Temporal cavity solitons (CSs) are stable, localized particle-like objects in the form of optical pulses that circulate indefinitely in coherently driven nonlinear resonators. In the spectral domain, they form highly coherent frequency combs. Owing to their remarkable stability, they are attracting attention for applications in sensing, metrology, or optical signal synthesis. In this work, we report on the dynamics of CSs interacting with a trapping potential. We demonstrate that this interaction provides a powerful means to control their properties such as position, speed, and central frequency. Our theoretical analysis predicts fundamental limitations on the spectral shift of CSs relative to the driving frequency. Specifically, it reveals that within a broad range of detunings, frequencyshifted CSs encounter destabilization through a Hopf bifurcation. Moreover, we find that with periodic potentials, the Kelly sidebands emitted by trapped solitons undergo Bloch oscillations. In our experiments, we use an intracavity phase modulator to create the equivalent of an external real potential. We observe stable blue- and red- shifted solitons up to a limit close to our theoretical predictions. We then show theoretically and experimentally that this unprecedented level of control over the CS spectrum can be leveraged to cancel the Raman-induced self-frequency shift and even to stabilize CSs beyond the limitation imposed by stimulated Raman scattering. Our results provide valuable insights for applications requiring robust and potentially rapid tunable control over the cavity soliton properties.

### I. INTRODUCTION

Solitons are waveforms that maintain their shape during propagation, owing to a delicate balance between dispersion and nonlinearity. First observed in hydrodynamics, they have since become a key concept in various branches of science and engineering [1], extending from plasma physics [2] and matter-waves [3] to optics [4]. Dissipative solitons (DSs) are a particular type of solitons encountered in non-conservative systems [5-8]. They require an additional balance between the dissipation, inherent to the system, and gain. Besides, they represent fixed localized solutions determined by the system parameters [9]. Among them, temporal cavity solitons appear in the form of optical pulses propagating endlessly in coherently driven Kerr resonators [10– 13]. Owing to the stability of the pulse train leaving the cavity, CSs have attracted significant attention over the last decade and are used in a wide range of applications, including distance measurements [14], highresolution spectroscopy [15], telecommunication [16], and astronomy [17].

Both in fundamental research and practical applications, there is value in controlling the properties of cavity solitons [15, 18–20]. Considerable efforts have been made in this direction, notably by introducing driving field modulations in phase [21–24] and amplitude [25–28]. An alternative approach involves leveraging the interaction between nonlinear waves and an intracavity phase modulation (IPM) that plays the role of an external potential. Interestingly, in the context of particle-like solitons, such a potential acts as an additional control parameter and leads to novel and intriguing phenomena [29–31]. While extensively studied for conservative solitons (see e.g. [32–34] and reference therein), as well as for dissipative solitons in active mode-locked lasers [35], the dynamics of coherently driven cavity solitons in external potentials has only been recently explored, in the framework of periodic [36–38] and parabolic [39] potentials. However, the interplay between cavity solitons and trapping IPM remains, to the best of our knowledge, largely unknown [29].

In this work, we report on the dynamics of cavity solitons in the presence of stationary and drifting trapping potentials. We specifically demonstrate that it enables the control of the CS center frequency and the output soliton comb repetition rate. As an application of the CS frequency control, we study the competition between an IPM and the stimulated Raman scattering (SRS). We show that the CS frequency shift induced by SRS can be fully compensated and that the trapping extends the CS existence beyond the fundamental limit imposed solely by stimulated Raman scattering [40].

### II. RESULTS

**Theoretical analysis.** We first theoretically analyze the impact of a real potential (V), such as that generated by intracavity phase modulation, on the existence

<sup>\*</sup>Electronic address: simon.pierre.gorza@ulb.be

**Figure 1.** Trapping of a CS in a potential  $V(\tau)$  for negative (a), zero (b) and positive (c) drift *d*. Without drift (d = 0), cavity solitons are trapped at the potential, maximum corresponding to the minimum local detuning  $\Delta - V(\tau)$ . Stationary solitons are either blue- or red-shifted, depending on the sign of the drift.

and stability of CSs. The starting point is the drivendissipative nonlinear Schrödinger equation, also known as the Lugiato-Levefer equation (LLE), a mean-field model that describes remarkably well the dynamics of coherently driven passive Kerr resonators [41–43]. It is here generalized to include a potential term. As such, it can be seen as the driven-dissipative Gross-Pitaevskii equation. It reads in dimensionless form (see Supplemental Material [44] for the normalization) [39, 45]:

$$\frac{\partial A(t,\tau)}{\partial t} = S + \left( -1 - i \left[ \Delta - V(\tau) \right] + i |A|^2 \right.$$
(1)
$$\left. + \left[ d \frac{\partial}{\partial \tau} + i \frac{\partial^2}{\partial \tau^2} \right] \right) A,$$

where t is the (slow) time describing the evolution of the electric field envelope  $A(t, \tau)$  of a wave propagating in a dispersive resonator with anomalous group-velocity dispersion and focusing Kerr nonlinearity.  $\tau$  is a (fast) time variable defined in a co-moving reference frame in which  $V(\tau)$  is assumed stationary with time t. S is the driving amplitude and  $\Delta$  is the normalized phase detuning from the closest resonance. d is a drift coefficient that accounts for a non-zero group velocity at the driving frequency in the co-moving reference frame.

Dissipative Kerr cavity solitons are stationary solutions that are localized along the fast time  $\tau$ . Provided that the potential slowly varies over the soliton envelope, it can be linearized around the soliton position  $\tau = \tau_s$ . Eq. (1) then reveals that V modifies the local detuning experienced by the CS [i.e.  $\Delta \rightarrow \Delta - V(\tau_s)$ ], but also adds a linear phase  $\partial_{\tau}V \times (\tau - \tau_s)$ , hence shifting the frequency of the CS. The existence of stationary CSs in the reference frame of V can therefore be understood as follows. A positive (negative) slope at the soliton location  $\tau_s$ makes it travel slower (faster) than the driving frequency due to anomalous dispersion. This stabilizes the CS at the potential maximum or, equivalently, at the minimum local detuning for d = 0. Consequently, without drift, the CS spectrum is centered on the driving frequency (see Fig. 1b). Conversely, for  $d \neq 0$ , we expect the CS to settle at a position  $\tau_s = \tau^*$ , away from the maximum where it undergoes a frequency shift. The CS spectrum would thus be shifted towards the blue or the red, depending on the sign of the drift d, to achieve stationarity relative to the potential by virtue of chromatic dispersion (Figs. 1a,c). This has been demonstrated in [37] for a very small soliton frequency shift. Yet, little is known about the existence and stability of these solitons for large drifts and therefore large frequency shifts. Numerical simulations of Eq.1 with different slowly varying potentials confirm that stable solitons exist up to a critical drift value.

