Abstract

We study the asymptotic frequentist coverage of credible sets based on a novel Bayesian approach for a multiple linear regression model under variable selection. We initially ignore the issue of variable selection, which allows us to put a conjugate normal prior on the coefficient vector. The variable selection step is incorporated directly in the posterior through a sparsity-inducing map and uses the induced prior for making an inference instead of the natural conjugate posterior. The sparsity-inducing map minimizes the sum of the squared ℓ_2 -distance weighted by the data matrix and a suitably scaled ℓ_1 -penalty term. We obtain the limiting coverage of various credible regions and demonstrate that a modified credible interval for a component has the exact asymptotic frequentist coverage if the corresponding predictor is asymptotically uncorrelated with other predictors. Through extensive simulation, we provide a guideline for choosing the penalty parameter as a function of the credibility level appropriate for the corresponding coverage. We also show finite-sample numerical results that support the conclusions from the asymptotic theory. We also provide the **credInt** package that implements the method in **R** to obtain the credible intervals along with the posterior samples.

1 Introduction

The multiple linear regression model is one of the most useful tools for analyzing data, expressing an overall relationship between a response variable and a set of predictors as an affine function. Not all listed predictor variables are often active in the regression, prompting the need to select the relevant predictors for a better interpretable model and more precise estimation and prediction. The issue of variable selection is especially vital for data consisting of many predictors when a meaningful inference is possible only by incorporating such

^{*}spal4@ncsu.edu

a step in the analysis, but even for a fixed-dimensional setting, a variable selection step is highly desirable. This leads us to the model selection problem, which has been addressed by both Bayesian and non-Bayesian methods. Classical methods of model selection include forward selection and backward selection. The former begins with the null model and keeps adding predictors in the model sequentially as long as the predictive power goes up significantly, while the latter begins with the full model and sequentially removes unneeded until a stopping criterion is met. Another commonly employed approach involves penalization, which adds a penalty function to the objective function. This encourages the minimizer to produce solutions with greater sparsity than a minimizer without a penalty. The most notable such method is the LASSO [Tibshirani, 1996], which penalizes the ℓ_1 -norm of the coefficient vectors to obtain a sparse estimator. Asymptotic properties such as consistency and the limiting distribution of the LASSO were studied in Fu and Knight [2000] in the fixed dimensional setting. If the dimension of the model is large, possibly larger than the sample size, additional compatibility conditions are needed on the predictors and the true value of the vector of regression coefficients to ensure identifiability. For a detailed account of convergence and selection properties of LASSO-type estimators, see Bühlmann and van de Geer [2011].

In the Bayesian domain, the emphasis has been on formulating a prior distribution that encourages sparsity in the posterior model. The approach of a spike-and-slab prior [Mitchell and Beauchamp, 1988, Ishwaran and Rao, 2005] combines a point mass or an approximation to it (spike) at zero and a thick-tailed continuous distribution (slab). Gibbs sampling and a data augmentation technique are used to compute the posterior distribution; see George and McCulloch [1993]. A typically faster alternative is to adopt a continuous-shrinkage prior such as the horseshoe prior [Carvalho et al., 2010]. It incorporates a single density function to emulate the concentration at zero and the thickness of the tail in a spike-and-slab prior, simplifying the model by using a one-component approach. Asymptotic concentration and selection properties of the posterior based on a spike-and-slab prior were established in Castillo et al. [2015] and analogous properties for a continuous shrinkage prior in Song and Liang [2017]. Variational inference for the variable selection problem was recently considered by some authors as an approximate Bayesian inference method providing significantly faster computation; see Ray and Szabó [2022], Ormerod et al. [2017], Huang et al. [2016], Mukherjee and Sen [2022], Yang et al. [2020] Concentration properties for estimation and selection consistency properties were studied by Zhang and Gao [2020], Han and Yang [2019], Bai et al. [2020]. Yang and Martin [2020] showed asymptotic frequentist coverage of a credible ball assuming an orthogonal design matrix.

While penalization methods for variable selection like the LASSO are hugely popular and possess desirable convergence and model selection properties, they do not naturally quantify uncertainty. Even in the fixed dimensional case, because of the bias and degeneracy of the LASSO, the limiting distribution obtained in Fu and Knight [2000] cannot be used to construct a confidence region as the limiting distribution is dependent on the sparsity structure of the true regression coefficients. By applying a debiasing technique on the LASSO, Zhang and Zhang, 2014, van de Geer et al., 2014, Javanmard and Montanari, 2018] constructed confidence bands, but at the expense of losing sparsity. Modifying the idea of the bootstrap LASSO in Fu and Knight [2000], Chatterjee and Lahiri [2011] showed that the resulting confidence region has good coverage in the fixed-dimensional setting. Confidence regions for the regression vector in the high-dimensional linear regression setting under sparsity appear to have been studied only in Nickl and van de Geer [2013] and Cai and Guo [2017]. Bayesian methods automatically provide a measurement of uncertainty through the posterior distribution. However, the Bayesian way of quantifying the uncertainty may not match a frequentist assessment because these two use very different notions of randomness. For smooth fixed-dimensional parametric families, the Bernstein-von Mises theorem ensures the approximate agreement between Bayesian and frequentist measures of uncertainty, but this may not carry over to non-parametric and other settings; see $\cos [1993]$. In smoothing regimes, asymptotic coverage may be assured only by modifications such as undersmoothing or inflating a credible ball; see Knapik et al. [2011], Castillo and Nickl [2013], Szabó et al. [2015], Yoo and Ghosal [2016], Ray [2017], Sniekers and van der Vaart [2015], and others. For a high-dimensional setting, the problem of frequentist validation of Bayesian uncertainty quantification was addressed only by van der Pas et al. [2017], Belitser and Nurushev [2019], Belitser and Ghosal [2020,0].

A novel and convenient Bayesian approach to inference on a restricted subspace through the induced distribution by a restriction-complying "immersion" map, which can often be a projection, from a simple unrestricted posterior typically obtained through conjugacy. Lin and Dunson [2014] and Chakraborty and Ghosal [2021a,0,0] used the technique for inference on monotone functions; Bhaumik and Ghosal [2015,0], Bhaumik et al. [2022] for differential equation models, and Wang and Ghosal [2023a,0,0] for problems on multivariate monotonicity. The corresponding "projection-posterior", or a more general "immersion-posterior", can be easily computed by conjugate posterior sampling, typically followed by a simple optimization step. For differential equation models, a Bernstein-von Mises theorem holds, justifying the uncertainty quantification of the projection-posterior from the frequentist principle. For shape-restricted models, the asymptotic coverage is slightly higher than the credibility level, the opposite of the phenomenon observed in $\cos [1993]$ for smoothing problems. Interestingly, the relationship between the limiting coverage and credibility does not depend on the true function. Hence, a target exact asymptotic coverage can be obtained by starting from a predetermined lower level (Chakraborty and Ghosal [2021b,0], Wang and Ghosal [2023a,0]). In a linear regression model with variable selection, the need to address sparsity in the prior makes posterior distributions harder to compute and analyze theoretically. This is particularly apparent because results on coverage of Bayesian credible regions are largely absent from the literature. The problem can be alleviated by using an immersion posterior to make an inference. In the absence of sparsity, a multivariate normal prior is conjugate for the linear regression problem, leading to an explicit expression for the posterior distribution. An immersion map given by the minimizer of the sum of a weighted squared Euclidean distance and an ℓ_1 -penalty induces sparsity in the solution and is appropriate for the problem.

This paper studies the construction and frequentist coverage properties of credible sets for the coefficient vector using the sparse projection-posterior method under the fixed dimension setting. We derive a weak limit of the immersion-posterior distribution with an interesting structural similarity with the distributional limit of the LASSO derived in Fu and Knight [2000]. Using the weak limit, we derive an expression for the limiting coverage of a Bayesian credible ball. When a predictor variable is asymptotically uncorrelated with the remaining predictors, we simplify the expression for the coverage and compare it with the credibility level. While the limiting coverage is lower than the credibility level if the coefficient is non-zero, we can identify a higher credibility level, depending on the tuning parameter, such that the limiting coverage coincides with the targeted coverage. The corresponding limiting coverage is higher if the parameter assumes zero value, provided that the intended coverage level is sufficiently high. Apart from reconciling the Bayesian and frequentist notions of uncertainty quantification as in the Bernsterin-von Mises theorem for smooth fixed-dimensional parametric families, this result provides an automatic tuning mechanism.

The rest of the paper is organized as follows. The setup and the methodology are formally described in the next section. In Section 3, we derive the limiting results for establishing asymptotic coverage of the credible balls, stating the necessary assumptions and confirming their pragmatism. Section 4 shows finite-sample results of the proven asymptotic guarantees and provides a table for guidelines for choosing the correct penalty parameter. Finally, in Section 5, we discuss the contribution of this work and the future directions, followed by the proofs in the appendix.

2 Setup and Methodology

We consider the problem of model selection and uncertainty quantification of the chosen variables in the context of the linear regression model

$$\boldsymbol{Y} = \boldsymbol{X}\boldsymbol{\theta} + \boldsymbol{\varepsilon}, \quad \boldsymbol{\varepsilon} \sim N_n(\boldsymbol{0}, \sigma^2 \boldsymbol{I}_n), \tag{2.1}$$

where $\mathbf{Y} \in \mathbb{R}^n$ is the response vector observed for n samples, $\mathbf{X} \in \mathbb{R}^{n \times p}$ is a deterministic design matrix and $\boldsymbol{\theta} \in \mathbb{R}^p$ is the vector of regression coefficients. Regarding the methodology, the deterministic or random nature of the predictor variables is immaterial, but it matters in the study of asymptotic properties. If the predictors are random, the conditions imposed on the predictor variables will have to be satisfied with probability tending to one.

