Abstract. Heavy nuclei can be synthesized or entrained in gamma-ray bursts (GRBs) with implications on the high-energy neutrino emission. By means of a Monte-Carlo algorithm, we model nuclear cascades and investigate their impact on the neutrino production considering kinetic dominated jets (in the internal shock model, including a dissipative photosphere) as well as Poynting flux dominated jets (for a jet model invoking internal-collision-induced magnetic reconnection and turbulence, ICMART). We find that the ICMART model allows for efficient nuclear cascades leading to an overall larger neutrino fluence than in the other two jet models. The survival of nuclei and inefficient nuclear cascades lead to an overall reduction of the neutrino fluence up to one order of magnitude. However, if nuclei are disintegrated, the neutrino fluence may be comparable to the one emitted from a jet loaded with protons. Exploring the parameter space of jet properties, we conclude that the composition and the bulk Lorentz factor have significant impact on the efficiency of nuclear cascades as well as the spectral shape of the expected neutrino fluence. On the other hand, the neutrino spectral distribution is less sensitive to the power-law index of the accelerated population of protons or heavier nuclei. For what concerns the diffuse emission of neutrinos from GRBs, we find that the uncertainty due to the jet composition can be at most comparable to the one related to the GRB cosmological rate.

1 Introduction

Gamma-Ray Bursts (GRBs) are among the most energetic transient astrophysical phenomena discovered up to date, releasing isotropic energies up to $E_{\text{iso}} = 1.2 \times 10^{55}$ erg within a few seconds [1]. The observation of GRB 170817A in connection with the gravitational wave event GW 170817 has provided the first confirmation that binary neutron star mergers can harbor ultra-relativistic jets [2–8], known as short GRBs. Supernovae have instead been observed in connection with long duration gamma-ray bursts [9, 10]. However, recent observations

challenge the conjectured different origin of long and short GRBs [11–13]. Observed long duration GRBs can be divided in high-luminosity (HL, with isotropic luminosity $\mathcal{O}(10^{51}–10^{53})$ erg/s) and low-luminosity (LL, with isotropic luminosity smaller than $\mathcal{O}(10^{49})$ erg/s) GRBs [14, 15]. It is believed that HL and LL GRBs share similar properties, with LL GRBs having smaller Lorentz boost factor or perhaps corresponding to HL GRBs observed off-axis. The dynamical evolution of the GRB jet is linked to the properties of the central engine powering the jet; the jet could be magnetically driven, if the central engine harbors a strong magnetic field, or it would be better described by a fireball when the magnetic activity subsides [16, 17].

Gamma-ray bursts are observed as irregular pulses of gamma-rays, with a non-thermal photon spectral energy distribution. Such non-thermal features suggest efficient particle acceleration in the jet [18, 19]. Nevertheless, the physics driving the observed signals is still subject of active debate [17, 20–23].

Gamma-ray bursts are expected to be sources of ultra-high energy cosmic rays and high energy neutrinos [24–29], produced also thanks to heavier nuclei synthesized or entrained in the jet [30, 31] and eventually interacting with the photon background. In the aftermath of particle acceleration, the inelastic interaction of non-thermal high-energy photons with ultra-relativistic protons or nuclei could lead to the production of high-energy neutrinos, see e.g. Refs. [24, 32–36].

It is expected that the GRB jet may entrain nuclei, e.g. loaded at the base of the jet, captured from the stellar material surrounding the jet and entrained during propagation, or synthesized in situ [30, 31, 37]. Such nuclei could be accelerated in the GRB jet and therefore survive photodisintegration against the intense photon field, only if the dissipation radius and the bulk Lorentz factor are large enough. Assuming that such conditions are fulfilled, the resulting neutrino production would be strongly affected.

Previous work [32, 38] investigated the impact of the jet composition on the high energy neutrino flux, focusing on the internal shock model [18]. In the light of the strong dependence of the neutrino signal on the GRB emission mechanism [33], we extend such exploration to the photospheric [39] and the internal-collision-induced magnetic reconnection and turbulence (ICMART) [40] models, and explore the neutrino production for a range of jet properties.

This work is organized as follows. Section 2 provides an overview of the internal shock model, the photospheric one, and the ICMART model. Section 3 offers a summary of the acceleration and cooling timescales adopted to compute the maximum energies of protons and nuclei. A description of how neutrinos are produced through photohadronic interactions of protons and neutrons or nuclei is presented in Sec. 4. Section 5 focuses on the formalism adopted to compute the neutrino emission from jets loaded with heavier nuclei, including the modeling of the nuclear cascades using a Monte-Carlo method. Our findings on the impact of the jet composition on the neutrino emission for our three jet models are presented in Sec. 6, together with an exploration of the jet parameter space. We also discuss the consequences that the jet composition should have on the diffuse emission of high-energy neutrinos in Sec. 7. Finally, we critically review our findings and conclude in Sec. 8. Details on the Monte Carlo simulation of nuclear cascades are provided in Appendix A, while the nuclear photohadronic model is outlined in Appendix B.

2 Gamma-ray burst models

This section highlights the main features of the kinetic dominated and Poynting flux dominated jets considered in this work as well as the adopted photon spectral energy distributions. We refer the interested reader to Ref. [33] for a broader overview.

In the following, we distinguish among three reference frames: the comoving jet frame, the central engine frame, and the observer frame; any jet quantity X is denoted as X' , \tilde{X} , or X respectively according to the adopted reference frame. For example, energy or length transform as $X = \tilde{X}/(1+z) = \Gamma X'/(1+z)$, while time transforms as $X = (1+z) \tilde{X} = (1+z) X'/\Gamma$. We consider a relativistic jet propagating with bulk Lorentz factor Γ with respect to the central engine. During the prompt phase, it is expected that $\theta_{\text{op}} \gg \Gamma^{-1}$, with θ_{op} being the half opening angle [41]. This justifies the employment of the isotropic equivalent energy (\tilde{E}_{iso}) representing the energy content of the outflow. Additionally, GRBs are characterized by two timescales. The first one is the total duration of the event t_{dur} and the second one is the average variability timescale of the central engine t_{var} . We thus define the total isotropic luminosity $\tilde{L}_{\text{iso}} = \tilde{E}_{\text{iso}}/\tilde{t}_{\text{dur}}$. Any burst is also characterized by its redshift z .