To gain more insights into the properties of trapped CSs, we derive a reduced model by applying the Lagrangian perturbative approach to the solitary wave solutions of Eq. (1) [37, 46, 47]. Neglecting the background on which the solitons sit, we aim to describe the evolution of sech-shaped solitons whose center frequency is shifted by  $\Omega$ :  $A_s(t,\tau) = B \operatorname{sech} \left[ B(\tau - \tau_s)/\sqrt{2} \right] \exp(i \left[ \phi - \Omega(\tau - \tau_s) \right])$ , where B is the soliton amplitude,  $\phi$  its phase and  $\tau_s$  its position along the fast time. This yields the following motion equations for the model parameters:

$$\frac{d\Omega}{dt} = -\frac{\Omega}{B}\frac{dB}{dt} - 2\Omega - \frac{dV(\tau_s)}{d\tau_s},\tag{2}$$

$$\frac{dB}{dt} = -2B + \pi S \cos(\phi) \operatorname{sech}\left(\frac{\Omega \pi}{\sqrt{2}B}\right), \qquad (3)$$

$$\frac{d\phi}{dt} = \frac{B^2}{2} - \Omega^2 - \left[\Delta - V(\tau_s)\right] - \left(\frac{d\tau_s}{dt} + d\right)\Omega, \quad (4)$$

$$\frac{d\tau_s}{dt} = -2\Omega - d. \tag{5}$$

We here focus on steady-state solutions. From Eq. (5), we readily find  $\Omega = -d/2$ , revealing that the frequency shift is only governed by the drift. In dimensional units, this equation becomes  $\beta_2 L_c \delta \omega = dt_R$ , where  $L_c$  is the resonator length,  $t_{\rm R}$  is the roundtrip time,  $\beta_2$  is the groupvelocity dispersion coefficient, d is the dimensional drift coefficient and  $\delta \omega$  is the soliton frequency shift. It shows, as expected, that the CS is synchronized to the potential. Defining locally the gradient of V as a monotonic function  $\mathcal{D} = dV(\tau_s)/d\tau_s$ , the CS steady-state temporal position  $\tau^*$  is found from the reciprocal function  $(\mathcal{D}^{-1})$ . Indeed, from Eqs. (2) and (5) we have  $\tau^* = \mathcal{D}^{-1}|_{d}$ . Moreover, we see from Eq. (2) that the frequency shift is  $\Omega = -\frac{1}{2}\mathcal{D}$ . Recalling that the potential is an intracavity phase modulation  $\phi_{\text{int}}(\tau)$ , this frequency shift is in dimensional units  $\delta \omega = -\mathcal{F}/(2\pi) \times \phi'_{\text{int}}$  where  $\mathcal{F}$  is the cavity finesse and ' stands for the first derivative with respect to the fast time  $\tau$ . This result shows that the CS frequency shift is enhanced by the factor  $\mathcal{F}/2\pi$  for intracavity modulation compared with external phase modulations of the driving, [21] (see also Supplemental Material [44]). This is of prime interest for applications given the recent developments of on-chip high-finesse lithium

niobate microresonators that incorporate a high-speed electro-optic modulator [38]. Finally, we see that the frequency shift is bounded by the maximum value of the slope  $|\Omega_{\rm SL}| = \frac{1}{2} |\mathcal{D}_{max}|$ .

The combination of Eqs. (4)-(5) yields the stationary soliton amplitude

$$B = \sqrt{2[\Delta - V(\tau^*) - \Omega^2]} = \sqrt{2(\Delta^* - \Omega^2)}, \quad (6)$$

where we have introduced the local detuning  $\Delta^* = \Delta - V(\tau^*)$ . For V = 0, we retrieve the usual CS amplitude  $(B = \sqrt{2\Delta})$  [43]. For static potentials  $(d = 0 \Rightarrow \Omega = 0)$ , Eq. (2) shows that CSs are located at the extrema of V. However, only the maxima are stable. Consequently, CSs are trapped at minimum local detunings  $\Delta^* = \Delta - \max[V(\tau^*)]$ , which sets the soliton amplitude accordingly. Eventually, for drifting potentials  $(d \neq 0 \Rightarrow \Omega = -d/2)$ , the amplitude is further reduced because the actual detuning of the soliton is shifted from the detuning at the driving frequency as a result of the frequency shift and the dispersion. The CS amplitude and width are thus given by the effective detuning  $\Delta_{\text{eff}} = \Delta^* - \Omega^2$ .

Finally, the limit of existence of CSs, is found by setting  $\cos(\phi) = 1$  in Eq. (3):

$$\frac{2}{\pi}\sqrt{2(\Delta_{\rm DL}^* - \Omega_{\rm DL}^2)} = S \operatorname{sech}\left(\frac{\pi\Omega_{\rm DL}}{2\sqrt{\Delta_{\rm DL}^* - \Omega_{\rm DL}^2}}\right).$$
 (7)

The maximum detuning  $(\Delta_{\text{DL}}^*)$  can be seen as the pump depletion limit and corresponds to a saddle-node bifurcation. The predicted value by the LLE  $[\Delta_{\text{DL}}^{\text{LLE}} = (\pi S)^2/8]$ is once more retrieved for V = 0. This result is generalized for static potentials by considering the local detuning  $\Delta^*$ . In addition, this limit is lowered for  $d \neq 0$  because of the frequency shift. Rewriting Eq. (7) with the effective detuning  $\Delta_{\text{eff}}$ , the right-hand side of this equation suggests that the driving strength S is effectively diminished by the normalized spectral amplitude of the soliton at the driving frequency.

We now particularize to a periodic potential of the form  $V(\tau) = J\cos(\mathcal{W}\tau)$ , where we set the amplitude and frequency to J = 67.7 and  $\mathcal{W} \approx 0.52$ , respectively, for comparison with our experiments. The existence region of cavity solitons, plotted in the two-dimensional  $(\Delta^*, |\Omega|)$ parameter space, is reported in Fig.2. The limitation from the maximum slope is  $|d_{\rm SL}| = 2|\Omega_{\rm SL}|$ . However, with our parameters, it cannot be reached because the depletion limit is met first. Furthermore, as seen in the figure, the largest frequency shift, determined by the depletion limit  $(|\Omega_{DL}|)$ , shows a maximum. On the one hand, at large detunings, CSs are spectrally broad but close to the depletion limit without drift (i.e. for  $\Omega = 0$ ). A small decrease of the effective driving strength due to the frequency shift is thus sufficient to cross their existence limit. On the other hand, in the small detuning range, the spectral width of CSs is initially small. The effective driving strength is therefore quickly reduced by

**Figure 2.** Phase diagram in the  $(\Delta^*, |\Omega|)$ -parameter space showing the region of existence of cavity solitons and their stability for a cosine potential (J = 67.7, $\mathcal{W} = 0.52$ ), and S = 14.1. The horizontal dash-dotted line  $(\Omega_{SL})$  is the limit set by the maximum slope of V. The dashed blue line is the driving depletion limit of CS  $(\Omega_{\rm DL})$  given by the reduced model Eq. (7), while the two plain blue lines are the saddle-node bifurcations ( $\Omega_1$ ) and  $\Omega_{DL}$ ) of CS solutions of Eq. (1). The Hopf bifurcations  $(\Omega_{\rm H1,2})$  at which CSs gain or lose their stability are represented by the purple dotted lines. The grav dots show the frequency shift where the CS ceases to exist in direct numerical simulations of Eq. (1) when slowly increasing the drift d. The blue and red shaded areas indicate regions of stable and unstable CSs, respectively. All numerical continuations were performed with the Julia package BifucationKit [48].

the frequency shift, all the more so as the spectral width is also narrowed by the shift.