Throughout the paper, the number of explanatory variables p in this model is assumed to be fixed and smaller than the sample size n. A smaller number s of these p predictors are active, but s and the active predictor indices are unknown. Although the regression vector may be estimated at the parametric rate $n^{-1/2}$, identifying the model consisting only of the active predictors is desirable since it gives a more interpretable model. Let S_0 consist of the indices corresponding to active predictor variables in the model. We assume that the data $\mathbf{Y} = (Y_1, \ldots, Y_n)^{\mathrm{T}}$ is generated through the process

$$Y_i = \boldsymbol{X}_i^{\mathrm{T}} \boldsymbol{\theta}^0 + \varepsilon_i, \quad \varepsilon_1, \dots, \varepsilon_n \text{ are i.i.d. with mean 0 and variance } \sigma_0^2, \tag{2.2}$$

where X_i^{T} stands for the *i*th row of X (i.e., the vector of covariates for the *i*th observation). Thus, the true data generating process follows the linear model (2.1) with the true value of the regression coefficients θ^0 and the true value of the error standard deviation σ_0 , except that the error distribution need not be normal.

Throughout the paper, we will use the following notations. Probability under the true model will be denoted by \mathbb{P}_0 and the corresponding expectation by \mathbb{E}_0 . The normalized cross-products matrix is given by $C_n = n^{-1} X^T X$. For notational convenience in theoretical analysis, we shall place the s_0 active predictors corresponding to nonzero regression coefficients at the beginning of the arrangement: let $X_{(1)}$ stand for the submatrix of the data matrix X formed by the active predictors and $X_{(2)}$ stand for the submatrix corresponding to the remaining $p - s_0$ variables with zero true coefficients. Then, the matrix C_n can be split into block matrices

$$\begin{bmatrix} \boldsymbol{C}_{n(11)} & \boldsymbol{C}_{n(12)} \\ \boldsymbol{C}_{n(21)} & \boldsymbol{C}_{n(22)} \end{bmatrix} = \frac{1}{n} \begin{bmatrix} \boldsymbol{X}_{(1)}^{\mathrm{T}} \boldsymbol{X}_{(1)} & \boldsymbol{X}_{(1)}^{\mathrm{T}} \boldsymbol{X}_{(2)} \\ \boldsymbol{X}_{(2)}^{\mathrm{T}} \boldsymbol{X}_{(1)} & \boldsymbol{X}_{(2)}^{\mathrm{T}} \boldsymbol{X}_{(2)} \end{bmatrix}.$$
(2.3)

The q-norm of a vector $\mathbf{a} \in \mathbb{R}^d$ is given by $\|\mathbf{a}\|_q = (\sum_{i=1}^d |a_i|^q)^{1/q}$. For q = 2, this corresponds to the Euclidean norm, which is denoted by $\|\cdot\|$. For a matrix $\mathbf{M} \in \mathbb{R}^{d_1 \times d_2}$, we denote by \mathbf{M}_A the submatrix of containing the columns corresponding to a given set $A \subset \{1, 2, \ldots, d_2\}$. We denote the zero vector by $\mathbf{0}$ and the identity matrix of order r by \mathbf{I}_r . We use the \rightsquigarrow notation to denote weak convergence. For a sequence a_n and positive sequence b_n , let $a_n = \mathcal{O}(b_n)$ mean that $|a_n| \leq Cb_n$ for some constant C > 0. For a sample space \mathfrak{X} , let $\mathfrak{M}(\mathfrak{X})$ stand for the space of all probability measures on \mathfrak{X} . The distributional law of a random element T will be denoted by $\mathcal{L}(T)$. The symbol P refers to a probability statement with respect to a generic probability distribution. Let δ_0 denote the Dirac delta measure at the point 0. We shall write Φ for the standard normal cumulative distribution function and $z_{\alpha} = \Phi^{-1}(1-\alpha)$ for the $(1-\alpha)$ -quantile of it.

The proposed immersion-posterior methodology for the variable selection problem differs from the classical

Bayesian approach of putting a prior taking sparsity into account and then updating to the posterior distribution that puts weights on different models corresponding to different sets of selected predictors. In the proposed approach, we put a conditionally conjugate normal prior on the parameter vector given, disregarding the issue of variable selection at first, and then a conjugate inverse gamma prior for σ^2 : Further, we put an inverse gamma prior for σ^2 , that is,

$$\boldsymbol{\theta} | \boldsymbol{\sigma} \sim \mathcal{N}_p(\boldsymbol{0}, \sigma^2 a_n^{-1} \boldsymbol{I}_p), \qquad \sigma^{-2} \sim \mathrm{Ga}(b_1, b_2)$$
(2.4)

for some sequence $a_n > 0$ and constants $b_1, b_2 > 0$. The non-informative choice $b_1 = b_2 = 0$, which corresponds to the density σ^{-1} for σ , may also be used. The choices of b_1 and b_2 will not matter for the intended asymptotic study in this paper.

This results in the "unrestricted" posterior distribution given by

$$\boldsymbol{\theta}|(\boldsymbol{Y},\sigma) \sim N_p((\boldsymbol{X}^{\mathrm{T}}\boldsymbol{X} + a_n\boldsymbol{I}_p)^{-1}\boldsymbol{X}^{\mathrm{T}}\boldsymbol{Y}, \sigma^2(\boldsymbol{X}^{\mathrm{T}}\boldsymbol{X} + a_n\boldsymbol{I}_p)^{-1}).$$
(2.5)

Further, the marginal posterior for σ is given by

$$\sigma^{-2} | \boldsymbol{Y} \sim \operatorname{Ga}\left(b_1 + \frac{n}{2}, b_2 + \frac{1}{2} \boldsymbol{Y}^{\mathrm{T}} (\boldsymbol{I}_n - \boldsymbol{X} (\boldsymbol{X}^{\mathrm{T}} \boldsymbol{X} + a_n \boldsymbol{I}_p)^{-1} \boldsymbol{X}^{\mathrm{T}}) \boldsymbol{Y}\right).$$
(2.6)

We denote the posterior mean $(\boldsymbol{X}^{\mathrm{T}}\boldsymbol{X} + a_n\boldsymbol{I}_p)^{-1}\boldsymbol{X}^{\mathrm{T}}\boldsymbol{Y}$ by $\hat{\boldsymbol{\theta}}^{\mathrm{R}}$ owing to its interpretation as the ridge-regression estimator. The posterior distribution will be denoted by $\Pi(\cdot|\boldsymbol{Y})$.

Note that the posterior distribution disregards variable selection because the prior does not introduce such a mechanism. The issue is then addressed by "correcting" the unrestricted posterior through an immersion map that transforms dense vectors into sparse vectors, in that the distribution induced by this map from the unrestricted posterior is used for inference. We choose the sparsity-inducing immersion map given by

$$\iota: \boldsymbol{\theta} \mapsto \boldsymbol{\theta}^* \coloneqq \operatorname*{arg\,min}_{\boldsymbol{u}} \{ n^{-1} \| \boldsymbol{X} \boldsymbol{\theta} - \boldsymbol{X} \boldsymbol{u} \|^2 + \lambda_n \| \boldsymbol{u} \|_1 \}.$$

$$(2.7)$$

We shall call the map ι the sparse-projection operator. It depends on the choice of the tuning parameter λ_n . The map is motivated by the LASSO in that if $\boldsymbol{\theta} = \hat{\boldsymbol{\theta}}$, the least square estimator, then $\boldsymbol{\theta}^*$ is the LASSO estimator

 $\hat{\theta}^{\mathrm{L}}$ defined by

$$\hat{\boldsymbol{\theta}}^{\mathrm{L}} = \underset{\boldsymbol{u}}{\operatorname{arg\,min}} \{ n^{-1} \| \boldsymbol{Y} - \boldsymbol{X} \boldsymbol{u} \|^{2} + \lambda_{n} \| \boldsymbol{u} \|_{1} \}$$
$$= \underset{\boldsymbol{u}}{\operatorname{arg\,min}} \{ n^{-1} \| \boldsymbol{X} \hat{\boldsymbol{\theta}} - \boldsymbol{X} \boldsymbol{u} \|^{2} + \lambda_{n} \| \boldsymbol{u} \|_{1} \}.$$
(2.8)

The distribution induced from the unrestricted posterior by the map ι is an immersion posterior distribution in the terminology of Wang and Ghosal [2023a]. In our context, it will be called the sparse-projection posterior distribution and will be denoted by $\Pi^*(\cdot|\mathbf{Y})$, that is, $\Pi^*(B|\mathbf{Y}) = \Pi(\boldsymbol{\theta}^* \in B|\mathbf{Y})$ for $B \subset \mathbb{R}^p$.

The immersion posterior is easy to compute by sampling. Having obtained a dense posterior sample θ from (2.5), we compute $\theta^* = \iota(\theta)$ and record that as a sample from the immersion posterior distribution. We repeat the operation independently sufficiently many times so that posterior probabilities and expectations can be reliably calculated from sampling. In particular, the method also computes model posterior probabilities. As the method does not use any Markov chain Monte Carlo (MCMC) method, it promises faster computation. The method is also amenable to parallelization since both $X^T X$ and $X^T Y$ can be computed by dividing the dataset into several parts and computing the sum of products at different machines, followed by an aggregation step at the central server. This feature is especially useful if the sample size is huge.

It may be noted that the immersion posterior method may also be used in conjugation with other sparsityinducing operators instead of (2.7). Other penalties that may be used to define an immersion posterior include those appearing in defining estimators alternative to the LASSO such as the Minimax Concave Penalty (MCP) [Zhang, 2010], the Smoothly Clipped Absolute Deviation (SCAD) [Fan and Li, 2001], the Dantzig selector [Candes and Tao, 2007], the adaptive LASSO [Zou, 2006], the non-negative garrotte estimator [Breiman, 1995, Yuan and Lin, 2007] among others. In the present paper, we forgo other possible penalty functions and study the asymptotic coverage posterior credible regions corresponding only to the immersion map (2.7).