2.1 Internal shock model

The internal shock (IS) model has been widely investigated for the GRB prompt emission [18, 42, 43] because it allows to easily explain the variability of the GRB lightcurves. Due to the erratic activity of the central engine, the outflow results in several shells, each with different Lorentz factor Γ . When a faster shell hits a slower shell, dissipation of kinetic energy occurs. In the following, we focus on a one-zone collision model for the sake of simplicity, assuming that all collisions are identical. However, multi-zone collisions models are expected to lead to less efficient neutrino emission [35, 44–47]. We assume that, for a GRB of duration \tilde{t}_{dur} and variability time scale \tilde{t}_{var} , $N_{\text{shock}} = \tilde{t}_{\text{dur}}/\tilde{t}_{\text{var}}$ identical shocks occur at the radius $R_{\gamma} = R_{\text{IS}} = 2\Gamma^2 c \tilde{t}_{\text{var}}$, within a volume $V'_s = 4\pi R_{\text{IS}}^2 c t'_{\text{var}}$. Unless otherwise stated, the benchmark jet properties adopted for this model are summarized in Table 1; note that the large jet luminosity considered for our benchmark jet model most likely does not allow for the survival of all iron nuclei. While the assessment of the jet conditions leading to a specific jet composition is beyond the scope of this work, we generalize our findings in the second part of this paper, exploring variations of some of the jet characteristic properties.

The fraction of energy dissipated in particle acceleration, and the fractions of energy that effectively accelerates seed particles (protons, nuclei), electrons, or contributes to amplify the magnetic field are $\varepsilon_d = 0.2$, $\varepsilon_A = 0.1$ (where A indicates protons or nuclei), $\varepsilon_e = 0.01$, and $\varepsilon_B = 0.1$ [48, 49]. Hence the magnetic field is

$$B' = \sqrt{8\pi \frac{\varepsilon_B \varepsilon_d E'_{\text{iso},s}}{V'_s}}, \quad (2.1)$$

with $E'_{\text{iso},s} = E'_{\text{iso}}/N_{\text{shock}}$.

Shocks accelerate a certain fraction of the charged particles into a power-law distribution [50]:

$$n'_A(E'_A) = C E'^{-k}_A \exp \left[- \left(\frac{E'_A}{E'_{A,\text{max}}} \right)^2 \right] \Theta(E'_A - E'_{A,\text{min}}), \quad (2.2)$$

Table 1. Summary of the characteristic parameters assumed for our benchmark jet for the internal shock (IS), photospheric (PHOTO) and ICMART models, respectively.

Parameter	IS	PHOTO	ICMART
\tilde{E}_{iso}	4.5×10^{54} erg [51]		
z	2 [52]		
Γ	300 [53]		
t_{dur}	30 s [54]		
t_{var}	0.5 s [55]		
ε_d	0.2 [42, 44]	0.2 [42, 44]	0.35 [56]
ε_e	0.01 [48, 49]	0.01 [48, 49]	0.5 [57]
ε_X	0.1 [49]	0.1 [49]	0.5 [57]
ε_B	0.1 [49]	0.1 [49]	n/a
k	2.2 [58, 59]	2.2 [58, 59]	2.0 [60, 61]
σ	n/a	n/a	45 [33]

with $k \simeq 2.2$; imposing that $U_A = \int_{E'_{A,\min}}^{E'_{A,\max}} n'_A(E'_A) E'_A dE'_A$, we compute the normalization constant C , where $U_A = \varepsilon_d \varepsilon_A E'_{\text{iso},s}/V'_s$ is the energy density of accelerated seed particles.

The photon spectrum is modeled through a Band function [62]:

$$n'_\gamma(E'_\gamma) = C \begin{cases} \left(\frac{E'_\gamma}{E'_0}\right)^\alpha \exp\left(-\frac{(\alpha+2)E'_\gamma}{E'_{\gamma,p}}\right) & \text{if } E'_{\gamma,\min} \leq E'_\gamma \leq E'_{\gamma,c} \\ \left(\frac{E'_\gamma}{E'_0}\right)^\beta \exp(\beta-\alpha) \left(\frac{E'_{\gamma,c}}{E'_0}\right)^{\alpha-\beta} & \text{if } E'_{\gamma,c} \leq E'_\gamma \leq E'_{\gamma,\max} \end{cases} \quad (2.3)$$

with $E'_{\gamma,p}$, $E'_{\gamma,c}$, $E'_{\gamma,\min}$, $E'_{\gamma,\max}$ being the peak, cooling, minimum and maximum energies of the spectrum, $E'_{\gamma,0} = [(1+z)/\Gamma] \times 100$ keV, respectively. Relying on GRB observations from Fermi, we choose $\alpha \simeq -1.1$ and $\beta \simeq -2.2$ [63]. The normalization constant is given by $U_\gamma = \int_{E'_{\gamma,\min}}^{E'_{\gamma,\max}} n'_\gamma(E'_\gamma) E'_\gamma dE'_\gamma$ with $U_\gamma = \varepsilon_d \varepsilon_e E'_{\text{iso},s}/V'_s$. The peak energy is computed following the Amati relation [64]: $\tilde{E}_{\gamma,p} = 80 \left(\tilde{E}_{\gamma,\text{iso}}/10^{52} \text{ erg}\right)^{0.57}$ keV with $\tilde{E}_{\gamma,\text{iso}} = \varepsilon_d \varepsilon_e \tilde{E}_{\text{iso}}$, and the cooling energy is $E'_{\gamma,c} = (\alpha - \beta)/(\alpha + 2) E'_{\gamma,p}$. Note that our benchmark \tilde{E}_{iso} is such that, in the internal shock model, $\tilde{L}_{\text{iso},\gamma} \simeq \varepsilon_d \varepsilon_e \tilde{E}_{\text{iso}}/t_{\text{dur}}$ is slightly lower than what often considered in the literature. Yet, this value of \tilde{E}_{iso} [51] allows to recover the observed $\tilde{L}_{\text{iso},\gamma}$ for the photospheric and ICMART models; we choose to rely on the same jet benchmark properties to allow for a fair comparison across jet models.