To confirm the depletion limit from Eq. (7), we also compute this limit by finding the corresponding saddlenode solution of Eq. (1) using a continuation scheme. The agreement is excellent except for low detunings where the homogenous background of the CS solution is not negligible.

We then look at the stability of the localized solutions. Interestingly, we find that CSs can undergo a Hopf bifurcation below the depletion limit. This bifurcation (denoted as  $\Omega_{\rm H2}$ ) is not found with our reduced model from the motion equations, probably because the chirp is not included in the ansatz [49]. This new bifurcation connects to the well-known Hopf bifurcation  $(\Omega_{\rm H1})$  that stabilizes the CS solutions as the detuning increases. Simulations of Eq. (1) reveal that CSs cease to exist abruptly upon crossing the frequency shift threshold  $|\Omega_{\rm H2}|$ . Hence, there is a maximum frequency shift CSs can withstand before they disappear. It is set either by the depletion limit or the Hopf bifurcation. We note that for much smaller maximum slope of V, the  $|\Omega_{\rm SL}|$  threshold could be reached first as in [37]. Beyond  $\Omega_{\rm SL}$ , the existence limits given by  $\Omega_{\rm DL}$  and  $\Omega_{\rm H2}$  are thus not relevant, as they only concern steady-state CSs.

**Figure 3.** (a) Schematic of the experimental set-up. The coherently driven resonator is made of single-mode fiber (SMF) and includes an intracavity electro-optic phase modulator (EOM) to generate the periodic potential. The erbium-doped fiber (EDF) amplifier partially compensates for the cavity loss. Typical spectra measured for positive (b) or negative (c) potential drifts. The drift amplitude and sign control the CS spectral position, which can be blue or red-shifted with respect to the pump.

Experimental setup. We aim next to experimentally confirm our theoretical predictions. A schematic of the setup is shown in Fig.3 (see also Supplemental Material [44]). It mainly consists of a  $L_c = 64$  m-long single-mode fiber ring resonator (3.12 MHz free-spectral)range), incorporating an electro-optic modulator (EOM) to generate a periodic potential. It is driven with a radio-frequency harmonic signal whose amplitude and frequency can be tuned. The resonator also includes a short piece of erbium-doped fiber to partially compensate the cavity loss [50]. The resulting effective loss is  $\Lambda_e = 3\%$  (effective finesse  $\mathcal{F}_e = 206$ ). The resonator is driven by a highly coherent continuous-wave (CW) laser at  $1550.12 \,\mathrm{nm}$ . We note that despite the high effective finesse and CW driving, there is no isolator in the resonator to prevent Brillouin lasing because the intracavity phase modulation raises the Brillouin laser threshold above the continuous background powers on which CSs sit. Finally, a counter-propagating small signal, which can be frequency-shifted, is used to phase stabilize the detuning between the cavity and the driving laser.

**Temporal trapping by drifting potentials.** In a first experiment, we set the driving to S = 14.1 and the amplitude of the IPM to J = 66.7 to investigate the soliton dynamics as the drift coefficient is linearly scanned. We start with a frequency modulation (W = 0.52) that matches an exact integer multiple of the cavity FSR to generate a stationary phase modulation (d = 0, see Supplemental Material [44]). Once the cavity is stabilized at a given phase detuning, we excite a single CS using a single addressing pulse [10, 51]. After the transient, we slowly tune the frequency of the modulation to higher (d < 0) or lower (d > 0) values until the CS disappears. For each modulation frequency, we record the CS

Figure 4. (a) Experimental soliton peak power (circle) as a function of the frequency shift  $\Omega$  for S = 14.1. Plain lines: analytical solutions [see Eq. (6)]. The number below the curves corresponds to the normalized detuning  $\Delta$ . The last measurement before the soliton disappears is indicated by a triangle and is reported in panel (b). (b) Maximum relative shift  $r_{\Omega} = \Omega/(2\pi \times \text{FWHM}_{\nu})$  as a function of the soliton spectral full width at half maximum (FWHM<sub> $\nu$ </sub>) for different modulation amplitude J. To delimit the theoretical soliton region of existence, the depletion limit and the Hopf bifurcation are also shown (see Fig. 2).

spectrum (see examples in Fig. 3 as well as a full scan in the Supplemental Material [44]) from which we measure the CS spectral width ( $\propto B$ ) and frequency shift ( $\Omega$ ). Fig. 4(a) shows the evolution of  $B^2$  as a function of the frequency shift, for different values of the detuning and for both positive and negative drifts. The results match well with the analytical predictions from Eq. (6)with  $\tau^* = \mathcal{D}^{-1}|_{-2\Omega}$  and confirm the reduction of the peak power (<br/>  $\propto B^2)$  and spectral width of CSs with the frequency shift  $|\Omega|$ , i.e. with the drift. The results shown in Fig. 4(b) represent the measured maximum frequency shift, normalized to the CS spectral width. They are plotted as a function of the CS spectral width and compared with the depletion limit ( $|\Omega_{DL}|, Eq.7$ ) and the Hopf bifurcation  $(\Omega_{\rm H2})$ . We confirm the existence of a limit frequency shift and thus a maximum drift of the potential the CS can withstand. The measured values of the limit relative spectral shift are all in the range [0.3-0.4]

(see Supplemental Figure S5 [44] for experimental data acquired at different driving powers). They are also independent of the periodic modulation amplitude J, as expected for the amplitudes considered. The comparison with the theoretical predictions shows, however, that in the experiments the CSs does not always reach the theoretical maximum spectral shift. This discrepancy can likely be explained by the reduction of the robustness of CSs against perturbations as they approach their existence limit. Our results confirm the impact of the intracavity phase modulation on the existence and characteristics of trapped CSs. Particularly, the modulation enables to control the CS central wavelength as well as the repetition rate of the frequency comb leaving the cavity, which may open up interesting new avenues [38]. In what follows, as an illustration, we show how such control can be harnessed to overcome the detrimental effects of Raman scattering.

Competition between temporal trapping and Raman scattering. In resonators made of amorphous materials, stimulated Raman scattering (SRS) is a significant effect that red-shifts the spectrum of cavity solitons relative to the driving laser wavelength and whose magnitude depends on the detuning [47, 52]. This frequency shift, in turn, changes the soliton repetition rate, a coupling mechanism that is beneficial to filter out the frequency noise of the driving laser, though only in a limited spectral bandwidth[53], otherwise, it is detrimental. In addition, SRS is known to set an upper limit to the range of detunings over which CSs exist, owing to the onset of a Hopf bifurcation. This consequently restricts their duration and bandwidth. [40]. However, assuming that the SRS limitation finds its origin in the frequency shift, it should be possible to overcome this limit by trapping CSs within potentials. Indeed, the synchronization of a steady-state CS to an intracavity phase modulation without drift compels its spectrum to remain centered on the driving. To experimentally confirm this prediction, we use the same driving power and potential shape as in the previous experiments, but we now scan the detuning  $\Delta$  with d = 0. Our results are shown in Fig. 5(a)-(b). They confirm that stationary potentials do not prevent the existence of stable CSs in the presence of strong SRS. Moreover, with increasing detuning, the center of the CS spectrum remains fixed at the driving wavelength, even as the soliton duration decreases and its spectrum widens.