3 Main Results

Let the predictor dimension p be fixed. We make the following assumptions:

Assumption 1 (Predictor). The matrix $C_n \to C$ for some positive definite matrix C and $n^{-1} \max\{||\mathbf{X}_i||^2 : i = 1, ..., n\} \to 0.$

Assumption 2 (Tuning). The tuning parameter λ_n satisfies $\lambda_n \sqrt{n} \to \lambda_0$ for some $\lambda_0 \ge 0$.

Under the above conditions, Fu and Knight [2000] showed that the LASSO estimator $\hat{\theta}^{L}$ is weakly consistent and

the limiting distribution of $\sqrt{n}(\hat{\theta}^{L} - \theta^{0})$ puts a positive probability at zero for the components corresponding to the irrelevant variables.

Theorem 1 (Fu and Knight [2000]). Let p be fixed, and Assumptions 1 and 2 hold. Then $\hat{\boldsymbol{\xi}}_n := \sqrt{n}(\hat{\boldsymbol{\theta}}^{\mathrm{L}} - \boldsymbol{\theta}^0) \rightsquigarrow \boldsymbol{\xi}$, where

$$\boldsymbol{\xi} = \underset{\boldsymbol{v} \in \mathbb{R}^{p}}{\operatorname{arg\,min}} \{ \boldsymbol{v}^{\mathrm{T}} \boldsymbol{C} \boldsymbol{v} - 2\sigma_{0} \boldsymbol{v}^{\mathrm{T}} \boldsymbol{C}^{1/2} \boldsymbol{\Delta} + \lambda_{0} \big[\sum_{j=1}^{s_{0}} v_{j} \operatorname{sign}(\theta_{j}^{0}) + \sum_{j=s_{0}+1}^{p} |v_{j}| \big] \},$$
(3.1)

with $\boldsymbol{\Delta} \sim N_p(\boldsymbol{0}, \boldsymbol{I}_p)$.

It also follows that under the stated conditions, the variance estimator $\hat{\sigma}^2 = n^{-1} \| \mathbf{Y} - \mathbf{X} \hat{\theta} \|^2$ is \sqrt{n} -consistent for σ^2 , where $\hat{\theta}$ is the least square estimator or a ridge-regression estimator $\hat{\theta}^{\mathrm{R}}$; see Remark 3. Assumption 1 holds with probability tending to one for random predictors if the values are sampled independently from a fixed nonsingular distribution. The second part of the assumption clearly holds if the predictors are uniformly bounded, a restriction often imposed by scaling.

Under the same condition on the tuning parameter $\lambda_n \sqrt{n} \to \lambda_0$ for some constant $\lambda_0 \ge 0$, and assuming that $a_n/\sqrt{n} \to 0$, we obtain below a joint weak limit of the posterior distribution of $\sqrt{n}(\theta^* - \theta^0)$ given the data in the space $\mathfrak{M}(\mathbb{R}^p)$, equipped with the topology of weak convergence, and the distribution of the normalized LASSO estimator in \mathbb{R}^p .

Theorem 2. Let Conditions 1 and 2 hold, and $a_n/\sqrt{n} \to 0$. Then

$$\left(\Pi(\sqrt{n}(\boldsymbol{\theta}^* - \boldsymbol{\theta}^0) \in \cdot | \boldsymbol{Y}), \sqrt{n}(\hat{\boldsymbol{\theta}}^{\mathrm{L}} - \boldsymbol{\theta}^0)\right) \rightsquigarrow \left(\mathcal{L}(\boldsymbol{T}^* \in \cdot | \boldsymbol{\Delta}), \boldsymbol{\xi}\right)$$
(3.2)

on the product space $\mathfrak{M}(\mathbb{R}^p) \times \mathbb{R}^p$, where

$$\boldsymbol{T}^* = \underset{\boldsymbol{t}\in\mathbb{R}^p}{\operatorname{arg\,min}} \{\boldsymbol{t}^{\mathrm{T}}\boldsymbol{C}\boldsymbol{t} - 2\boldsymbol{t}^{\mathrm{T}}\boldsymbol{C}\boldsymbol{W}^* + \lambda_0 \big[\sum_{j=1}^{s_0} t_j \operatorname{sign}(\theta_j^0) + \sum_{j=s_0+1}^p |t_j|\big]\},\tag{3.3}$$

for $W^* | \Delta \sim N(\sigma_0 C^{-1/2} \Delta, \sigma_0^2 C^{-1})$ and $\boldsymbol{\xi}$ is defined in (3.1).

As shifting the random distribution by $\hat{\xi}_n = \sqrt{n}(\hat{\theta}_n - \theta^0)$ is a continuous operation in $\mathfrak{M}(\mathbb{R}^p)$, we conclude the following.

Corollary 1. Under the conditions of Theorem 2,

$$\left(\Pi(\sqrt{n}(\boldsymbol{\theta}^* - \hat{\boldsymbol{\theta}}^{\mathrm{L}}) \in \cdot | \boldsymbol{Y}), \sqrt{n}(\hat{\boldsymbol{\theta}}^{\mathrm{L}} - \boldsymbol{\theta}^{0})\right) \rightsquigarrow \left(\mathcal{L}(\boldsymbol{T}^* - \boldsymbol{\xi} \in \cdot | \boldsymbol{\Delta}), \boldsymbol{\xi}\right).$$
(3.4)

We show in Lemma 3 that when $\theta_j^0 = 0$ for all $j = s_0 + 1, ..., p$, the minimizer T^* assumes the value 0 for its last $p - s_0$ components with positive probability. The distribution has no closed-form expression except for some special cases, and the statement is only marginally useful. However, we can compute the limiting frequentist coverage of a Bayesian credible region defined by the quantiles of the posterior distribution of $\sqrt{n}(\theta^* - \theta^0)$, which can be obtained from Theorem 2.

For $\bar{\boldsymbol{\theta}} \in \mathbb{R}^p$ and r > 0, let

$$B_{\mathcal{K}}(\bar{\boldsymbol{\theta}}, r) = \{\boldsymbol{\theta} : \|\sqrt{n}(\boldsymbol{\theta} - \bar{\boldsymbol{\theta}})\|_{\mathcal{K}} \le r\},\tag{3.5}$$

where the seminorm $\|\cdot\|_{\mathcal{K}}$ is defined by

$$\|\boldsymbol{x}\|_{\mathcal{K}} = \inf\{\lambda > 0 : \boldsymbol{x}/\lambda \in \mathcal{K}\},\tag{3.6}$$

the Minkowski functional of a convex set \mathcal{K} containing 0 in its interior. Define a $(1 - \alpha)$ -credible set to be $B_{\mathcal{K}}(\hat{\theta}^{\mathrm{L}}, r_{1-\alpha})$, where $r_{1-\alpha}$ is the $(1 - \alpha)$ -quantile of the posterior distribution of $\|\sqrt{n}(\theta^* - \hat{\theta}^{\mathrm{L}})\|_{\mathcal{K}}$, that is

$$\Pi^*(B_{\mathcal{K}}(\hat{\boldsymbol{\theta}}^{\mathrm{L}}, r_{1-\alpha})|\boldsymbol{Y}) = \Pi(\boldsymbol{\theta}^* : \|\sqrt{n}(\boldsymbol{\theta}^* - \hat{\boldsymbol{\theta}}^{\mathrm{L}})\|_{\mathcal{K}} \le r_{1-\alpha}|\boldsymbol{Y}) = 1 - \alpha.$$
(3.7)

If the equality cannot be obtained, we choose $r_{1-\alpha}$ the infimum of all r > 0 such that $\Pi^*(B_{\mathcal{K}}(\hat{\theta}^L, r)|Y) > 1-\alpha$. For different choices of \mathcal{K} , we can have coverage results for different norms or pseudo-norms. For example, choosing $\mathcal{K} = [-1, 1]^p$, we get the max norm $\|\cdot\|_{\infty}$, choosing \mathcal{K} as a unit sphere, we get the unit norm $\|\cdot\|_2$, choosing \mathcal{K} as a unit diamond, we get the ℓ_1 -norm $\|\cdot\|_1$, and choosing $\mathcal{K} = \mathbb{R} \times \cdots \times \mathbb{R} \times [-1, 1] \times \mathbb{R} \times \cdots \times \mathbb{R}$, we get credible intervals for individual components.

Theorem 3. For a given level of confidence $(1 - \alpha)$ and $\Delta \sim N_p(\mathbf{0}, \mathbf{I}_p)$, we have under Assumptions 1 and 2

and $a_n/\sqrt{n} \to 0$,

$$P\left(P(\|\boldsymbol{T}^{*} - \boldsymbol{\xi}\|_{\mathcal{K}} \leq \|\boldsymbol{\xi}\|_{\mathcal{K}} | \boldsymbol{\Delta}) < 1 - \alpha\right)$$

$$\leq \liminf_{n \to \infty} \mathbb{P}_{0}\left(\boldsymbol{\theta}^{0} \in B_{\mathcal{K}}(\hat{\boldsymbol{\theta}}^{\mathrm{L}}, r_{1-\alpha})\right)$$

$$\leq \limsup_{n \to \infty} \mathbb{P}_{0}\left(\boldsymbol{\theta}^{0} \in B_{\mathcal{K}}(\hat{\boldsymbol{\theta}}^{\mathrm{L}}, r_{1-\alpha})\right)$$

$$\leq P\left(P(\|\boldsymbol{T}^{*} - \boldsymbol{\xi}\|_{\mathcal{K}} \leq \|\boldsymbol{\xi}\|_{\mathcal{K}} | \boldsymbol{\Delta}) \leq 1 - \alpha\right), \qquad (3.8)$$

where T^* and $\boldsymbol{\xi}$ are as in Theorem 2.

The limiting coverage of a sparse-projection posterior credible region is thus assured to be at least the probability on the right side, but it may not equal the credibility level $1 - \alpha$. The limiting coverage depends on C, σ_0 , λ_0 and α . In the following subsection, we evaluate the limiting coverage explicitly for a credible interval for a component under an asymptotic orthogonality setting.