Note that we do not consider neutrino production below the photosphere [23, 36, 65–69], as neutrinos would be produced with GeV–TeV energies, while we are interested in comparing different models for neutrino production in the optically thin region with overall larger energies.

2.2 Photospheric model

The photospheric model (PHOTO) is a variation of the internal shock model that assumes that dissipative processes shape the radiation bulk produced in the optically thick region below the photosphere [20]. We assume all characteristic jet parameters as being the same as the ones of the internal shock model, except for the ones related to the photon spectrum.

Protons or nuclei interact with a photon spectrum described by three components [33, 39]: a non-thermal photospheric component defined by a Band spectrum and undergoing dissipation at the internal shock radius, a photospheric Compton up-scattered spectrum, and a synchrotron component due to electrons cooling in the shock region. The accelerated particle spectrum is given by Eq. (2.2) with $k = 2.2$; the photon spectrum is [33]:

$$n'_\gamma(E'_\gamma) = \left(\frac{R_{\text{PH}}}{R_{\text{IS}}}\right)^2 n'_{\gamma,\text{PH}}(E'_\gamma) + n'_{\gamma,\text{SYNC}}(E'_\gamma) + n'_{\gamma,\text{UP}}(E'_\gamma), \quad (2.4)$$

with $R_{\text{PH}} = \sigma_T \tilde{L}_{\text{iso}}/(4\pi\Gamma^3 m_p c^3)$ being the radius of the photosphere. Each spectral component is normalized at the emission radius independently, using the fractions x_{PH} , x_{SYNC} and x_{UP} of E'_{iso} going into each part of the spectrum, respectively. We have $x_{\text{PH}} = 0.2$, $x_{\text{SYNC}} = 1.6 \times 10^{-4}$, and $x_{\text{UP}} = 0.002$ [33]. The spectral component $n'_{\gamma,\text{PH}}(E'_\gamma)$ is given by Eq. (2.3). The spectral components $n'_{\gamma,\text{SYNC}}(E'_\gamma)$ and $n'_{\gamma,\text{UP}}(E'_\gamma)$ are joint broken power laws, describing synchrotron self-Compton emission of charged particles in the fast-cooling regime [70]:

$$n'_\gamma(E'_\gamma) = C \begin{cases} \left(\frac{E'_\gamma}{E'_{\gamma,c}}\right)^{-2/3} & \text{if } E'_{\gamma,\text{min}} \leq E'_\gamma \leq E'_{\gamma,c} \\ \left(\frac{E'_\gamma}{E'_{\gamma,c}}\right)^{-3/2} & \text{if } E'_{\gamma,c} \leq E'_\gamma \leq E'_{\gamma,p} \\ \left(\frac{E'_{\gamma,p}}{E'_{\gamma,c}}\right)^{-3/2} \left(\frac{E'_\gamma}{E'_{\gamma,p}}\right)^{-(k+2)/2} & \text{if } E'_{\gamma,p} \leq E'_\gamma \leq E'_{\gamma,\text{max}} \end{cases} \quad (2.5)$$

For the synchrotron component, $E'_{\gamma,i} = (3/2)(\hbar e/m_e c)\gamma'_i{}^2 B'$ where $i = p, c$, $\gamma'_p = (m_p/m_e) \times (k_e - 2)/(k_e - 1) \varepsilon_d \varepsilon_e$ and $\gamma'_c = (3 m_e \Gamma)/(4 m_p n'_b x_{\text{PH}} \sigma_T R_{\text{IS}})$ [70], $\sigma_T = 6.65 \times 10^{-25} \text{ cm}^2$ is the Thompson cross-section, and $n'_b = \tilde{L}_{\text{iso}}/(4\pi R_{\text{IS}}^2 m_p c^3 \Gamma^2)$ is the total baryon density. For the up-scattered component, we use the same $E'_{\gamma,c}$ and $E'_{\gamma,p}$ as for the Band spectrum. Unless otherwise stated, the benchmark jet properties adopted for this model are summarized in Table 1.

2.3 ICMART model

The ICMART model belongs to the class of Poynting flux dominated jets and assumes that energy is dissipated at very large distance from the central engine [40]. In the ICMART model, it is assumed that the jet is composed of magnetized shells with constant initial magnetization $\sigma = 45$ and different bulk Lorentz factors. Similarly to the internal shock model, these shells collide with each other. These internal shocks in the optically thick region alter the ordered magnetic field configuration, triggering magnetic reconnection and the release of stored magnetic energy at large radii [40]. The radius at which gamma-rays and neutrinos are emitted is independent of the jet properties ($R_\gamma = R_{\text{ICMART}} = 10^{15} \text{ cm}$).

For the ICMART model, the photon spectrum is also a Band function, see Eq. (2.3), and the accelerated particle spectrum is a cut-off power law (Eq. 2.2). However, magnetic reconnection is more efficient than relativistic shocks at accelerating particles, meaning that a smaller power law index ($k \simeq 2.0$) and larger microphysical parameters than the ones characteristic of the internal shock model are considered: $\varepsilon_d = 0.35$, $\varepsilon_A = 0.5$ and $\varepsilon_e = 0.5$ [56, 57, 71, 72]. Table 1 summarizes the benchmark jet properties adopted for this model.