In order to have a better understanding of the competition between SRS and an intracavity phase modulation, we first extend our previous Lagrangian analysis to include the Raman scattering. To this end, we add the term  $-i\tau_R A\partial_\tau |A|^2$  in the right-hand side of Eq. (1), with  $\tau_R$ the normalized Raman time constant (see Supplemental Material [44]). We note that we here consider the linear approximation of the Raman spectral gain, which is valid given the typical duration of CSs in fiber resonators (> 100 fs) [54]. In the steady-state, the motion equation

Figure 5. (a) Two-dimensional map of experimentally recorded spectra of the solitons trapped in a stationary intra-cavity phase modulation as a function of the detuning. The white dashed line shows the theoretically predicted CS central wavelength and range of existence without modulation (V = 0). (b) Two experimental spectra corresponding to different cavity detunings  $\Delta$ (solid lines), and predicted CS spectra by numerical integration of the mean-field model with S = 14.1, J = 66.67, W = 0.52 and  $\tau_R = 4.3 \times 10^{-4}$  (dashed lines). (c) Intracavity peak power of stable CSs  $(|B|^2)$ as a function of the detuning. The black curve represents the solutions of the mean-field model with SRS (solid) and the circles indicate the result of the motion equations. The red and blue curves show the solutions for V = 0 with and without SRS, respectively. We note that the black curves are shifted by the modulation amplitude J for small detunings, i.e., small soliton bandwidths, as the CS remains located close to the minimum local detuning  $\Delta^* \approx \Delta - J$ . The squares are the experimental values reported in (b).

for the soliton position  $\tau_s$  still gives  $\Omega = -d/2$ . For stationary IPM, we thus have  $\Omega = 0$ , and the motion equation for the frequency shift gives:

$$-\frac{dV(\tau_s)}{d\tau_s}|_{\tau^*} = J\mathcal{W}\sin(\mathcal{W}\tau^*) = 4\tau_R B^4/15.$$
(8)

It shows that the CS stabilizes at a position  $\tau^*$  such that the corresponding potential-induced spectral blue-shift exactly compensates the Raman soliton red-shift (see also Supplemental Material [44] for the evolution of the CS spectrum over one roundtrip). Finally, the CS amplitude (B) is found by combining this latter equation with the Eq. (6), which is unmodified by the SRS. The solutions from the motion equations are shown in Fig. 5(c). An excellent agreement with the numerical continuation of the solutions of the mean-field equation is obtained. The comparison with and without IPM reveals that higher peak powers and thus shorter CSs can be obtained with SRS when they are trapped in the modulation. In the experiment, we measure a 790 fs CS persisting endlessly in the resonator, while stable CSs are limited to 988 fs by the SRS without the potential. (We note that we have not performed measurements at V = 0 because of the Brillouin lasing.) Yet, with the experimental parameters, the limit detuning ( $\Delta_{\text{lim}}$ ) is here set by the depletion limit (equation 7 for  $\Omega_{\text{DL}} = 0$ ). The shortest CS is thus identical to the one given by the LLE.

Equation 8 suggests that the LLE limit could always be reached providing that the potential is sufficiently steep. To broaden our analysis, we investigate how far the balance between the Raman red-shift and the potential-induced blue-shift can be maintained. We find that at large detunings, CSs can undergo a new saddlenode bifurcation before reaching the depletion limit. Figure 6 shows for S = 30 the duration of the shortest stable CS as a function of the cavity characteristic time,  $\tau_c = \sqrt{-\beta_2 L_c / \Lambda_e}$ , for a large amplitude harmonic IPM, as well as for its parabolic approximation  $V(\tau) = J[1 - (\mathcal{W}\tau)^2/2]$ . These results are compared to the corresponding shortest CS without trapping IPM both in the absence and presence of SRS. We see that the modulation enables the CS to approach or even reach the standard limit without SRS. Yet, as  $\tau_c$  decreases, the compensation of the self-frequency shift becomes less effective. Ultimately, the confinement in the IPM does not suffice to stabilize the CS beyond the Raman limit. Interestingly, for stationary quadratic modulations, the motion equations can be solved to find this new limit (See Supplemental Material [44]). In dimensional units, it reads:

$$\Delta \tau_{\rm FWHM,min} \approx 2.02 \left( \frac{\alpha_e \overline{\tau_R}^2 \tau_c^2}{J_{\rm RF} \omega_{\rm RF}^2} \right)^{1/6}, \qquad (9)$$

where  $\overline{\tau_R} = \tau_r \tau_c$  is the Raman time constant,  $\omega_{\rm RF} = W/\tau_c$  is the modulation frequency and  $J_{\rm RF} = J\Lambda_e/2$  its amplitude. An excellent agreement with the numerical solutions of the mean-field model is obtained for  $\tau_c$  above  $\approx 2 \,\mathrm{ps}$ .

Bloch oscillations of the Kelly sidebands. Perturbations over the roundtrip of a CS and its subsequent reshaping into a fundamental soliton result in the emission of linear waves[55]. Typically, these are observed as narrowband spectral features, known as Kelly sidebands, with their location satisfying the phase-matching relation  $[\beta(\omega) - \beta(\omega_0) - \beta_1 \times (\omega - \omega_0)]L_c = 2\pi m + \delta_0$ , where  $\beta$  is the propagation constant,  $\beta_1$  is the inverse of the group velocity,  $\omega_0$  is the CS central frequency,  $\delta_0$  is the cavity detuning in radian and m is an integer. In stark contrast, the spectra reported in Fig.5 display broad and highly

**Figure 6.** Shortest cavity soliton duration as a function of the characteristic times  $\tau_c$  with S = 30. Solid curves correspond to the results from numerical continuations of solutions of the mean-field model. The dots show the limit given by Eq. 9. The parameters for the potentials are J = 209,  $\omega_{\rm RF} = 2\pi \times 20$  GHz and d = 0. The Raman time constant is the value typical for silica fibers,  $\overline{\tau_R} = 3$  fs. We note that  $\tau_c = 7$  ps in the experiments.

structured features in the CS spectral wings. Figure 7(a)shows the spectrum of a CS numerically simulated with a lumped-element model of our cavity. It confirms that ultra-stable CSs display structured Kelly sidebands in the presence of periodic potentials. Yet, their width and central location cannot be accurately predicted by a generalized phase-matching condition that accounts for the modulation in the fast time:  $\delta_0 \rightarrow \delta_0 - \phi_{int}(\tau)$  in the previous equation, where  $\phi_{int}(\tau)$  is the intracavity phase modulation in physical units (see Supplemental Material [44]). To gain more insight, Fig.7(b) shows the spectrogram of the intracavity field. It reveals that the complex shape of the Kelly-bands in the spectrum comes from the interference of very regular oscillations of the Kelly waves in the time-frequency domain. These oscillations, which originate from the relative drift between the linear waves and the intracavity phase modulation, can be seen as Bloch oscillations (BOs) along a synthetic frequency dimension[56]. However, contrary to BO experiments with linear wave packets in recirculation loops[56] or CSs in driven resonators [37], the linear (Kelly) waves are here continuously generated by the soliton. Hence, this results in a stationary pattern, round-trip after round-trip. The effective force responsible for the oscillatory motion in the synthetic frequency lattice is  $F = \Delta \nu / (n \times FSR)$ , where  $\Delta \nu = n \times \text{FSR} - \nu_{\text{RF}}$  with  $\nu_{\text{RF}}$  the frequency of the phase modulation and n the closest integer multiple between  $\nu_{\rm RF}$  and the FSR [37]. Yet, owing to the dispersion, for a stationary phase modulation at  $\omega_0$  (d = 0), F is directly proportional to  $\Delta \omega = \omega - \omega_0$ , where  $\omega$  is the frequency of the sideband. Since the amplitude of BOs is given by  $A_{\rm BO} = J_{\rm RF}/F$ , this explains the decrease in the amplitude of the spectral oscillations with the distance of the spectral sideband from the central CS position seen