3.1 Special Case: Asymptotically Uncorrelated Predictor

We now explicitly evaluate the limiting coverage of a credible interval of a single regression coefficient θ_j , assuming that the *j*th predictor is asymptotically uncorrelated with the rest, for some $j = 1, \ldots, p$.

Assumption 3 (Asymptotically uncorrelated predictor). The *j*th predictor variable X_j is asymptotically uncorrelated with the remaining predictors $\{X_1, \ldots, X_{j-1}, X_{j+1}, \ldots, X_p\}$, that is, $C = \lim_{n \to \infty} n^{-1} \mathbf{X}^T \mathbf{X}$ is blockdiagonal with blocks $\{j\}$ and $[-j] := \{1, \ldots, j-1, j+1, \ldots, p\}$.

Let c_j stand for the *j*th diagonal entry of C. Note that, under the above assumption, all other entries of the *j*th row and *j*th column of C are 0.

Although the assumption of asymptotic uncorrelatedness is very special, it may naturally hold for predictors not related to other predictors. Moreover, the condition can be enforced by an orthogonalization technique, but it then changes the meaning of the coefficient.

Consider the credible interval $[\hat{\theta}_j^{\mathrm{L}} - r_{1-\alpha,j}, \hat{\theta}_j^{\mathrm{L}} + r_{1-\alpha,j}]$, where $\hat{\theta}_j^{\mathrm{L}}$ is the *j*th coordinate of the LASSO estimator $\hat{\theta}^{\mathrm{L}}$ and $r_{1-\alpha,j}$ is the $(1-\alpha)$ -quantile of the induced posterior distribution of $|\theta_j^* - \hat{\theta}_j^{\mathrm{L}}|$. This credible interval corresponds to the credible region in (3.5) with $\mathcal{K} = \mathbb{R} \times \cdots \times \mathbb{R} \times [-1, 1] \times \mathbb{R} \times \cdots \times \mathbb{R}$, where [-1, 1] appears

at the *j*th coordinate. Under Assumption 3, it follows from (3.1) that the *j*th component ξ_j of $\boldsymbol{\xi}$ is given by

$$\xi_{j} = \operatorname{argmin}\{c_{j}v_{j}^{2} - 2\sigma_{0}\sqrt{c_{j}}\Delta_{j}v_{j} + \lambda_{0}[v_{j}\operatorname{sign}(\theta_{j}^{0}) + |v_{j}|\mathbb{1}(\theta_{j} = 0)] : v_{j} \in \mathbb{R}\}$$

$$= \begin{cases} \frac{\sigma_{0}}{\sqrt{c_{j}}}\Delta_{j} - \frac{\lambda_{0}}{2c_{j}}, & \text{if } \theta_{j}^{0} > 0, \\ \frac{\sigma_{0}}{\sqrt{c_{j}}}\Delta_{j} + \frac{\lambda_{0}}{2c_{j}}, & \text{if } \theta_{j}^{0} < 0, \\ (\frac{\sigma_{0}}{\sqrt{c_{j}}}\Delta_{j} - \frac{\lambda_{0}}{2c_{j}})\mathbb{1}\{\Delta_{j} > \frac{\lambda_{0}}{2\sigma_{0}\sqrt{c_{j}}}\} \\ + (\frac{\sigma_{0}}{\sqrt{c_{j}}}\Delta_{j} + \frac{\lambda_{0}}{2c_{j}})\mathbb{1}\{\Delta_{j} < -\frac{\lambda_{0}}{2\sigma_{0}\sqrt{c_{j}}}\}, & \text{if } \theta_{j}^{0} = 0. \end{cases}$$

$$(3.9)$$

Thus, ξ_j depends on Δ only through its j component Δ_j and is independent of the remaining components. Similarly, from (3.3), it follows that the *j*th coordinate T_j^* of T^* is given by

$$T_{j}^{*} = \operatorname{argmin}\{c_{j}t_{j}^{2} - 2c_{j}W_{j}^{*}t_{j} + \lambda_{0}[t_{j}\operatorname{sign}(\theta_{j}^{0}) + |t_{j}|\mathbb{1}(\theta_{j} = 0)] : t_{j} \in \mathbb{R}\}$$

$$= \begin{cases} W_{j}^{*} - \frac{\lambda_{0}}{2c_{j}}, & \text{if } \theta_{j}^{0} > 0, \\ W_{j}^{*} + \frac{\lambda_{0}}{2c_{j}}, & \text{if } \theta_{j}^{0} < 0, \\ (W_{j}^{*} - \frac{\lambda_{0}}{2c_{j}})\mathbb{1}\{W_{j}^{*} > \frac{\lambda_{0}}{2c_{j}}\} \\ + (W_{j}^{*} + \frac{\lambda_{0}}{2c_{j}})\mathbb{1}\{W_{j}^{*} < -\frac{\lambda_{0}}{2c_{j}}\}, & \text{if } \theta_{j}^{0} = 0, \end{cases}$$

$$(3.10)$$

where W_j^* is the *j*th component of \boldsymbol{W}^* , and that $W_j^* | \Delta_j \sim \mathcal{N}(\Delta_j, 1)$.

We then introduce the notations

$$h_{+}(\lambda_{0},\zeta) = 2\Phi(|\zeta - \lambda_{0}/2|) - 1,$$

$$h_{-}(\lambda_{0},\zeta) = 2\Phi(|\zeta + \lambda_{0}/2|) - 1 = h_{+}(\lambda_{0}, -\zeta),$$

$$h_{0}(\lambda_{0},\zeta) = \begin{cases} \Phi(\zeta - \lambda_{0}/2) - \Phi(-\zeta - \lambda_{0}/2), & \text{if } \zeta > \lambda_{0}/2, \\ \Phi(-\zeta + \lambda_{0}/2) - \Phi(\zeta + \lambda_{0}/2), & \text{if } \zeta < \lambda_{0}/2, \\ \Phi(\zeta + \lambda_{0}/2) - \Phi(\zeta - \lambda_{0}/2), & \text{if } |\zeta| \le \lambda_{0}/2. \end{cases}$$
(3.11)

and

$$\psi(\alpha, \lambda_0) = \Phi(\lambda_0/2 + z_{\alpha/2}) - \Phi(\lambda_0/2 - z_{\alpha/2}), \tag{3.12}$$

$$\psi_0(\alpha,\lambda_0) = \int_{-\infty}^{\infty} \mathbb{1}\big(h_0(\lambda_0,\zeta) \le 1-\alpha\big)\phi(\zeta)d\zeta.$$
(3.13)

The asymptotic coverage of the credible interval $[\hat{\theta}_j^{L} - r_{1-\alpha,j}, \hat{\theta}_j^{L} + r_{1-\alpha,j}]$ for θ_j is characterized in the following theorem.

Theorem 4. If Assumptions 1, 2 and 3 hold and $a_n/\sqrt{n} \to 0$, then for a given level of confidence $0 < 1 - \alpha < 1$,

$$\mathbb{P}_{0}\left(\theta_{0j} \in [\hat{\theta}_{j}^{\mathrm{L}} - r_{1-\alpha,j}, \hat{\theta}_{j}^{\mathrm{L}} + r_{1-\alpha,j}]\right) \to \begin{cases} \psi(\alpha, \lambda_{0}\sqrt{c_{j}}/\sigma_{0}), & \text{if } \theta_{j} \neq 0, \\ \psi_{0}(\alpha, \lambda_{0}\sqrt{c_{j}}/\sigma_{0}), & \text{if } \theta_{j} = 0. \end{cases}$$
(3.14)

Remark 1. The original data generating process

$$Y_i = \sum_{k=1}^p X_{ik}\theta_k + \varepsilon_i = X_{ij}\theta_j + \sum_{k=1:k\neq j}^p X_{ik}\theta_k + \varepsilon_i$$

can be rewritten as

$$\tilde{Y}_{i} = \tilde{X}_{ij}\tilde{\theta}_{0j} + \sum_{k=1:k\neq j}^{p} X_{ik}\frac{\theta_{0k}}{\sigma_{0}} + \tilde{\varepsilon}_{i}, \qquad (3.15)$$

where $\tilde{Y}_i = Y_i/\sigma_0$, $\tilde{X}_{ij} = x_{ij}/\sqrt{c_j}$, $\tilde{\varepsilon}_i = \varepsilon_i/\sigma_0$ and $\tilde{\theta}_j^0 = \theta_j^0\sqrt{c_j}/\sigma_0$. For the transformed process, the *j*th predictor \tilde{X}_j still remains asymptotically uncorrelated with the remaining predictors, and the corresponding *C*-matrix has the *j*th diagonal entry 1. The true error variance also reduces to 1. Thus, the asymptotic coverage for the credible interval for θ_j using the penalty parameter λ_0 coincides with that for $\tilde{\theta}_j = \theta_j \sigma_0/\sqrt{c_j}$ using the penalty parameter $\lambda_0 \sqrt{c_j}/\sigma_0$. Hence, to prove Theorem 4, we can assume, without loss of generality, that $c_j = 1$ and $\sigma_0 = 1$.

Below, in Figure 1, we provide the plots of $h_+(\lambda_0, \zeta)$ and $h_0(\lambda_0, \zeta)$ against ζ for different choices of the limiting penalty λ_0 as well as the limiting coverage probabilities against the confidence level for the signal and noise components. Since $\psi(\alpha, \lambda_0) \leq 1 - \alpha$ with equality holding only for $\lambda_0 = 0$, for the signal components, no non-zero value of the penalty parameter λ_0 can lead to the exact $(1 - \alpha)$ asymptotic coverage, or more, of a $(1 - \alpha)$ sparse-projection posterior credible interval. However, by fixing a penalty parameter λ_0 , we can ensure that for some γ depending on λ_0 and α , a $(1 - \gamma)$ credible interval will have exactly $(1 - \alpha)$ asymptotic coverage if $\theta_j^0 \neq 0$. Moreover, in Figure 2, the function $\psi(\alpha, \lambda_0)$ is shown to be uniformly bounded above by $\psi_0(\alpha, \lambda_0)$ for a given α , meaning that the limiting coverage of a noise component will always be higher than that of a signal component. Thus, owing to the fact that $\psi_0(\alpha, \lambda_0) \geq \psi(\alpha, \lambda_0)$, as shown by numerical evaluation in Figure 2, it follows that the asymptotic coverage of the corresponding interval is at least $(1 - \alpha)$.