Moreover, the magnetic field is [40]

$$B' = \sqrt{\frac{2\tilde{L}_{\text{iso}}}{c\Gamma^2 R_{\text{ICMART}}^2} \frac{\sigma}{\sigma+1}}. \quad (2.6)$$

3 Acceleration and cooling timescales

We present in this section the acceleration and cooling timescales used to compute the maximum energy ($E'_{A,\text{max}}$) up to which a nucleus of mass number A and charge Z inside the jet can be accelerated (see Eq. 2.2). We highlight that any equation presented in the following section is also valid for protons and neutrons, which correspond to ($A = 1$, $Z = 1$) and ($A = 1$, $Z = 0$) respectively.

The inverse of the acceleration timescale is

$$\tau'_{\text{acc}}{}^{-1} = \frac{cZeB'}{E'_A}, \quad (3.1)$$

with E'_A being the energy of the nucleus ${}_Z^AX$. We need to compare $\tau'_{\text{acc}}{}^{-1}$ with the inverse of the total cooling timescale given by

$$\tau'_{\text{cool}}{}^{-1} = \sum_i \tau'_i{}^{-1}; \quad (3.2)$$

τ_i stands for the adiabatic cooling, synchrotron, inverse Compton, Bethe-Heitler pair creation, and collisions with thermal protons [73, 74]:

$$\tau'_{\text{ad}}{}^{-1} = \frac{c\Gamma}{R}, \quad (3.3)$$

$$\tau'_{\text{synch}}{}^{-1} = \frac{4Z^4\sigma_T m_e^2 E'_A B'^2}{8\pi \times 3m_A^4 c^3}, \quad (3.4)$$

$$\tau'_{\text{IC}}{}^{-1} = \frac{3(m_e c^2)^2 Z^2 \sigma_T c}{16\gamma_A'^2 (\gamma_A' - 1)\beta_A'} \int_{E'_{\gamma,\text{min}}}^{E'_{\gamma,\text{max}}} F(E'_\gamma, \gamma'_A) n'_\gamma(E'_\gamma) \frac{dE'_\gamma}{E_\gamma'^2}, \quad (3.5)$$

$$\tau'_{\text{BH}}{}^{-1} = \frac{\alpha r_e^2 c Z^2 (m_e c^2)^2}{E'_A} \int_2^{\frac{2\gamma'_A E'_{\gamma,\text{max}}}{m_e c^2}} n'_\gamma \left(\frac{\epsilon'_\gamma}{2\gamma'_A} \right) \frac{\varphi(\epsilon'_\gamma)}{\epsilon_\gamma'^2} d\epsilon'_\gamma, \quad (3.6)$$

$$\tau'_{Ap}{}^{-1} = cn'_p \sigma_{Ap}(E'_A), \quad (3.7)$$

and $\tau'_{A\gamma}{}^{-1} \equiv R'_{A\gamma}$ is the photohadronic interaction rate:

$$R'_{A\gamma} = \frac{c}{2\gamma_A'^2} \int_{\frac{E_{\gamma,r}^{\text{th}}}{2\gamma_A'}}^{+\infty} \frac{n'_\gamma(E'_\gamma)}{E_\gamma'^2} \int_{E_{\gamma,r}^{\text{th}}}^{2\gamma'_A E'_\gamma} E_{\gamma,r} \sigma_{A\gamma}(E_{\gamma,r}) dE_{\gamma,r} dE'_\gamma. \quad (3.8)$$

In the equations above $\epsilon'_\gamma = E'_\gamma/(m_e c^2)$, $E_{\gamma,r}$ is the energy of the photon in the reference frame of the nucleus, $\gamma'_A = E'_A/(m_A c^2)$, $r_e = e^2/(m_e c^2) \approx 2.82 \times 10^{-13}$ cm is the classical radius of the electron, $\alpha \approx 1/137$ is the fine structure constant, and $n'_p = \tilde{L}_{\text{iso}}/(4\pi R_{\text{IS}}^2 m_p c^3 \Gamma^2)$ is the density of thermal protons in the jet. The functions $\varphi(\epsilon'_\gamma)$ and $F(E'_\gamma, \gamma'_A)$ model the Bethe-Heitler and inverse Compton processes and are respectively defined in Eqs. (9.36) and (9.37) of Ref. [74] and Eqs. (13)–(15) of Ref. [75]. The hadronic cross-section is σ_{Ap} ; we

Figure 1. Acceleration (Eq. 3.1), inverse cooling (Eqs. 3.2–3.7) timescales, and photohadronic interaction rate (Eq. 3.8) for protons (on the left) and iron (on the right) as functions of the comoving proton energy and normalized iron energy respectively. We consider a jet with characteristic properties as in Table 1 for the internal shock model. The maximum comoving energy is obtained computing the energy for which $\tau_{\text{cool}}'^{-1} = \tau_{\text{acc}}'^{-1}$ (cf. thick black and red curves). One can see that the normalized maximum energy for iron is smaller than the proton one because of photonuclear interactions contributing to the total cooling of iron and being irrelevant for protons.

follow Ref. [76] for the proton-proton cross-section and Ref. [77] for the extension of such cross section to any nucleus. The total inelastic photohadronic cross-section is $\sigma_{A\gamma}(E_r)$ and is modeled as described in Appendix A. Note that we rely on the photohadronic interaction rate instead of the photohadronic cooling timescale since any isotope undergoing a photohadronic interaction is photodisintegrated, leaving behind a new isotope which is then consistently treated as another nuclear species in our Monte-Carlo algorithm (see Sec. 5). This approach warrants the conservation of the nucleon number and energy. For the sake of simplicity, the set of cooling timescales and photohadronic interaction rate is dubbed “cooling timescale” hereafter.