Figure 7. (a) Spectrum of a CS displaying structured Kelly sidebands (50 pm resolution) due to periodic intracavity modulation. The shadowed regions highlight the extension of the Kelly sidebands. (b) Corresponding spectrogram of the intracavity field (gate function: 20 ps-wide super-Gaussian of order 6). The vertical line at the center is the background, while the soliton spectrum is seen as the horizontal band around the zero delay. The parameters are identical to the experiment reported in Fig.5(b) for  $\Delta = 280$ .

in Fig.7(b). More precisely, the oscillation amplitudes from the simulation agree very well with the  $1/\Delta\omega$  scaling expected for BOs (see Supplemental Material [44]).

# III. DISCUSSION

In this work, we have studied how the unique particlelike characteristics of solitons and their interaction with slowly varying trapping potentials can be leveraged to control the properties of cavity solitons. In our experiments, the potential is generated by intracavity phase modulation at a frequency close to a high harmonic of the free spectral range of our fiber resonator. We have shown that the locking of the cavity soliton to the modulation enables to up- or dow-shift its spectrum with respect to the driving frequency by desynchronizing the modulation to the cavity round-trip time. We theoretically found that for deep potentials, the limit spectral shift ( $\delta \omega_{max}$ ) is fundamentally set either by the driving pump depletion limit or a Hopf bifurcation, while it is set by the maximum potential slope for shallow potentials [37]. For temporal cavity solitons, the maximum shift, in turn, sets a limitation on the tuning of the output soliton comb repetition rate:  $\Delta FSR_{max} = -\beta_2 L_c FSR^2 \delta \omega_{max}$ .

Experimentally, we have investigated the trapping by intracavity phase modulations. We have observed that the soliton spectrum can robustly be spectrally blue- or red-shifted and that the reduction of the CS amplitude with the frequency shift is very well predicted by our theoretical model. The experimental maximum relative frequency shifts globally agree with the theoretical predictions but seem restricted to about 0.4, which could indicate a fundamental practical limitation.

We then demonstrated that the ability to deterministically manipulate the soliton frequency can be exploited to overcome the soliton self-frequency shift arising from the stimulated Raman scattering (SRS). We observed the formation of potential-stabilized solitons that would not otherwise have existed [40]. However, we theoretically showed that there is a minimum soliton duration below which the balance between the potential induced blueshift and the Raman red-shift cannot be maintained.

Previous works have shown that cavity solitons can also be trapped and manipulated by external phase modulations [21, 23] of the coherent driving. Yet, compared to external modulations, intracavity phase modulations enhance the tuning range of the CS spectral shift, and thus of the soliton comb repetition rate, by the inverse of the cavity loss  $\Lambda_e$  (see Supplemental Material [44]). The improvement can be significant for low-loss resonators, emphasizing the importance of dissipation on the dynamics of CSs in internally modulated resonators.

We envision intracavity phase modulation to play an important role in the future of cavity soliton based frequency combs. On the one hand, the robust locking mechanism can be leveraged for generating ultralownoise optical combs and microwave signals. This can be achieved through direct synchronization of the cavity solitons to an external microwave reference [38] or by employing a coupled optoelectronic oscillator scheme [57– 59]. On the other hand, the motion equations show that the potential gradient governs the rate at which the soliton frequency can be changed per round trip. The ability to rapidly vary the soliton frequency and, thus, the soliton comb repetition rate by steep potentials can benefit many applications, such as LiDAR and sensing. Finally, our findings could shed light on recently reported results in internally modulated cavity soliton microcombs [38], and could be extended to solitary waves of the parametrically driven nonlinear Schrödinger equation in optics [60, 61] and hydrodynamics [7], for which the potential will interact with the attraction or repulsion force in soliton pairs [62].

### A. Modelling - Driven-dissipative Gross-Pitaevskii equation

### 1. Dimensional form

The dynamics of Kerr cavity solitons (CSs) in trapping potentials  $\overline{V}$  can be described by a Lugiato-Lefever equation (LLE) [1, 2], generalized to account for the intracavity phase modulation,  $\phi_{int} = \overline{V}$ , [3] and the stimulated Raman scattering (SRS) [4, 5]. Such generalization corresponds to a driven-dissipative Gross-Pitaevskii equation, which reads:

$$t_{\rm R}\frac{\partial E}{\partial t} = \left(-\frac{\Lambda_e}{2} - i\left[\delta_0 - \overline{V}(\tau)\right] + \left[t_R d\frac{\partial}{\partial \tau} - i\frac{\beta_2 L_c}{2}\frac{\partial^2}{\partial \tau^2}\right] + i\gamma L_c \left[E^2 - \overline{\tau_R}\frac{\partial |E|^2}{\partial \tau}\right]\right) E + \sqrt{\theta P_{\rm in}} \tag{S1}$$

where  $t_{\rm R} = {\rm FSR}^{-1}$  is defined as the inverse of the cavity free spectral range (FSR) and corresponds to the cavity roundtrip time at the driving wavelength. t is the (slow) time describing the evolution of the electric field envelope  $E(t,\tau)$  with  $\tau$ , a (fast) time variable defined in a co-moving reference frame in which the potential  $\overline{V}(\tau)$  is stationary with time t.  $\Lambda_e = -\ln(T \times G)$  denotes the effective cavity loss that takes into account the "cold cavity" transmission (T)and the intracavity gain of the optical amplifier (amplification factor G) [6]. The phase detuning between the driving field and the closest cavity resonance is  $\delta_0 = 2\pi m - \beta L_c$ , with  $L_c$ , the cavity length,  $\beta$ , the propagation constant, and m, an integer.  $\beta_2$  and  $\gamma$  are, respectively, the group-velocity dispersion and the nonlinear Kerr coefficient of the resonator.  $\overline{\tau_R}$  is the Raman time constant.  $\theta$  and  $P_{\rm in}$  are the input coupler ratio and coherent driving power, respectively. Finally, d is the drift coefficient of a wave at the driving frequency in the reference frame co-moving with the potential. For an intracavity phase modulation of the form  $J_{\rm RF} \cos(\omega_{\rm RF} t)$ , we thus have  $\overline{V} = J_{\rm RF} \cos(\omega_n \tau)$ and  $d = \Delta \omega / \omega_n$ , where  $\Delta \omega = \omega_n - \omega_{\rm RF}$  is the frequency difference between the n<sup>th</sup> harmonic of the cavity FSR ( $\omega_n = n \times 2\pi \times {\rm FSR}$ ) and the modulation frequency.