Based on the above discussion and the figures displayed above, we provide a guideline for choosing the confidence

Figure 1: The upper panel shows the graph of $h_+(\lambda_0, \zeta)$ for the positive coefficients (left), and that of $h(\lambda_0, \zeta)$ for the zero-valued components (right) as a function of ζ for various values of λ_0 . The lower panel shows coverage as a function of the credibility level for non-zero (left) and zero (right) components for various values λ_0 . The black diagonal line corresponds to the exact coverage.

Figure 2: Plot of coverage probabilities against λ for positive components (*dashed lines*) and zero components (*solid lines*) for a few interesting values of $1 - \alpha$.

level for a wide range of coverage requirements. In Table 1, we give the value of γ that attains the limiting coverage $1 - \alpha$ for any penalty parameter between 0.05 to 4. For any value of the penalty parameter not listed in Table 1, the solve_gamma function in the credInt R package [Pal, 2024] may be used. Moreover, from the plot of $\psi_0(\alpha, \lambda)$ in Figure 1, we can ensure higher than $(1 - \alpha)$ -coverage for the zero components for the chosen $(1 - \gamma)$ level credible intervals. Thus, choosing γ according to the table attains the limiting coverage exactly $1 - \alpha$ for a non-zero parameter value and at least $1 - \alpha$ for a zero value of the parameter.

Table 1: Calibration table for credibility level for an intended asymptotic coverage.

Remark 2. The component-wise credible intervals can be further used to get joint credible hyper-rectangle.

Fix $k \leq p$ components. Suppose we want a $1-\beta$ credible region for those k components. Then, we first build the individual $1-\alpha$ credible intervals for each of those k chosen components using the sparse-projection posterior method with the corresponding credibility levels calculated from Table 1. Using the asymptotic independence resulting from the diagonal nature of the limiting covariance matrix, the asymptotic coverage of the joint k-dimensional hyper-rectangle thus formed is $(1-\alpha)^k$. Consequently, choosing $1-\alpha = (1-\beta)^{1/k}$, the targeted asymptotic coverage $1-\beta$ for the joint credible region can be achieved.

4 Numerical Results

We conduct a small-scale simulation to capture the performance of the credible sets obtained by projecting the conjugate posterior samples to the sparse subspace. We study several scenarios and report a complete numerical performance encompassing the dimension, the sparsity, and the signal strength of the underlying model. First, fixing the true sparsity at s = 5 and dimension at p = 20, we first generate data using an independent design matrix and signal strength (-2, -1.5, 0.5, 1, 2). We repeat this study with a correlated design matrix where an autoregressive process with a correlation of 0.7 has been used. We study the coverage and length of the $(1-\gamma)$ credible intervals of the 5 signals and 5 randomly chosen noise variables. Here, γ is chosen in accordance with Table 1 to achieve our target coverage of 0.95. We will need the value of the penalty parameter used in the projection map to use the calibration information in Table 1. To specifically know what γ value returns the credible intervals with exact $(1 - \alpha)$ coverage, the solve_gamma function within the credInt R package [Pal, 2024] can be used. For all the simulations, we implement the LASSO regression of Y on X and use the cross-validated penalty parameter in all the R = 5000 posterior maps. These cases are observed under three sample sizes, n = 500, 1000, and 5000. The credInt function returns the $(1 - \gamma)$ credible intervals for all the regression coefficients. We repeat the simulations 200 times and report the average coverage values. The goal is to see if the coverage of the component-wise credible intervals increases and attains the desired level with the increase in sample size.

Besides this, we study the impact of sparsity on coverage for different significance levels. We vary s_0 from 5 to 30 and consider three levels, 90%, 95%, and 99%, to see how coverage changes as sparsity increases and whether the results improve when the sample size increases from 500 to 1000. Note that the design matrix in this case is independent, and the error is normally distributed with error variance 1.

Table 2 provides the coverage and lengths of the component-wise intervals for the cases $(p = 20 \text{ and } \theta_{S_0}^0 = (-2, -1.5, 0.5, 1, 1.5))$ under the two setups, namely, independent design and correlated design. We observe that in both cases, there is a general pattern that coverage increases with an increase in sample size and almost attains the desired level, which is 95% in this case. The numerical results thus align with the theoretical

Design	Model		S_1	S_2	S_3	S_4	S_5	N_1	N_2	N_3	N_4	N_5

Table 2: Coverage and length of $(1 - \gamma)$ credible interval of 5 signals and randomly chosen 5 noise variables studied over 3 sample sizes, under the independent and correlated design settings with target coverage 0.95.

findings and provide enough support that the projection method leads to almost accurate asymptotic coverage. It is noteworthy that although the theoretical results for this method have only been proven under a limiting independence condition on the covariates, the method is capable of performing well even when some correlation is present between the explanatory variables in the model.

Figure 3, on the other hand, depicts the coverage property as the model becomes sparser. We see the general tendency is that the coverage slightly degrades as the number of truly active predictors decreases. However, the solid line (showing the coverage for n = 1000) stays uniformly above the dashed line (showing coverage for n = 500) for all three significance levels. This guarantees that the asymptotic full coverage will hold as the sample size grows. Moreover, the sparse projection-posterior method is much more flexible in terms of coverage as the choice of the λ_0 values is user-dependent.

Next, in Figures 4 and 5, we compare the average signal and noise coverage and length of credible intervals for the Bayesian methods of Bayesian LASSO, Horseshoe, and the proposed sparse projection-posterior method, along with the frequentist method of Bootstrap LASSO. We repeat the study for three levels of significance $1 - \alpha = 0.9, 0.95, 0.99$, and for two dimensions p = 50, 100. We observe whether there is any change in the coverage over three sample sizes n = 500, 1000, 5000, keeping the sparsity and the signal intensity fixed at s = 20and $\beta_j^0 = 1.5$, $j = 1, 2, \ldots, s$, respectively. Again, all the projections computed used the LASSO cross-validated penalty parameter. We drew R = 5000 posterior samples. The corresponding γ was chosen from Table 1. Although the Bayesian LASSO does well in covering the true parameter values for low dimensions, there are two more aspects to consider. Firstly, the Bayesian LASSO does not have a model selection ability and always returns the full feature space. This causes a problem in identifying weaker signals. Secondly, the method is computationally infeasible when the dimension exceeds 100. On the other hand, the horseshoe method provides over-coverage for any choice of $1 - \alpha$ at the high cost of yielding very long credible intervals. Accounting for

Coverage Probability across varying sparsity

Figure 3: The average signal coverage of τ -credible regions for three different levels $\tau = 0.9, 0.95, 0.99$ (averaged over the *s* signals) are plotted against the degree of sparsity s = 30, 25, 20, 15, 10, 5 with two choices of the sample size n = 500, 1000. The signal strength in all cases was $\theta_j^0 = 1$ for all $j \in S = \{1, \ldots, s\}$ and the results are based on 200 replications.

Figure 4: Comparison of Horseshoe, Bayesian LASSO, Bootstrap LASSO average signal (*upper panel*) and noise (*lower panel*) coverage with dimension p = 50, sparsity s = 20 and signal intensity $\beta_j^0 = 1.5$ for all j = 1, 2, ..., s, corresponding to three sample sizes, n = 500, 1000 and 2000.

Figure 5: Comparison of Horseshoe, Bayesian LASSO, Bootstrap LASSO average signal (*upper panel*) and noise (*lower panel*) coverage with dimension p = 100, sparsity s = 20 and signal intensity $\beta_j^0 = 1.5$ for all $j = 1, 2, \ldots, s$, corresponding to three sample sizes, n = 500, 1000 and 2000.

these drawbacks, the sparse projection-posterior method is the only Bayesian method capable of providing exact coverage with reasonable lengths and comparable to the bootstrap LASSO technique of Chatterjee and Lahiri [2011]. Its coverage is sometimes even better than the bootstrap LASSO method, especially for larger sample sizes. Moreover, the bootstrap LASSO often fails to cover the noise variables, but the sparse-projection posterior method successfully provides coverage. As predicted by the theory, the cost is a slightly elongated interval.

5 Conclusion

This study shows that the proposed Bayesian technique of projecting a dense conjugate posterior sample to a sparser domain performs well, offering adequate coverage by a modified credible under the fixed-dimensional setting. The method's ability to achieve reliable and consistent coverage holds promising implications for applications in various fields, as it successfully overcomes the drawbacks of existing methodologies to quantify the associated uncertainties in sparse regression. This technique may be extended to address the high dimensional setting and correlated predictors, and the method's robustness under different data distributions may be explored.

Appendix: Proofs

Lemma 1. Under Assumptions 1 and 2, and $a_n/\sqrt{n} \to 0$, we have that $\sqrt{n}(\hat{\theta}^{\mathrm{R}} - \theta^0) \rightsquigarrow \mathrm{N}_p(\mathbf{0}, \sigma_0^2 \mathbf{C}^{-1})$.