For illustrative purposes, Fig. 1 shows a comparison among the cooling and acceleration timescales obtained for protons and iron, assuming a jet with characteristic properties summarized in Table 1 for the internal shock model. The maximum energy at which p or ^{56}Fe can be accelerated is given by the crossing between the acceleration and total cooling timescales. The energy for iron useful to compute the neutrino emission is the energy per nucleon. In this example, $E'_{p,\text{max}} = 1.9 \times 10^9 \text{ GeV}$ and $E'_{\text{Fe,max}}/A_{\text{Fe}} = 4.2 \times 10^8 \text{ GeV}$, i.e. acceleration of iron is slightly less efficient than proton acceleration. This result is coherent with the fact that photonuclear interactions add an important contribution to the radiative processes associated to iron, while this is not the case for protons.

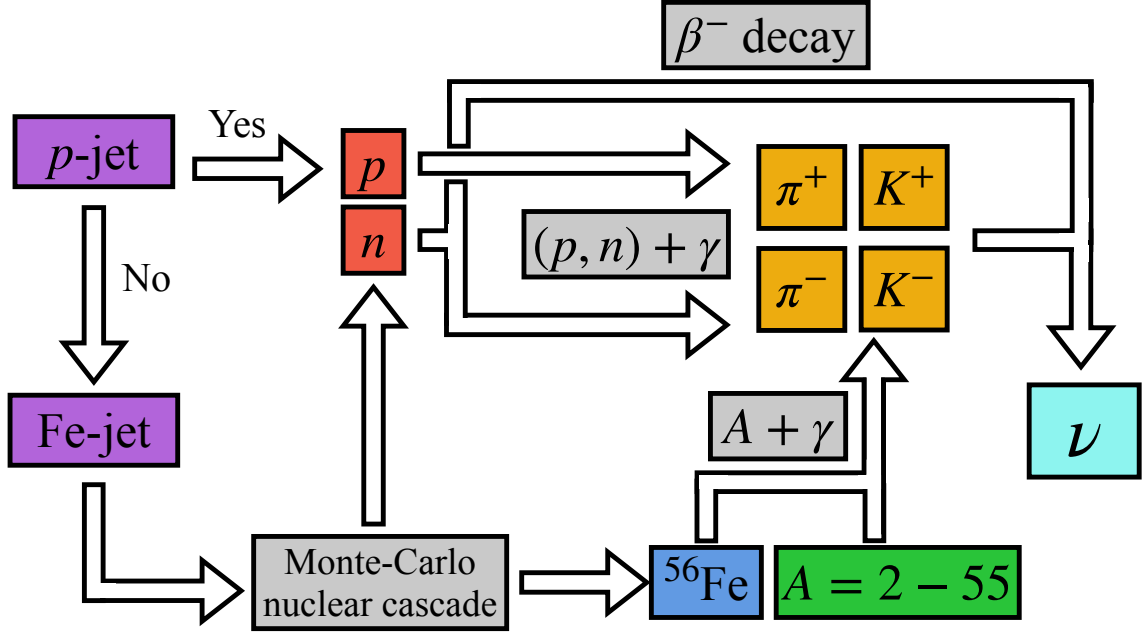

Figure 2. Flow chart illustrating the approach adopted to compute neutrino production in jets loaded with protons only (p -jet) and jets loaded with iron (Fe-jet).

4 Neutrino production from proton and neutron photohadronic interactions

Neutrinos can be produced thanks to photohadronic interactions of protons and neutrons or nuclei. In this section, we focus on $p\gamma$ interactions, following Refs. [50, 78]. We adopt the same approach for what concerns $n\gamma$ interactions after applying charge symmetry on the mesons. We also illustrate how to compute the neutrino fluence expected at Earth.

4.1 Photohadronic interactions

The physical processes leading to the production of neutrinos, discussed in this section, are illustrated in Fig. 2. Photohadronic interactions can lead to the production of mesons, if the energy of the photon in the reference frame of the proton is larger than 140 MeV [79]. The production channels can be classified as follows [78]:

$$\text{Resonances: } p + \gamma \rightarrow (\Delta, N, \rho) \rightarrow n + \pi^+ \quad (4.1)$$

$$\text{Direct production: } p + \gamma \rightarrow n + \pi^+ \quad (4.2)$$

$$\text{Multi-pion production: } p + \gamma \rightarrow n + \pi_1 + \pi_2 + \dots \quad (4.3)$$

The production rate for the particle \mathcal{M} (with $\mathcal{M} = \pi^+, \pi^-, K^+$ or K^-) is defined as the number of particles created per volume, per unit of time and per energy interval (in units of $\text{cm}^{-3} \text{s}^{-1} \text{GeV}^{-1}$) and it is given by:

$$Q'_{\mathcal{M}}(E'_{\mathcal{M}}) = \sum_{\alpha} \int n'_p(E'_p) \Gamma_{p\gamma \rightarrow \mathcal{M}}^{\alpha} \frac{dn'^{\alpha}_{p\gamma \rightarrow \mathcal{M}}}{dE'_p}(E'_p, E'_{\mathcal{M}}) dE'_p. \quad (4.4)$$

The sum runs over all possible interactions α , see Eqs. (4.1)–(4.3). The seed proton density per unit energy is $n'_p(E'_p)$ (in units of $\text{cm}^{-3} \text{GeV}^{-1}$), while $\Gamma_{p\gamma\rightarrow\mathcal{M}}^\alpha(E'_p)$ is the production rate for a given interaction (in units of s^{-1}), and $dn'_{p\gamma\rightarrow\mathcal{M}}/dE'_p$ represents the probability density for production of a meson with energy $E'_\mathcal{M}$ given that the incident proton has an energy E'_p .