# 2. Normalized form

It is convenient to introduce dimensionless parameters to carry out theoretical analyses and draw general conclusions. Choosing the usual LLE normalization with  $\tau_c = \sqrt{-\beta_2 L_c / \Lambda_e}$  and  $\alpha_e = \Lambda_e / 2$  [2]:

$$t \to \frac{\alpha_e t}{t_R}, \qquad \tau \to \frac{\tau}{\tau_c}, \qquad A = E \sqrt{\frac{\gamma L_c}{\alpha_e}}, \qquad S = \sqrt{\frac{\gamma L_c \theta_{\rm in} P_{\rm in}}{\alpha_e^3}}, \tag{S2}$$
$$\Delta = \frac{\delta_0}{\alpha_e}, \qquad V = \frac{\overline{V}}{\alpha_e}, \qquad d = d \frac{t_R}{\tau_c \alpha_e}, \qquad \tau_R = \frac{\overline{\tau_R}}{\tau_c},$$

Eq. (S1) becomes:

$$\frac{\partial A(t,\tau)}{\partial t} = S + \left( -1 - i \left[ \Delta - V(\tau) \right] + i \left[ |A|^2 - \tau_R \frac{\partial |A|^2}{\partial \tau} \right] + \left[ d \frac{\partial}{\partial \tau} + i \frac{\partial^2}{\partial \tau^2} \right] \right) A, \tag{S3}$$

which corresponds to Eq. (1) of the main manuscript when  $\tau_R = 0$ .

# B. Reduced model – Equations of motion

# 1. Dimensional form

There are no known closed-form analytical expressions that would describe CS solutions of the mean-field equation (S1), with or without the SRS term. However, equations of motion can be found by using a perturbative Lagrangian approach [7]. Starting with the soliton ansatz [5, 7]:

$$E_s(t,\tau) = \overline{B}\operatorname{sech}\left(\frac{\overline{B}(\tau-\tau_s)}{\sqrt{-\beta_2/\gamma}}\right) e^{-i\overline{\Omega}(\tau-\tau_s)} e^{i\overline{\phi}}$$
(S4)

where  $\overline{\Omega}$  corresponds to the soliton central frequency,  $\overline{B}$  is the soliton amplitude (with units of W<sup>1/2</sup>),  $\tau_s$  is the soliton position along the fast-time, and  $\overline{\phi}$  is the cavity soliton phase. Following the procedure described in [5, 7, 8], one can find the equations of motion for each of the CS (dimensional) parameters:

$$\begin{split} t_{R} \frac{d\overline{\Omega}}{dt} &= -\frac{\overline{\Omega}}{\overline{B}} t_{R} \frac{d\overline{B}}{dt} - 2\alpha_{e}\overline{\Omega} - \frac{d\overline{V}(\tau_{s})}{d\tau_{s}} + \frac{8\overline{\tau_{R}}\gamma^{2}L_{c}}{15\beta_{2}}\overline{B}^{4}, \\ t_{R} \frac{d\overline{B}}{dt} &= -2\alpha_{e}\overline{B} + \pi\sqrt{\theta}P_{\mathrm{in}}\cos(\overline{\phi})\operatorname{sech}\left(\sqrt{\frac{-\beta_{2}}{\gamma}}\frac{\overline{\Omega}\pi}{2\overline{B}}\right), \\ t_{R} \frac{d\tau_{s}}{dt} &= \beta_{2}L_{c}\overline{\Omega} - t_{R}d + \frac{\pi^{2}}{2\overline{B}^{2}}\sqrt{\frac{-\beta_{2}}{\gamma}}\theta P_{\mathrm{in}}\sin(\overline{\phi})\operatorname{sech}\left(\sqrt{\frac{-\beta_{2}}{\gamma}}\frac{\overline{\Omega}\pi}{2\overline{B}}\right) \operatorname{tanh}\left(\sqrt{\frac{-\beta_{2}}{\gamma}}\frac{\overline{\Omega}\pi}{2\overline{B}}\right), \\ t_{R} \frac{d\overline{\phi}}{dt} &= \frac{\gamma L_{c}\overline{B}^{2}}{2} + \frac{\beta_{2}L_{c}}{2}\overline{\Omega}^{2} - [\delta_{0} - \overline{V}(\tau_{s})] - t_{R}\overline{\Omega}\left[\frac{d\tau_{s}}{dt} + d\right] \\ &\quad + \frac{\pi^{2}}{2\overline{B}^{2}}\overline{\Omega}\sqrt{\frac{-\beta_{2}}{\gamma}}\theta P_{\mathrm{in}}\sin(\overline{\phi})\operatorname{sech}\left(\sqrt{\frac{-\beta_{2}}{\gamma}}\frac{\overline{\Omega}\pi}{2\overline{B}}\right) \operatorname{tanh}\left(\sqrt{\frac{-\beta_{2}}{\gamma}}\frac{\overline{\Omega}\pi}{2\overline{B}}\right), \end{split}$$
(S5)

### Normalized form 2.

Applying the normalization Eq. (S2) to the system of equations (S5) and neglecting the terms proportional to  $B^{-2}$ yield Eqs. (2)-(5) of the main manuscript (for  $\tau_R = 0$ ):

$$\frac{d\Omega}{dt} = -\frac{\Omega}{B}\frac{dB}{dt} - 2\Omega - \frac{dV(\tau_s)}{d\tau_s} - \frac{4\tau_R}{15}B^4,$$

$$\frac{dB}{dt} = -2B + \pi S\cos(\phi)\operatorname{sech}\left(\frac{\Omega\pi}{\sqrt{2B}}\right),$$

$$\frac{d\phi}{dt} = \frac{B^2}{2} - \Omega^2 - \left[\Delta - V(\tau_s)\right] - \left(\frac{d\tau_s}{dt} + d\right)\Omega,$$

$$\frac{d\tau_s}{dt} = -2\Omega - d.$$
(S6)

### $\mathbf{C}.$ Cancellation of the Raman-induced self-frequency shift by external potentials: limit of shortest CSs

From the motion equations, we can find the conditions under which a potential completely cancels the Ramaninduced frequency shift of cavity solitons. To do so, we look at the stationary solutions at  $\Omega = 0$  (we note that redand blue-shifted CSs still exist in the presence of SRS, but we here restrict ourselves to unshifted solutions). The stationary solution of S6 reads:

$$\Omega = d = 0,$$
  

$$\cos(\phi) = \frac{2B}{\pi S},$$
  

$$\frac{B^2}{2} = \Delta - V(\tau^*),$$
  

$$\mathcal{D}(\tau^*) = -\frac{4\tau_R}{15}B^4,$$
  
(S7)

where  $\tau^*$  is the position of the CS in the fast time and  $\mathcal{D}(\tau^*) = \frac{dV(\tau)}{d\tau}|_{\tau^*}$  is the local potential gradient. First, the motion equation for the CS amplitude gives  $\cos(\phi) = \frac{2B}{\pi S} < 1$ , which corresponds to the depletion limit. It implicitly accounts for the local detuning  $\Delta^* = \Delta - V(\tau^*)$  through the soliton amplitude B. A second existence condition arises from the combination of the two last equations:

$$\Delta = \frac{B^2}{2} + V \left[ \mathcal{D}^{-1} \left( -\frac{4\tau_R}{15} B^4 \right) \right],\tag{S8}$$

where  $\mathcal{D}^{-1}$  is the reciprocal of the potential gradient. We now focus on trapping by parabolic potentials of the form  $V(\tau) = -a\tau^2/2 < 0$ , for which there is no slope limit and an explicit analytical solution can be found. We note that we do not consider any offset on the potential since this term simply shifts the detuning  $[\Delta \rightarrow \Delta - V(0)]$ . We thus have  $V\left[\mathcal{D}^{-1}(x)\right] = -\frac{x^2}{2a}$ , which yields:

$$\Delta = \frac{B^2}{2} - \frac{1}{2a} \left(\frac{4\tau_R}{15}\right)^2 B^8 = \frac{B^2}{2} - \frac{1}{8} \frac{B^8}{B_{\text{max}}^6},\tag{S9}$$

where we have introduced  $B_{\text{max}} = (225a/64\tau_R^2)^{1/6}$  for convenience (see below). The right-hand side of this later equation shows that there is a maximum possible value for  $\Delta$  (see also Fig.1). It is found by looking at the soliton amplitude such that  $\partial \Delta / \partial B = 0$ , which occurs at  $B = B_{\text{max}}$  and  $\Delta = \Delta_{\text{max}} = (3/8)B_{\text{max}}^2$ . This gives the maximum peak power  $B_{\text{max}}^2$  of stable CSs for which the interaction with the intracavity phase modulation can cancel the SRS. We note that this limit is independent of the driving amplitude S. In conclusion, there are two limitations:

$$B < B_{\max}$$
 and  $B < \frac{\pi S}{2}$ . (S10)

Fig. S1. Peak power of the cavity solitons as a function of the detuning  $\Delta$  with a trapping parabolic potential and when considering the Raman self-frequency shift. The parameters are  $\tau_R = 1.5 \times 10^{-3}$  ( $\overline{\tau_R} = 3 \text{ fs}[4]$ ,  $\tau_c = 2 \text{ ps}$ ), S = 30, and a = 13.2 [parabolic approximation of a cosine modulation at frequency  $\mathcal{W} = 0.25$  ( $\nu_{\text{RF}} = 20 \text{ GHz}$ ) and J = 209]. The dark blue line shows results from the numerical continuations of solutions of the mean-filed model, where unstable solutions are indicated in dashed lines. H<sub>1</sub>, Hopf bifurcation that stabilizes the solution. The two saddle-node bifurcations,  $\text{SN}_{\text{R}}$  and  $\text{SN}_{\text{DL}}$ , correspond to the conditions  $B = B_{\text{max}}$  and  $B = \pi S/2$ , respectively. For detunings  $\Delta$  below  $\text{SN}_{\text{R}}$ , there are two different soliton solutions, with different positions  $\tau^*$  and local detuning  $\Delta^*$ (see also inset), but only one is stable. Equation (S9) is plotted in light blue. We note a very good agreement between the two models regarding the peak power (and thus the soliton duration) at the saddle-node  $\text{SN}_{\text{R}}$ .

Looking at the SRS limitation and applying the denormalization  $a \to \bar{a}\tau_c^2/\alpha_e$  [see also Eq. (S2)], the corresponding minimum CS duration in dimensional units reads:

$$\text{FWHM}_{\text{min}} = 4\sqrt{2}\ln\left(1+\sqrt{2}\right)\sqrt[3]{\frac{1}{15}}\left(\frac{\alpha_e \tau_c^2 \overline{\tau_R}^2}{\overline{a}}\right)^{1/6} \approx 2.02 \left(\frac{\alpha_e \tau_c^2 \overline{\tau_R}^2}{\overline{a}}\right)^{1/6}.$$
(S11)

Considering the parabolic approximation of a cosine potential of the form  $\overline{V} = J_{\rm RF} \cos(\omega_{\rm RF}\tau)$ , we have  $\overline{a} = J_{\rm RF}\omega_{\rm RF}^2$ . It follows Eq.(9) of the main manuscript. This limit is in excellent agreement with the results of the numerical continuations (Figure S1) of the solutions of the mean-field model. We finally note that exact cosine potentials can also be solved. In this case, finding the maximum CS amplitude for which  $\partial \Delta / \partial B = 0$  requires computing the unique positive root of a third-order polynomial.

### D. Schematic of the experimental set-up

Figure S4 depicts the full experimental setup used to investigate the dynamics of cavity solitons in trapping potentials. It consists of an active fiber ring resonator [6] of length  $L_c = 64 \,\mathrm{m}$  (free spectral range of  $3.12 \,\mathrm{MHz}$ ,  $\tau_c=7$  ps). Specifically, it is made of 63 m of standard telecommunication single-mode fibre (SMF-28,  $\gamma = 1.3 \text{ W}^{-1} \text{ km}^{-1}$ ,  $\beta_2 = -2.3 \times 10^{-26} \text{ s}^2 \text{m}^{-1}$ ) spliced to a 75 cm-long segment of erbium-doped fibre (EDF, Liekki<sup>®</sup> ER16-8/125). The aim of the doped fiber is to partially compensate for the high cavity roundtrip loss ( $T = -2.8 \,\mathrm{dB}$  when the EDF is removed, corresponding to an intrinsic finesse  $\mathcal{F} = 9.7$ ). The length of the amplifying section has been carefully adjusted following the method described in ref. [6]. The EDF is pumped by a 1480 nm laser through a wavelength division multiplexer, with a power  $P_p^{\text{in}} = 2$  W. The unabsorbed pump power  $P_p^{\text{out}}$  after the EDF is rejected by a second WDM. In addition, to individually address a soliton by means of a single writing pulse [9, 10], the cavity includes a 1535/1550 WDM. The writing pulses come from a 1535 nm mode-locked laser and are gated using an acousto-optic modulator (not shown). The three WDMs combined spectral transmission prevents lasing at shorter wavelengths [10]. With intracavity amplification, the effective loss at small signal is  $\Lambda_e = 3\%$  (effective finesse  $\mathcal{F}_e = 209$ ), while the saturation power (neglected in the mean-field simulations) is estimated to 250 mW. The resonator includes an electrooptic phase modulator to generate the (real) potential. The EOM is driven by a harmonic RF signal whose amplitude  $(J_{\rm BF})$  and frequency  $(\nu_{\rm BF})$  can be freely chosen.  $J_{\rm BF}$  is experimentally limited to 1 rad at the modulation frequency  $(\approx 12 \text{ GHz})$ . In addition, an intracavity polarization controller limits the EOM polarization-dependent insertion loss (not shown). The optical cavity is coherently driven with a sub-100-Hz continuous wave laser, centered on 1550.12 nm. It is amplified by a commercial erbium-doped fiber amplifier (EDFA) before being injected into the cavity through

the 90/10 input coupler. The driving beam polarization is adjusted at the cavity input with a polarization controller to excite one eigen polarization mode of the cavity. Part of the intracavity power is extracted at the output coupler (99/1) to perform spectral measurements of the intracavity field. We note that the intracavity phase modulation prevents the build-up of stimulated Brillouin scattering. Therefore, there is no need for an optical isolator, even if the cavity is pumped by a highly coherent CW laser. This enables sending a co-polarized counter-propagating CW control signal to stabilize the cavity detuning. Its polarization is identical to the driving beam to avoid large insertion loss in the EOM. The cavity detuning is actively stabilized by using a proportional-integral-derivative (PID) controller fed by the signal generated by the output control beam on a photodiode (200 kHz bandwidth). The cavity detuning is tuned by slightly shifting the frequency of the control signal with a frequency shifter (FS).