Proof. If ε is normally distributed, representing

$$\hat{\boldsymbol{\theta}}^{\mathrm{R}} = (\boldsymbol{X}^{\mathrm{T}}\boldsymbol{X} + a_n \boldsymbol{I}_p)^{-1} \boldsymbol{X}^{\mathrm{T}} \boldsymbol{X} \boldsymbol{\theta}^0 + (\boldsymbol{X}^{\mathrm{T}} \boldsymbol{X} + a_n \boldsymbol{I}_p)^{-1} \boldsymbol{X}^{\mathrm{T}} \boldsymbol{\varepsilon},$$

we observe that $\hat{\theta}^{\mathrm{R}}$ is also normally distributed and hence it suffices to show that

$$\begin{split} \sqrt{n}(\mathbb{E}_0(\hat{\boldsymbol{\theta}}^{\mathrm{R}}) - \boldsymbol{\theta}^0) &= \sqrt{n}((\boldsymbol{X}^{\mathrm{T}}\boldsymbol{X} + a_n\boldsymbol{I}_p)^{-1}\boldsymbol{X}^{\mathrm{T}}\boldsymbol{X}\boldsymbol{\theta}^0 - \boldsymbol{\theta}^0) \to \boldsymbol{0},\\ n\mathbb{E}_0[(\hat{\boldsymbol{\theta}}^{\mathrm{R}} - \boldsymbol{\theta}^0)(\hat{\boldsymbol{\theta}}^{\mathrm{R}} - \boldsymbol{\theta}^0)^{\mathrm{T}}] &= n\sigma_0^2(\boldsymbol{X}^{\mathrm{T}}\boldsymbol{X} + a_n\boldsymbol{I}_p)^{-1}\boldsymbol{X}^{\mathrm{T}}\boldsymbol{X}(\boldsymbol{X}^{\mathrm{T}}\boldsymbol{X} + a_n\boldsymbol{I}_p)^{-1}\\ &\to \sigma_0^2\boldsymbol{C}^{-1}. \end{split}$$

Since $n^{-1}X^{\mathrm{T}}X \to C$ and $a_n/\sqrt{n} \to 0$, we have $(X^{\mathrm{T}}X + a_nI_p)^{-1}X^{\mathrm{T}}X = I_p + o(n^{-1/2})$; here and elsewhere $o(n^{-1/2})$ stands for a $p \times p$ -matrix with all entries $o(n^{-1/2})$. The first relation now follows. The second relation holds even under the weaker condition $a_n/n \to 0$.

In general, when ε may not be normal, we verify, for any fixed non-zero linear combination $\boldsymbol{b}^{\mathrm{T}}\hat{\boldsymbol{\theta}}$, Lindeberg's condition for the central limit theorem. The condition reduces to $(\max_{1 \le i \le n} |\boldsymbol{b}^{\mathrm{T}}\boldsymbol{X}_i|^2) / \sum_{i=1}^n |\boldsymbol{b}^{\mathrm{T}}\boldsymbol{X}_i|^2 \to 0$, owing to the identical distribution of the error variables, invoke the Cramér-Wold device. Since

$$\max_{1 \le i \le n} n^{-1} |\boldsymbol{b}^{\mathrm{T}} \boldsymbol{X}_{i}|^{2} \le \|\boldsymbol{b}\|^{2} \max_{1 \le i \le n} n^{-1} |\boldsymbol{X}_{i}\|^{2} \to 0, \ n^{-1} \sum_{i=1}^{n} |\boldsymbol{b}^{\mathrm{T}} \boldsymbol{X}_{i}|^{2} \to \boldsymbol{b}^{\mathrm{T}} \boldsymbol{C} \boldsymbol{b} > 0$$

by Assumption 1, Lindeberg's condition is verified. As

$$\operatorname{Cov}(n^{-1/2}\sum_{i=1}^{n} x_{ij}\varepsilon_i, n^{-1/2}\sum_{i=1}^{n} x_{ik}\varepsilon_i) = n^{-1}\sigma_0^2\sum_{i=1}^{n} x_{ij}x_{ik} \to \sigma_0^2 c_{jk},$$

the multivariate central limit theorem applies to $(n^{-1/2}\sum_{i=1}^n x_{ij}\varepsilon_i: 1 \le j \le p)$ with mean the zero vector and the dispersion matrix $\sigma_0^2 C$. Hence it follows that $(\mathbf{X}^T \mathbf{X} + a_n \mathbf{I}_p)^{-1} \mathbf{X}^T \boldsymbol{\varepsilon} \rightsquigarrow N_p(\mathbf{0}, \sigma_0^2 \mathbf{C}^{-1})$.

Lemma 2. Under Assumptions 1 and 2, and $a_n/\sqrt{n} \to 0$, the posterior distribution of σ contracts at σ_0 at the rate $n^{-1/2}$, that is, for any $M_n \to \infty$

$$\mathbb{E}_0 \Pi(|\sigma - \sigma_0| > M_n n^{-1/2} | \mathbf{Y}) \to 0.$$

$$(.1)$$

Proof. It suffices to prove that the posterior for $\tau = \sigma^{-2}$ concentrates in $n^{-1/2}$ -sized neighborhoods of $\tau_0 = \sigma_0^{-2}$, which we verify from (2.6) using Chebyshev's inequality. We show that $\mathbb{E}(\tau | \mathbf{Y}) = \tau_0 + O_p(n^{-1/2})$ and $\operatorname{Var}(\tau | \mathbf{Y}) = O_p(n^{-1})$. Let $\boldsymbol{\delta}_n = n^{-1} \mathbf{X}^{\mathrm{T}} \boldsymbol{\epsilon}$. Then, we can write $(b_1 + n/2) [\mathbb{E}(\tau | \mathbf{Y})]^{-1} / (n/2) - 2b_2 / n$ as

$$(\boldsymbol{\theta}^0)^{\mathrm{T}} \boldsymbol{C}_n \boldsymbol{\theta}^0 + 2\boldsymbol{\delta}_n^{\mathrm{T}} \boldsymbol{\theta}^0 + \|\boldsymbol{\varepsilon}\|^2 / n - (\boldsymbol{C}_n \boldsymbol{\theta}^0 + \boldsymbol{\delta}_n)^{\mathrm{T}} (\boldsymbol{C}_n + n^{-1} a_n \boldsymbol{I}_p)^{-1} (\boldsymbol{C}_n \boldsymbol{\theta}^0 + \boldsymbol{\delta}_n).$$

This reduces to

$$\begin{aligned} \sigma_0^2 + O_p(n^{-1/2}) - (\boldsymbol{\theta}^0)^{\mathrm{T}} (\boldsymbol{C}_n + o(n^{-1/2})) \boldsymbol{\theta}^0 \\ &- 2\boldsymbol{\delta}_n^{\mathrm{T}} (\boldsymbol{I}_p + o(n^{-1/2})) \boldsymbol{\theta}^0 - \boldsymbol{\delta}_n^{\mathrm{T}} (\boldsymbol{C}^{-1} + o(n^{-1/2})) \boldsymbol{\delta}_n, \end{aligned}$$

which is $\sigma_0^2 + O_p(n^{-1/2})$. This implies the first assertion.

The second assertion follows because $\mathbf{Y}^{\mathrm{T}}[\mathbf{I}_n - \mathbf{X}(\mathbf{X}^{\mathrm{T}}\mathbf{X} + a_n\mathbf{I}_p)^{-1}\mathbf{X}]\mathbf{Y}$ grows at the rate n in \mathbb{P}_0 -probability. \Box

Remark 3. It is well-known that the least square estimator $\hat{\boldsymbol{\theta}}$ is \sqrt{n} -consistent for $\boldsymbol{\theta}$, and the variance estimator $\hat{\sigma}^2 = n^{-1} \|\boldsymbol{Y} - \boldsymbol{X}\hat{\boldsymbol{\theta}}\|^2$ is \sqrt{n} -consistent for σ^2 . We can write $\hat{\boldsymbol{\theta}}^{\mathrm{R}} = (\boldsymbol{C}_n + n^{-1}a_n\boldsymbol{I}_p)^{-1}\boldsymbol{C}_n\hat{\boldsymbol{\theta}} = (\boldsymbol{I}_p + \boldsymbol{o}(n^{-1/2}))\hat{\boldsymbol{\theta}}$. Hence $\|\hat{\boldsymbol{\theta}}^{\mathrm{R}} - \hat{\boldsymbol{\theta}}\| = o_p(n^{-1/2})$, and in particular, $\hat{\boldsymbol{\theta}}^{\mathrm{R}}$ is \sqrt{n} -consistent for $\boldsymbol{\theta}$. Then it follows from the Cauchy-Schwarz inequality and Assumption 1 that

$$n^{-1} \| \boldsymbol{Y} - \boldsymbol{X} \hat{\boldsymbol{\theta}}^{\mathrm{R}} \|^{2} = n^{-1} [\| \boldsymbol{Y} - \boldsymbol{X} \hat{\boldsymbol{\theta}} \|^{2} - 2(\boldsymbol{Y} - \boldsymbol{X} \hat{\boldsymbol{\theta}})^{\mathrm{T}} \boldsymbol{X} (\hat{\boldsymbol{\theta}}^{\mathrm{R}} - \hat{\boldsymbol{\theta}}) + \| \boldsymbol{X} (\hat{\boldsymbol{\theta}}^{\mathrm{R}} - \hat{\boldsymbol{\theta}}) \|^{2}]$$

is also \sqrt{n} -consistent for σ^2 .