In order to simplify the numerical solution of the integral above, we assume that all pions are produced with a certain energy that does not depend on the parent proton energy:

$$\frac{dn'_{p\gamma\rightarrow\mathcal{M}}}{dE'_p} \simeq M_\mathcal{M}^\alpha \times \delta(E'_\mathcal{M} - \chi_\mathcal{M}^\alpha E'_p) , \quad (4.5)$$

where $M_\mathcal{M}^\alpha$ is the multiplicity of the interaction and $\chi_\mathcal{M}^\alpha$ describes the amount of energy transferred to the produced meson. We also assume an isotropic photon distribution. Hence, Eq. (4.4) becomes:

$$Q'_\mathcal{M}(E'_\mathcal{M}) = \sum_\alpha n'_p \left(\frac{E'_\mathcal{M}}{\chi_\mathcal{M}^\alpha} \right) \frac{m_p c^2}{E'_\mathcal{M}} M_\mathcal{M}^\alpha \int_{E_{\gamma,r}^{\text{th},\alpha}/2}^{+\infty} f^\alpha(y) n'_\gamma \left(y \frac{\chi_\mathcal{M}^\alpha m_p c^2}{E'_\mathcal{M}} \right) dy , \quad (4.6)$$

with

$$f^\alpha(y) = \frac{1}{2y^2} \int_{E_{\gamma,r}^{\text{th},\alpha}}^{2y} E_{\gamma,r} \sigma^\alpha(E_{\gamma,r}) dE_{\gamma,r} . \quad (4.7)$$

The parameters characterizing each interaction α (namely $\chi_\mathcal{M}^\alpha$, $M_\mathcal{M}^\alpha$, $f^\alpha(y)$ and $E_{\gamma,r}^{\text{th},\alpha}$) can be found in Ref. [78].

4.2 Neutrino production

The mesons (π^+ , π^- , K^+ and K^-) produced in the reactions illustrated above can decay into neutrinos through the following channels:

$$\pi^+ \rightarrow \mu^+ + \nu_\mu \rightarrow e^+ + \nu_e + \bar{\nu}_\mu + \nu_\mu \quad (4.8)$$

$$K^+ \rightarrow \mu^+ + \nu_\mu \rightarrow e^+ + \nu_e + \bar{\nu}_\mu + \nu_\mu \quad (4.9)$$

and similar reactions hold for the antiparticle conjugates. Other channels of kaon decay are neglected since their branching ratio is smaller and they would generate lower energy neutrinos.

The neutrino production for the flavor ν_β from the decay of \mathcal{M} is given by [78]:

$$Q'_{\nu_\beta}(E'_{\nu_\beta}) = \int_{E'_{\nu_\beta}}^{+\infty} Q'_\mathcal{M}(E'_\mathcal{M}) \left[1 - \exp \left(-\frac{\tau'_{\text{cool}}}{\tau'_l} \right) \right] \frac{1}{E'_\mathcal{M}} F_{\mathcal{M}\rightarrow\nu_\beta} \left(\frac{E'_{\nu_\beta}}{E'_\mathcal{M}} \right) dE'_\mathcal{M} . \quad (4.10)$$

with ν_β representing one neutrino (or antineutrino, $\bar{\nu}_\beta$) species. The exponential term in the equation above takes into account the cooling of the decaying particle, with τ'_{cool} and τ'_l being the total cooling timescale and the mean lifetime of \mathcal{M} , respectively. The function $F_{\mathcal{M}\rightarrow\nu_\beta}(E'_{\nu_\beta}/E'_\mathcal{M})$ encapsulates the reaction kinematics and is defined as in Ref. [50]. In particular, the muon decay into neutrinos depends on the muon helicity, as illustrated in Ref. [50].

4.3 Neutrino fluence at Earth

En route to the Earth, neutrinos change their flavor, with transition and survival probabilities defined as follows [80]:

$$P_{\nu_e \rightarrow \nu_\mu} = P_{\nu_\mu \rightarrow \nu_e} = \frac{1}{4} \sin^2 2\theta_{12} , \quad (4.11)$$

$$P_{\nu_\mu \rightarrow \nu_\mu} = \frac{1}{8} (4 - \sin^2 2\theta_{12}) , \quad (4.12)$$

$$P_{\nu_e \rightarrow \nu_e} = 1 - \frac{1}{2} \sin^2 2\theta_{12} , \quad (4.13)$$

with $\theta_{12} = 33.5^\circ$ [81]. Transition and survival probabilities are the same assuming antineutrinos instead of neutrinos. Hence the neutrino fluence F_{ν_β} (in units of $\text{cm}^{-2} \text{GeV}^{-1}$) is:

$$F_{\nu_\beta}(E_{\nu_\beta}) = V'_s t_{\text{dur}} \frac{(1+z)^2}{4\pi d_L(z)^2} \sum_{\alpha} P_{\nu_\alpha \rightarrow \nu_\beta} Q'_{\nu_\alpha} \left(\frac{E_{\nu_\beta}(1+z)}{\Gamma} \right) . \quad (4.14)$$

Within a flat Λ CDM cosmology, the luminosity distance is given by

$$d_L(z) = \frac{c(1+z)}{H_0} \int_0^z \frac{dz'}{\sqrt{\Omega_\Lambda + \Omega_M(1+z')^3}} , \quad (4.15)$$

where $H_0 = 67.4 \text{ km s}^{-1} \text{ Mpc}^{-1}$, $\Omega_M \simeq 0.315$, and $\Omega_\Lambda \simeq 0.685$ [82].

5 Neutrino production from nuclear photohadronic interactions

The outflows of GRB jets may contain a certain fraction of nuclei [30]. Nuclei can be synthesized along the jet, loaded at the base of the jet, or produced in the stellar ejecta and entrained in the jet. However, photodisintegration from high-energy photons and spallation from protons and neutrons may disintegrate such nuclei. In fact, Ref. [31] concluded that the survival of nuclei up to the region of neutrino production is unlikely in HL-GRBs in the internal shock and photospheric models, but nuclei could easily survive in magnetized jets or LL-GRBs due to the smaller photon density. In this section, we introduce the method adopted to model jets containing nuclei through photohadronic interactions.

