an incentive $u_2 : A \rightarrow U$ and an adjustment $\pi : A^2 \rightarrow \overline{\mathbb{R}}$ for the second stage.
 - The agent plays $a_1 \in A$, which is observed by the principal.
- (2) At stage $t = 2$:
 - The incentive $u_2(a_1)$ is realized according to the principal's commitment at the first stage.
 - The agent plays $a_2 \in A$, which is also observed by the principal.
 - The adjustment $\pi(a_1, a_2)$ is realized according to the principal's commitment at the first stage.

In the modified contract above, the cumulative utility of a non-myopic agent of type $\theta \in \Theta$ is given by

$$V_a(a_1, a_2; \theta) = v_a(u_1, a_1; \theta) + v_a(u_2(a_1), a_2; \theta) - \pi(a_1, a_2) \quad (14a)$$

$$= u_1 a_1 - \theta \phi(a_1) + u_2(a_1) a_2 - \theta \phi(a_2) - \pi(a_1, a_2). \quad (14b)$$

4.1 Inducing Truthful Play through Adjustment Function

The goal of the principal is now to jointly design the functions u_2 and π so as to guarantee that an agent of type θ maximizes his cumulative utility by (i) playing a best-response to u_1 in the first stage: $a_1 = a_\theta(u_1)$, and (ii) playing a best-response to $u_2(a_1)$ in the second stage: $a_2 = a_\theta(u_2(a_1))$. When this is the case, we say that the pair (u_2, π) *induces truthful play*.

In case of truthful play by the agent, there is a form of *consistency* satisfied by the pair of actions (a_1, a_2) . Indeed, since the agent plays according to his true type θ at both stages of the game, we have by Lemma 3 that

$$\frac{\phi'(a_1)}{u_1} = \frac{\phi'(a_2)}{u_2(a_1)}$$

which allows us to write the second stage action as a function of the first stage action

$$a_2 = c(a_1) := (\phi')^{-1} \left(\frac{u_2(a_1)}{u_1} \phi'(a_1) \right).$$

We will henceforth refer to the graph of the function c as the *consistency curve*.

The following proposition shows that any choice of (differentiable) incentive function u_2 can induce truthful play when paired with a suitable adjustment function π .

Proposition 12. Assume $\Theta = \mathbb{R}_+^*$ and $U = \mathbb{R}_+^*$. Let $u_2 : A \rightarrow U$ be a differentiable function and consider an adjustment function of the form

$$\pi(a_1, a_2) = \begin{cases} f(a_1) & \text{if } a_2 = c(a_1) \\ +\infty & \text{otherwise} \end{cases} \quad (15)$$

for some function $f : A \rightarrow \mathbb{R}$.

Then, the pair (u_2, π) induces truthful play iff f is differentiable with

$$f'(a_1) = g'(a_1) - u_1 \frac{(\phi \circ c)'(a_1)}{\phi'(a_1)}. \quad (16)$$

Proof. We consider a deviation (\hat{a}_1, \hat{a}_2) by the agent. Since $\pi(\hat{a}_1, \hat{a}_2) = +\infty$ if $\hat{a}_2 \neq c(\hat{a}_1)$, we can assume without loss generality that $\hat{a}_2 = c(\hat{a}_1)$. Then inducing truthful play (10) is equivalent to

$$f(\hat{a}_1) - f(a_1) \geq g(\hat{a}_1) - g(a_1) - \frac{u_1}{\phi'(a_1)} \left[D_\phi(\hat{a}_1, a_1) + \phi \circ c(\hat{a}_1) - \phi \circ c(a_1) \right] \quad (17)$$

where $a_1 = a_\theta(u_1)$ and $\hat{a}_1 \in A$.

Sufficiency. By integrating (16) from $a_1 = a_\theta(u_1)$ to $\hat{a}_1 \in A$, where $\hat{a}_1 \geq a_1$ (the proof for $\hat{a}_1 \leq a_1$ is similar), we obtain

$$f(\hat{a}_1) - f(a_1) = g(\hat{a}_1) - g(a_1) - u_1 \int_{a_1}^{\hat{a}_1} \frac{(\phi \circ c)'(z)}{\phi'(z)} dz.$$

Since ϕ is convex, $\phi'(z) \geq \phi'(a_1)$ and $D_\phi(\hat{a}_1, a_1) \geq 0$. Therefore, we conclude that (17) is satisfied.

Necessity [proof sketch]. Let (17) hold. Then, by approaching $\hat{a}_1 \downarrow a_1$ and $\hat{a}_1 \uparrow a_1$, one obtains (16). \square

4.2 Consistency-inducing Penalty is Extreme

For a pair (u_2, π) that induces truthful play as in Proposition 12, we see that the function π plays two distinct roles: (i) it penalizes inconsistent pairs of actions ($a_2 \neq c(a_1)$), and (ii) it properly compensates pairs of actions along the consistency curve.

In this section, we focus on the first of these two roles and consider adjustment functions which *only* penalize inconsistent play, but vanish on the consistency curve. This leads to the following definition.

Definition 13. We say that the adjustment function $\pi : A^2 \rightarrow \overline{\mathbb{R}}$ penalizes inconsistency if it is non-negative and if

$$\pi(a_1, a_2) = 0 \iff a_2 = c(a_1).$$

Equivalently, the agent incurs no penalty when playing consistently, but incurs a positive penalty otherwise. \diamond

The following proposition shows that the only choice of penalty that guarantees consistency is the extreme one with infinitely penalizes inconsistency.

Proposition 14. Assume that π penalizes inconsistency and that $a_1 = a_{\hat{\theta}}(u_1)$ for some $\hat{\theta} \in \Theta$. Then the choice of consistent second-stage action, $a_2 = c(a_1)$, maximizes the agent's cumulative utility (14) if and only if

$$\pi(a_1, a_2) = \begin{cases} 0 & \text{if } a_2 = c(a_1) \\ +\infty & \text{otherwise.} \end{cases} \quad (18)$$

Proof. Let $a_1 = a_{\hat{\theta}}(u_1)$ and $a_2 = c(a_1)$. If π is given by (18), we have

$$V_a(a_1, a_2) = u_1 a_1 - \theta \phi(a_1) + u_2(a_1) a_2 - \theta \phi(a_2) \quad (19)$$

and, for any $\hat{a}_2 \neq a_2$,

$$V_a(a_1, \hat{a}_2) = u_1 a_1 - \theta \phi(a_1) + u_2(a_1) \hat{a}_2 - \theta \phi(\hat{a}_2) - \pi(a_1, \hat{a}_2). \quad (20)$$

Sufficiency. Since $\pi(a_1, \hat{a}_2) = +\infty$ for $\hat{a}_2 \neq a_2$, we have $V_a(a_1, a_2) \geq V_a(a_1, \hat{a}_2)$ for every $\hat{a}_2 \in A$.

Necessity. Assume $V_a(a_1, a_2) \geq V_a(a_1, \hat{a}_2)$ for every $\hat{a}_2 \in A$, then from (19) and (20), we have

$$\pi(a_1, \hat{a}_2) \geq \theta[\phi(a_2) - \phi(\hat{a}_2)] - u_2(a_1)(a_2 - \hat{a}_2).$$

The above inequality must hold for every $\theta \in \mathbb{R}_+^*$, and neither a_2 nor \hat{a}_2 depend on θ . Therefore, as $\theta \rightarrow \infty$, the only penalty satisfying the above inequality is (18). \square