Lemma 3. Suppose $\theta_j^0 = 0$ for $j = s_0 + 1, \dots, p$. Then for any Δ , almost surely

$$P(\boldsymbol{T}_{S_0^c}^* = \boldsymbol{0}_{S_0^c}) | \Delta) > 0.$$

Proof. The minimizer of (2) can be expressed as $T^* = \begin{vmatrix} T^*_{S_0} \\ T^*_{S_0^*} \end{vmatrix}$. Write

$$oldsymbol{C} = egin{bmatrix} oldsymbol{C}_{11} & oldsymbol{C}_{12} \ oldsymbol{C}_{21} & oldsymbol{C}_{22} \end{bmatrix} ext{ and } oldsymbol{W}^* = egin{bmatrix} oldsymbol{W}_1^* \ oldsymbol{W}_2^* \end{bmatrix}.$$

If $T^*_{S^c_0} = \mathbf{0}_{S^c_0} \in \mathbb{R}^{p-s_0}$, then, the KKT conditions of (2) can be written as

$$\boldsymbol{C}_{11}\boldsymbol{T}_{S_0}^* - (\boldsymbol{C}\boldsymbol{W}^*)_1 = -\frac{\lambda_0}{2} \begin{bmatrix} \operatorname{sign}(\theta_1^0) \\ \vdots \\ \operatorname{sign}(\theta_{s_0}^0) \end{bmatrix}$$
(.2)

and

$$-\frac{\lambda_0}{2}\mathbf{1} \le C_{21}T_{S_0}^* - (CW^*)_2 \le \frac{\lambda_0}{2},\tag{.3}$$

where $(CW^*)_1 = C_{11}W_1^* + C_{12}W_2^*$, $(CW^*)_2 = C_{21}W_1^* + C_{22}W_2^*$ and **1** is a $(p - s_0)$ dimensional vector of 1's. Then, solving for $T_{S_0}^*$ from (.2) and substituting in (.3), we have

$$-\frac{\lambda_0}{2}\mathbf{1} \leq \boldsymbol{C}_{21}\boldsymbol{C}_{11}\big((\boldsymbol{C}\boldsymbol{W}^*)_1 - \frac{\lambda_0}{2} \begin{bmatrix} \operatorname{sign}(\theta_1^0) \\ \vdots \\ \operatorname{sign}(\theta_{s_0}^0) \end{bmatrix} \big) - (\boldsymbol{C}\boldsymbol{W}^*)_2 \leq \frac{\lambda_0}{2}\mathbf{1}$$

Now, recalling that $\boldsymbol{W}^* | \boldsymbol{\Delta} \sim \mathcal{N}(\sigma_0 \boldsymbol{C}^{-1/2} \boldsymbol{\Delta}, \sigma_0^2 \boldsymbol{C}^{-1})$, we have the result.

Proof of Theorem 2. In view of Lemma 2, it suffices to restrict σ to a shrinking neighborhood \mathcal{U}_n of σ_0 and derive the result by conditioning on σ to a value σ_n , uniformly in $\sigma_n \in \mathcal{U}_n$. We can write $\theta^* = \arg \min_{\boldsymbol{u}} M_n(\boldsymbol{u})$, where

$$M_n(\boldsymbol{u}) = \operatorname*{arg\,min}_{\boldsymbol{u}} \{ (\boldsymbol{u} - \boldsymbol{\theta})^{\mathrm{T}} \boldsymbol{X}^{\mathrm{T}} \boldsymbol{X} (\boldsymbol{u} - \boldsymbol{\theta}) + \lambda_0 \sqrt{n} \|\boldsymbol{u}\|_1 \}$$

Then, defining $\boldsymbol{t} = \sqrt{n}(\boldsymbol{u} - \boldsymbol{\theta}^0)$, we have

$$\boldsymbol{T}_n^* = \sqrt{n}(\boldsymbol{\theta}^* - \boldsymbol{\theta}^0) = \operatorname*{arg\,min}_{\boldsymbol{t}} \left\{ M_n(\boldsymbol{\theta}^0 + n^{-1/2}\boldsymbol{t}) - M_n(\boldsymbol{\theta}^0) \right\}.$$

Because $\boldsymbol{\theta}|(\boldsymbol{Y}, \sigma = \sigma_n) \sim N(\hat{\boldsymbol{\theta}}^R, \sigma_n^2 (\boldsymbol{X}^T \boldsymbol{X} + a_n \boldsymbol{I}_p)^{-1})$, we can rewrite $\boldsymbol{\theta} = \hat{\boldsymbol{\theta}}^R - \sigma_n (\boldsymbol{X}^T \boldsymbol{X} + a_n \boldsymbol{I}_p)^{-1/2} \boldsymbol{U}_n^*$, where $\boldsymbol{U}_n^* \sim N_p(\boldsymbol{0}, \boldsymbol{I}_p)$. Then, writing $\boldsymbol{\Delta}_n = -\sqrt{n} \boldsymbol{C}_n^{1/2} (\hat{\boldsymbol{\theta}}^R - \boldsymbol{\theta}^0) / \sigma_n$, we have

$$\begin{split} M_n(\theta^0 + n^{-1/2}t) &- M_n(\theta^0) \\ = & (\theta^0 + n^{-1/2}t - \theta)^{\mathrm{T}} X^{\mathrm{T}} X(\theta^0 + n^{-1/2}t - \theta) + \lambda_0 \sqrt{n} \|\theta^0 + n^{-1/2}t\|_1 \\ & - (\theta^0 - \theta)^{\mathrm{T}} X^{\mathrm{T}} X(\theta^0 - \theta) - \lambda_0 \sqrt{n} \|\theta^0\|_1 \\ = & t^{\mathrm{T}} C_n t + 2t^{\mathrm{T}} C_n \sqrt{n} (\theta - \theta^0) + \lambda_0 \sqrt{n} (\|\theta^0 + n^{-1/2}t\|_1 - \|\theta^0\|_1) \\ = & t^{\mathrm{T}} C_n t + 2t^{\mathrm{T}} C_n \sqrt{n} (\hat{\theta}^{\mathrm{R}} - \sigma_n (nC_n + a_n I)^{-1/2} U_n^* - \theta^0) \\ & + \lambda_0 \sqrt{n} (\|\theta^0 + n^{-1/2}t\|_1 - \|\theta^0\|_1) \\ = & t^{\mathrm{T}} C_n t - 2\sigma_n t^{\mathrm{T}} C_n^{1/2} \Delta_n - 2\sigma_n t^{\mathrm{T}} C_n (nC_n + a_n I)^{-1/2} U_n^* \\ & + \lambda_0 \sqrt{n} (\|\theta^0 + n^{-1/2}t\|_1 - \|\theta^0\|_1). \end{split}$$

In view of Lemma 1, Δ_n converges weakly to $\Delta \sim N_p(\mathbf{0}, \mathbf{I}_p)$. Writing U^* for a $N_p(\mathbf{0}, \mathbf{I}_p)$ variable independent of Δ , it follows that the weak limit of $M_n(\boldsymbol{\theta}^0 + n^{-1/2}\boldsymbol{v}) - M_n(\boldsymbol{\theta}^0)$, conditional on the data and $\sigma = \sigma_n$, is the stochastic process

$$\boldsymbol{t}^{\mathrm{T}}\boldsymbol{C}\boldsymbol{t} - 2\sigma_{0}\boldsymbol{t}^{\mathrm{T}}\boldsymbol{C}^{1/2}(\boldsymbol{U}^{*} + \boldsymbol{\Delta}) + \lambda_{0} \Big[\sum_{j=1}^{s_{0}} t_{j} \mathrm{sign}(\theta_{j}^{0}) + \sum_{j=s_{0}+1}^{p} |t_{j}|\Big].$$
(.4)

The limiting process has a unique separated maximum. Hence, by the Argmax Theorem (Theorem 3.2.2 of van der Vaart and Wellner [2023]), the conditional distribution of T_n^* given the data converges to the distribution of

$$\boldsymbol{T}^* = \arg\min_{\boldsymbol{t}} \{ \boldsymbol{t}^{\mathrm{T}} \boldsymbol{C} \boldsymbol{t} - 2\sigma_0 \boldsymbol{t}^{\mathrm{T}} \boldsymbol{C}^{1/2} (\boldsymbol{U}^* + \boldsymbol{\Delta}) + \lambda_0 \big[\sum_{j=1}^{s_0} t_j \mathrm{sign}(\theta_j^0) + \sum_{j=s_0+1}^{p} |t_j| \big] \}$$

given Δ , in the space of probability measures $\mathfrak{M}(\mathbb{R}^p)$ under the weak topology. Writing $W^* = \sigma_0 C^{-1/2} (U^* + \Delta)$, the distributional representation in (3.3) is obtained.

Let Ξ_n stand for the random probability measure $\mathcal{L}(\mathbf{T}_n^* \in \cdot | \mathbf{Y}, \sigma = \sigma_n)$. Writing Ξ for the random probability measure $\mathcal{L}(\mathbf{T} \in \cdot | \mathbf{\Delta})$, we have $\Xi_n \rightsquigarrow \Xi$ in the space $\mathfrak{M}(\mathbb{R}^p)$ with respect to the topology of weak convergence.

We also note that the conditional distribution of the process $M_n(\theta^0 + n^{-1/2}t) - M_n(\theta^0)$ given the data and $\sigma = \sigma_n$ depends on the data through Δ_n , which is a continuous function of $X^{\mathrm{T}}\varepsilon$. Also, $\sqrt{n}(\theta^{\mathrm{L}} - \theta_0)$ is a continuous function of $X^{\mathrm{T}}\varepsilon$ too. Further $n^{-1/2}X^{\mathrm{T}}\varepsilon \rightsquigarrow \Delta$ on \mathbb{R}^p . Hence, combining with Theorem 3.1, we can conclude that $(\Xi_n, \xi_n) \rightsquigarrow (\Xi, \xi)$; that is, the joint weak convergence holds in the space $\mathfrak{M}(\mathbb{R}^p) \times \mathbb{R}^p$ with respect to the product of the weak topology and the Euclidean topology.

Proof of Theorem 3. Since a norm is a continuous functional, it follows from (3.4) that

$$\left(\mathcal{L}(\|\boldsymbol{T}_{n}^{*}-\hat{\boldsymbol{\xi}}_{n}\|_{\mathcal{K}}\in\cdot|\boldsymbol{Y}),\|\hat{\boldsymbol{\xi}}_{n}\|_{\mathcal{K}}\right)\rightsquigarrow\left(\mathcal{L}(\|\boldsymbol{T}-\boldsymbol{\xi}\|_{\mathcal{K}}\in\cdot|\boldsymbol{\Delta}),\|\boldsymbol{\xi}\|_{\mathcal{K}}\right)$$
(.5)

in the space $\mathfrak{M}(\mathbb{R}^p) \times \mathbb{R}^p$. To obtain the limiting coverage of the obtained credible region, note that $\{\boldsymbol{\theta}^0 \in B_r\} = \{\|\sqrt{n}(\boldsymbol{\theta}^0 - \hat{\boldsymbol{\theta}}^L)\|_{\mathcal{K}} \leq r_{1-\alpha,n}\}$, and

$$\begin{aligned} \{\Pi(\|\sqrt{n}(\boldsymbol{\theta}^* - \hat{\boldsymbol{\theta}}^{\mathrm{L}})\|_{\mathcal{K}} &\leq \|\sqrt{n}(\boldsymbol{\theta}^0 - \hat{\boldsymbol{\theta}}^{\mathrm{L}})\|_{\mathcal{K}}|\boldsymbol{Y}) < 1 - \alpha\} \\ &\subset \{\boldsymbol{\theta}^0 \in B_r\} \\ &\subset \{\Pi(\|\sqrt{n}(\boldsymbol{\theta}^* - \hat{\boldsymbol{\theta}}^{\mathrm{L}})\|_{\mathcal{K}} \leq \|\sqrt{n}(\boldsymbol{\theta}^0 - \hat{\boldsymbol{\theta}}^{\mathrm{L}})\|_{\mathcal{K}}|\boldsymbol{Y}) \leq 1 - \alpha\}. \end{aligned}$$

The assertion is now immediate.