5.1 Monte Carlo simulation of nuclear cascades

In order to model the neutrino emission, interactions of nuclei in the jet should be taken into account. To this purpose, Ref. [32] numerically solved a system of partial differential equations to compute the spectrum of any nucleus as a function of time and energy; while Ref. [47] relied on the SOPHIA event generator to compute energy loss and photodisintegration processes of accelerated nuclei. In the following, we first model nuclear disintegration and nuclear decay. Then, along the lines of Ref. [47], we outline a Monte-Carlo algorithm that generates nuclear cascades, the Nuclear Cascade Monte Carlo (NCMC). The steps leading to the production of neutrinos, presented in this section, are illustrated in Fig. 2.

5.1.1 Nuclear photodisintegration

Nuclei undergo photon-nucleus and nucleus-nucleus collisions. However, since the photon density in the jet is several orders of magnitude larger than the density of nuclei, we only focus on photon-nucleus interactions and neglect any nucleus-nucleus collision.

Photonuclear interactions are fundamentally different than $p\gamma$ and $n\gamma$ interactions. Indeed, nuclei are made of bonded nucleons. Photons with enough energy can break the nuclear bond, leading to the emission of one or several nucleons. We should distinguish between two ranges for the energy of the incident photon in the rest frame of the nucleus: The Giant Dipole Resonance (GDR) with $E_{\gamma,r} \in [E_{\gamma,r}^{\text{th}}, 140 \text{ MeV}]$ and the photomeson (PM) range for $E_{\gamma,r} > 140 \text{ MeV}$ [79]. The GDR threshold energy $E_{\gamma,r}^{\text{th}}$ varies as a function of (Z, A) , but it is approximately 10 MeV [83].

Data from photonuclear reactions are relatively scarce compared to $(p, n)\gamma$ interactions. However, a few models for the cross-section and branching ratios for any nucleus with mass number $A \leq 56$ exist. Major improvements on the estimation of these cross-sections have been made thanks to the Monte-Carlo event generation software Geant4 [84]. We adopt fits from Refs. [85] and [79] for the GDR and PM ranges of the cross section. Regarding the branching ratios of these processes, we draw from Refs. [86] and [79] for the giant dipole resonance and the photomeson energy ranges, as illustrated in Appendix A (this appendix presents an extensive description of the modeling of the cross section, the branching ratios and the adopted parameters).

5.1.2 Nuclear decay

Any stable nucleus that loses nucleons may become a radioactive isotope. We have refined the NCMC by taking into account both lifetimes and radioactive decay mechanisms of any isotope of mass number $A \leq 56$. To this purpose, we have retrieved nuclear decay data from Ref. [87] (cf. Appendix A.2).

When a nucleus undergoes photodisintegration, we compute its new isotope lifetime at rest t_l , randomly extracting a time from a distribution following the exponential probability density:

$$p(t_l) = \frac{1}{\bar{t}_l} e^{-\frac{t_l}{\bar{t}_l}}, \quad (5.1)$$

with \bar{t}_l being the mean decay time of the isotope at rest. The lifetime in the reference frame of the jet is

$$t'_l = \frac{E'_A}{m_A c^2} t_l, \quad (5.2)$$

where t'_l is the comoving lifetime of the isotope in the jet frame. Assuming that the isotope is created at $t' = 0$, if photodisintegration does not happen at t'_l , the isotope decays as illustrated in Appendix A.2.

Following the computed branching ratios, we can see that it is unlikely for a nucleus to stray from the valley of stability, as shown in Fig. 3. Since we are interested in the high-energy tail of the spectral energy distribution of nuclei, the lifetime of radioactive nuclei in the comoving frame is large (see Eq. 5.2). This implies that the nucleus is relatively stable and neutrino emission from β^+/β^- processes from radioactive decays is negligible with respect to photohadronic interactions [32]. The only exception is the β^- decay of free neutrons, which we take into account given that the related radioactive isotope can be abundant, see for example Fig. 3.

5.1.3 Monte Carlo algorithm and particle spectra

Accelerated nuclei can be injected anytime during the interaction time interval, $t'_{\text{shock}} = t'_{\text{dur}}/N_{\text{shock}}$. This implies that we can compute a random interaction time for each Monte-Carlo event as $t'_{\text{eff}} = t'_{\text{shock}} U(0, 1)$, with $U(0, 1)$ being the uniform probability density function

Figure 3. Contour plot of the fraction of the total energy (initially injected in ^{56}Fe) carried by the different isotopes in the plane spanned by N and Z for our benchmark GRB (cf. Table 1 for Fe-jet). The results for the internal shock, photospheric and ICMART models are plotted from left to right, respectively. In order to guide the eye, ^{56}Fe , ^{28}Si , ^{16}O , and p are marked with red stars. The internal shock model does not favor efficient nuclear cascades with respect to the other two models. The ICMART model leads to the most efficient cascades, which in turn determine the largest neutrino emission as shown in Fig. 4.

between 0 and 1. For each Monte-Carlo event, t'_{eff} is split into N equal time steps $\Delta t' = t'_{\text{eff}}/N$. Hence, the probability of a photonuclear interaction for a nucleus $^A_Z X$ of energy E'_A , during the time interval $\Delta t'$ in the comoving frame of the jet is:

$$p_{A\gamma}(E'_A, A, Z) = R'_{A\gamma}(E'_A, A, Z) \Delta t' , \quad (5.3)$$

with $R'_{A\gamma}$ being the photonuclear interaction rate computed according to Eq. (3.8). At each time step, nuclei can interact or not with photons according to Eq. (5.3). If an interaction occurs, one of the physical processes described in Sec. 5.1.1 is randomly selected according to the branching ratios. In parallel, nuclei lose energy at each time step, following the adiabatic cooling; excluding the photodisintegration cooling which is already taken into account through the NCMC, adiabatic processes always dominate the total cooling timescale, as shown in Fig. 1. If no interaction takes place, when the nucleus is unstable it radioactively decays, as described in Sec. 5.1.2.