### E. Bloch oscillations of the Kelly bands

The electro-optic phase modulator included in the fiber loop introduces a coupling between the modes of the resonator with a strength given by  $J = J_{\rm RF}/(2t_R)$  for a modulation  $J_{\rm RF} \cos(2\pi\nu_{\rm RF}t)$ , where  $\nu_{\rm RF}$  is a frequency close to an integer multiple (n) of the FSR. These coupled sites form a synthetic 1D lattice along the frequency axis [8]. By detuning the modulation from a resonant frequency ( $\nu_{\rm RF} = n \times \text{FSR} + \Delta f$ ), an effective force along the frequency axis is implemented. This force, which is responsible for the Bloch oscillations (BOs) in the synthetic frequency lattice, is given by:

$$F = d = \frac{n \times \text{FSR} - \nu_{\text{RF}}}{n \times \text{FSR}}.$$
(S12)

Assuming that the modulation is resonant at the driving frequency  $\omega_0$  ( $\nu_{\rm RF} = n_0 \times {\rm FSR}|_{\omega_0}$ ), this modulation becomes detuned from resonance at  $\omega$  because of chromatic dispersion. We thus have  $\Delta f = n_0 ({\rm FSR}|_{\omega_0} - {\rm FSR}|_{\omega}) \approx \frac{\beta_2}{\beta_1} n_0 {\rm FSR}|_{\omega_0} \times (\omega - \omega_0)$ . The effective force thus reads:

$$F \approx \frac{\Delta f}{\nu_{\rm RF}} = \frac{\beta_2}{\beta_1} \Delta \omega, \tag{S13}$$

where  $\Delta \omega = \omega - \omega_0$ .

BOs are characterized by an oscillation amplitude  $A_{\rm BO} = 2J/F$ . This amplitude thus reads:

$$A_{\rm BO}|_{\omega} = \frac{J_{\rm RF}\beta_1}{t_R\beta_2} \frac{1}{\Delta\omega} = \frac{J_{\rm RF}}{L_c\beta_2} \frac{1}{\Delta\omega},\tag{S14}$$

with  $t_R = \beta_1 L_c$ .

The amplitude of the BOs as a function of the inverse of the frequency shift from the driving is shown in figure 3. The circles denote the data measured from the numerical simulation of the dynamics of CS with a periodic potential, which is reported in Fig.7 of the main manuscript. These results are in excellent agreement with the theoretical model Eq. (S14), confirming that the oscillations of the Kelly bands can be interpreted as Bloch oscillations.

Fig. S3. Amplitude of the spectral oscillations of the Kelly sidebands as a function of the inverse of their frequency shift from the driving ( $\Delta \nu = \Delta \omega / 2\pi$ ). The circles are the amplitudes extracted from the numerical simulation shown in Fig.7 of the main manuscript. The parameters are  $\beta_2 = -2.3 \times 10^{-26} \,\mathrm{s}^2 \mathrm{m}^{-1}$ ,  $L_c = 64 \,\mathrm{m}$ . The red line shows the theoretical relation Eq.S14.

### F. Internal versus external phase modulation

Studies of the motion dynamics of cavity solitons in presence of a modulated driving field, either in phase or in amplitude, have revealed that cavity solitons can be manipulated and trapped by the modulations [11–14]. For instance, such trapping as been used to control and stabilize the soliton repetition rate [15], which is interesting for applications. Real potentials, as considered in this work, correspond to phase modulations of the intracavity field. Of particular interest for comparison are, therefore, external purely phase-modulated driving fields.

For an *external* phase modulation, the CS drift velocity in normalized variables reads [14]:

$$v_{\rm ext} = \frac{d\tau_s}{dt} = 2\phi_{\rm ext}' - d,\tag{S15}$$

where 'stands for the first derivative with respect to the slow time  $\tau$ . The corresponding dimensional expression of the drift velocity is:

$$\overline{v}_{\text{ext}} = \frac{L_c}{t_R} |\beta_2| \frac{d\phi_{\text{ext}}}{d\tau} |_{\tau_s} - d.$$
(S16)

This can be compared with Eq. (5) of the main manuscripts for *internal* phase modulations:

$$v_{\rm int} = -2\Omega - d,\tag{S17}$$

with  $\Omega$  the normalized frequency shift of the CS. Hence, this gives for  $\overline{V} = \phi_{\text{int}}$ :

$$\overline{v}_{\rm int} = -\frac{1}{\Lambda_e} \frac{L_c}{t_R} |\beta_2| \frac{d\phi_{\rm int}}{d\tau}|_{\tau_s} - d.$$
(S18)

We can see that the equations (S16) and (S18) are identical, providing that

$$\phi_{\rm int} = \Lambda_e \phi_{\rm ext}.\tag{S19}$$

This result shows that a phase modulation amplitude  $1/\Lambda_e$  times smaller is required for internally modulated resonators to achieve the same effect as with external modulation of the driving beam. The locking range, and hence the maximum frequency shift of the CS or the tuning range of the soliton repetition rate, is thus enhanced by the same factor, which can also be written  $\mathcal{F}/2\pi$  or  $Q\nu_0/(2\pi \times \text{FSR})$ , with Q the resonator Q-factor and  $\nu_0$  the soliton carrier frequency.

This emphasizes the importance of the loss in the dynamics of CSs in internally modulated resonators as well as the interest of internal modulations for applications.

Fig. S4. Soliton single-roundtrip dynamic. Evolution of (a) the soliton frequency shift, (b) peak power, and (c) temporal full width at half maximum (FWHM) over one roundtrip. The simulation corresponds to a lumped element model of the system using the following parameters: L = 64 m,  $\gamma = 1.3 \times 10^{-3} \text{ W}^{-1} \text{ m}^{-1}$ ,  $\beta_2 = -23 \times 10^{-27} \text{ s}^2 \text{ m}^{-1}$ ,  $\delta_0 = 4.1 \text{ rad}$ ,  $P_{\text{in}} = 250 \text{ mW}$ ,  $\theta_{\text{in}} = 0.1$ ,  $J_{\text{RF}} = 1 \text{ rad}$ ,  $\omega_{\text{RF}} = 2\pi \times 11.8 \text{ rad}$ .GHz, d = 0,  $\overline{\tau_R} = 3 \text{ fs}$ .

Fig. S5. Maximum relative shift  $r_{\Omega} = \Omega/(2\pi \times \text{FWHM}_{\nu})$  as a function of the soliton spectral full width at half maximum (FWHM<sub> $\nu$ </sub>) for different driving power  $P_{in}$  at a fixed modulation amplitude of J = 66.67.