Proof of Theorem 4. Let the limit C of $n^{-1}X^{T}X$ be a block-diagonal matrix with blocks $\{j\}$ and [-j]. As argued in Remark 1, it suffices to prove the result under the additional assumption that $c_{j} = 1$ and $\sigma_{0} = 1$. Then ξ_{j} reduces to $\arg\min\{v_{j}^{2} - 2\Delta_{j}v_{j} + \lambda_{0}[v_{j}\mathrm{sign}(\theta_{j}^{0}) + \mathbb{1}(\theta_{j}^{0} = 0)|v_{j}|]\}$ For a non-zero-component, the minimizer of $v_{j}^{2} - 2\Delta_{j}v_{j} + \lambda_{0}v_{j}\mathrm{sign}(\theta_{j}^{0})$ is

$$\xi_j = \begin{cases} \Delta_j - \lambda_0/2, & \text{if } \theta_j^0 > 0, \\ \Delta_j + \lambda_0/2, & \text{if } \theta_j^0 < 0, \end{cases}$$
(.6)

while for a zero-component, the minimizer of $v_j^2 - 2\Delta_j v_j + \lambda_0 |v_j|$ is

$$\xi_j = \begin{cases} \Delta_j - \lambda_0/2, & \text{if } \Delta_j > \lambda_0/2, \\ \Delta_j + \lambda_0/2, & \text{if } \Delta_j < -\lambda_0/2, \\ 0, & \text{if } |\Delta_j| \le \lambda_0/2. \end{cases}$$
(.7)

In both cases, we note that ξ_j is a continuous function of Δ_j . In the first case, ξ_j is a continuous random variable, while in the second case, ξ_j has a point mass at 0. Proceeding in the same way, we have for a non-zero component

$$T_{j}^{*} = \arg\min\{t_{j}^{2} - 2W_{j}^{*}t_{j} + \lambda_{0}t_{j}\operatorname{sign}(\theta_{j}^{0})\} = \begin{cases} W_{j}^{*} - \lambda_{0}/2, & \text{if } \theta_{j}^{0} > 0, \\ W_{j}^{*} + \lambda_{0}/2, & \text{if } \theta_{j}^{0} < 0. \end{cases}$$
(.8)

and for a zero-component

$$T_{j}^{*} = \arg\min\{t_{j}^{2} - 2W_{j}^{*}t_{j} + \lambda_{0}|t_{j}|\} = \begin{cases} W_{j}^{*} - \lambda_{0}/2, & \text{if } W_{j}^{*} > \lambda_{0}/2, \\ W_{j}^{*} + \lambda_{0}/2, & \text{if } W_{j}^{*} < -\lambda_{0}/2, \\ 0, & \text{if } |W_{j}^{*}| \le \lambda_{0}/2, \end{cases}$$
(.9)

where $W_j^*|\Delta_j \sim N(\Delta_j, 1)$. Writing $Z_j = W_j^* - \Delta_j$, and noting that $Z_j|\Delta_j \sim N(0, 1)$, we obtain that for $\theta_j^0 > 0$,

$$P(|T_j^* - \xi_j| \le |\xi_j| | \Delta_j) = P(|Z_j| \le |\xi_j| | \Delta_j) = 2\Phi(|\xi_j|) - 1 = h_+(\lambda_0, \Delta_j),$$
(.10)

because $T_j^* - \xi_j = (W_j^* - \lambda_0/2) - (\Delta_j - \lambda_0/2) = Z_j$ in this case.

Similarly, for $\theta_j < 0$, $T_j^* - \xi_j = (W_j^* + \lambda_0/2) - (\Delta_j + \lambda_0/2) = Z_j$ again, and hence

$$P(|T_j^* - \xi_j| \le |\xi_j| | \Delta_j) = P(|Z_j| \le |\xi_j| | \Delta_j) = 2\Phi(|\xi_j|) - 1 = h_-(\lambda_0, \Delta_j).$$
(.11)

Since $2\Phi(|\xi_j|) - 1$ is a continuous random variable, the coverage probability $\mathbb{P}_0(\theta_j^0 \in [\hat{\theta}_j^{\mathrm{L}} - r_{1-\alpha,j}, \hat{\theta}_j^{\mathrm{L}} + r_{1-\alpha,j}])$ converges to

$$P(2\Phi(|\xi_j|) - 1 \le 1 - \alpha) = P(|\xi_j| \le z_{\alpha/2}) = \Phi(\lambda_0/2 + z_{\alpha/2}) - \Phi(\lambda_0/2 - z_{\alpha/2})$$

whenever $\theta_j^0 \neq 0$.

To compute $P(|T_j^* - \xi_j| \le |\xi_j| | \Delta_j)$ for $\theta_j^0 = 0$, we consider the three cases separately. For $\Delta_j > \lambda_0/2$, we have

 $\xi_j = \Delta_j - \lambda_0/2 > 0$ so that from (.9) and (.7),

$$\begin{split} \mathbf{P}(|T_{j}^{*} - \xi_{j}| \leq |\xi_{j}| |\Delta_{j}) &= \mathbf{P}(|W_{j}^{*} - \lambda_{0}/2 - \xi_{j}| \leq \xi_{j}, W_{j}^{*} > \lambda_{0}/2 |\Delta_{j}) \\ &+ \mathbf{P}(|W_{j}^{*} + \lambda_{0}/2 - \xi_{j}| \leq \xi_{j}, W_{j}^{*}| < -\lambda_{0}/2 |\Delta_{j}) \\ &+ \mathbf{P}(|0 - \xi_{j}| \leq \xi_{j}, |W_{j}^{*}| \leq \lambda_{0}/2 |\Delta_{j}) \\ &= \mathbf{P}(|Z_{j}| \leq \Delta_{j} - \lambda_{0}/2, Z_{j} > -\Delta_{j} + \lambda_{0}/2 |\Delta_{j}) \\ &+ \mathbf{P}(|Z_{j} + \lambda_{0}| \leq \Delta_{j} - \lambda_{0}/2, Z_{j} < -\Delta_{j} - \lambda_{0}/2 |\Delta_{j}) \\ &+ \mathbf{P}(|-\Delta_{j} + \lambda_{0}/2| \leq \Delta_{j} - \lambda_{0}/2, |Z_{j} + \Delta_{j}| \leq \lambda_{0}/2 |\Delta_{j}) \\ &= \mathbf{P}(-\Delta_{j} + \lambda_{0}/2 \leq Z_{j} \leq \Delta_{j} - \lambda_{0}/2 |\Delta_{j}) + \mathbf{O} \\ &+ \mathbf{P}(-\Delta_{j} - \lambda_{0}/2 \leq Z_{j} \leq -\Delta_{j} + \lambda_{0}/2 |\Delta_{j}) \\ &= \Phi(\Delta_{j} - \lambda_{0}/2) - \Phi(-\Delta_{j} - \lambda_{0}/2) \end{split}$$

For the case where $\Delta_j < -\lambda_0/2$, we have $|\xi_j| = -\xi_j$, so that

$$P(|T_j^* - \xi_j| \le |\xi_j| | \Delta_j) = P(|Z_j - \lambda_0| \le -\Delta_j - \lambda_0/2, Z_j > -\Delta_j + \lambda_0/2 | \Delta_j)$$
$$+ P(|Z_j| \le -\Delta_j - \lambda_0/2, Z_j < -\Delta_j - \lambda_0/2 | \Delta_j)$$
$$+ P(|\Delta_j + \lambda_0/2| \le |\Delta_j + \lambda_0/2|, |Z_j + \Delta_j| \le \lambda_0/2 | \Delta_j)$$
$$= \Phi(-\Delta_j + \lambda_0/2) - \Phi(\Delta_j + \lambda_0/2).$$

Finally, when $|\Delta_j| \leq \lambda_0/2$, $\xi_j = 0$ so that

$$P(|T_j^* - \xi_j| \le |\xi_j| | \Delta_j) = P(T_j^* = 0 | \Delta_j)$$
$$= P(|Z_j + \Delta_j| \le \lambda_0/2 | \Delta_j)$$
$$= \Phi(\Delta_j + \lambda_0/2) - \Phi(\Delta_j - \lambda_0/2).$$

Thus in all cases for $\theta_j^0 = 0$, $P(|T_j^* - \xi_j| \le |\xi_j| | \Delta_j) = h_0(\lambda_0, \Delta_j)$, which is a continuous random variable because $\zeta \mapsto h_0(\lambda_0, \zeta)$ is continuous and not flat, and $\Delta_j \sim N(0, 1)$ is continuous. Therefore, it follows that

$$\mathbb{P}_0(\theta_j^0 \in [\hat{\theta}_j^{\mathrm{L}} - r_{1-\alpha,j}, \hat{\theta}_j^{\mathrm{L}} + r_{1-\alpha,j}]) \to \mathbb{P}(h_0(\lambda_0, \Delta_j) \le 1-\alpha) = \psi_0(\alpha, \lambda_0),$$

when $\theta_j^0 = 0$.