We assume that, after a photonuclear interaction that generates (N_p, N_n) protons and neutrons, only nucleons and no nuclei can be emitted. For instance, the loss of 2 protons and 2 neutrons generates 2 free protons and 2 free neutrons, and not ^4_2He . The energy of the produced nucleon $\mathcal{N} = (p, n)$ is $E'_{\mathcal{N}} = E'_A/A$, with E'_A being the energy of the parent particle $^A_Z X$ in the comoving frame of the jet.

For any accelerated nuclear species, the spectral energy distribution $n'_A(E'_A)$ (in units of $\text{cm}^{-3} \text{GeV}^{-1}$) of the seed population is adopted to draw the injected nuclear species in the NCMC. For simplicity, we only inject pure isotopes. In order to do this, we randomly select the initial energy of the seed nuclei following a uniform probability in logarithmic scale. Then, for any given energy, each seed nucleus is associated to a certain density computed following $n'_A(E'_A)$. The nuclear cascade is then generated and we retrieve the density and final energy of each isotope eventually created. We then add each contribution to the final spectra. For more details, we refer the reader to Appendix A.3.

5.2 Nuclear photohadronic interactions

It is now possible to compute the neutrino production associated to each isotope, while for the production of mesons from protons and neutrons, we rely on Sec. 4. For nuclei with mass number $A \leq 56$, the meson production $Q'_{\mathcal{M}}(E'_{\mathcal{M}})$ (in units of $\text{cm}^{-3} \text{s}^{-1} \text{GeV}^{-1}$) is given by [78]:

$$Q'_{\mathcal{M}}(E'_{\mathcal{M}}) = \sum_{\Delta E} n'_A \left(\frac{E'_{\mathcal{M}}}{\chi_{\mathcal{M}}^{\Delta E}} \right) \frac{m_A c^2}{E'_{\mathcal{M}}} M_{\mathcal{M}}^{\Delta E} \int_{\Delta E} f^{\Delta E}(y) n'_\gamma \left(y \frac{\chi_{\mathcal{M}}^{\Delta E} m_A c^2}{E'_{\mathcal{M}}} \right) dy, \quad (5.4)$$

where \mathcal{M} is any meson (i.e., pions and kaons) and the sum runs over ΔE , which is an energy interval where the multiplicity and the fraction of the energy transferred to produced mesons are assumed to be constant (see Appendix B).

Each interaction type is characterized by three parameters: $\chi_{\mathcal{M}}^{\Delta E}$ represents the amount of energy transferred from the seed nucleus to the newly created meson ($E'_{\mathcal{M}} = \chi_{\mathcal{M}}^{\Delta E} E'_A$); the multiplicity, $M_{\mathcal{M}}^{\Delta E}$, describes how many mesons are created on average; $f^{\Delta E}(y)$ is computed as follows:

$$f^{\Delta E}(y) = \frac{1}{2y^2} \int_{E_{\gamma,r}^{\text{th},\Delta E}}^{2y} E_{\gamma,r} \sigma_{A\gamma \rightarrow \mathcal{M}}(E_{\gamma,r}) dE_{\gamma,r}, \quad (5.5)$$

with $E_{\gamma,r}^{\text{th},\Delta E}$ and $\sigma_{A\gamma \rightarrow \mathcal{M}}(E_{\gamma,r})$ being the threshold energy and the inelastic cross-section of photohadronic interactions for meson production, respectively.

In order to compute the cross section, previous work (e.g. Ref. [32]) relied on the Single Particle Model, according to which $\sigma_{A\gamma \rightarrow \mathcal{M}}(E_{\gamma,r}) \simeq A \sigma_{p\gamma \rightarrow \mathcal{M}}(E_{\gamma,r})$. However, since Ref. [79] showed that the Single Particle Model can be inaccurate in the photomeson regime, we adopt the empirical model proposed in Ref. [79], which provides more accurate results for nuclei up to ^{56}Fe . The function $f^{\Delta E}(y)$ is then computed using the empirical model total cross-section in the photomeson range (see Appendix B for details). The branching ratio for the photohadronic production is extracted from estimations of the cross-sections from Ref. [79]. Due to the lack of data, we model $M_{\mathcal{M}}^{\Delta E}$ and $\chi_{\mathcal{M}}^{\Delta E}$ adapting the method employed to compute $p\gamma$ interactions in Ref. [78]. The average values of $M_{\mathcal{M},p\gamma}^{\Delta E}$ and $\chi_{\mathcal{M},p\gamma}^{\Delta E}$ are taken into account for each ΔE , and we define $\chi_{\mathcal{M}}^{\Delta E} = \chi_{\mathcal{M},p\gamma}^{\Delta E} / A$, $M_{\mathcal{M}}^{\Delta E} = M_{\mathcal{M},p\gamma}^{\Delta E}$.

For the sake of simplicity, we assume that each nucleus contains an equal number of protons and neutrons. This approximation is reasonable given that it is unlikely for a nucleus to stray away from the valley of stability (which approximately corresponds to $N = Z = A/2$ for $A \leq 56$). This symmetry enables us to get comparable production of \mathcal{M} and $\bar{\mathcal{M}}$, reducing the computational time. For details on the inputs adopted for the different parameters, we refer the interested reader to Appendix B. Finally, the decay of each meson into neutrinos is computed as in Sec. 4.2 and the neutrino fluence expected at Earth follows Sec. 4.3, respectively.

6 Impact of the jet composition on the neutrino emission

In this section, we present our findings on the dependence of the neutrino signal on the jet composition. We investigate how the jet composition impacts the neutrino emission for the internal shock, photospheric and ICMART jet models. We then explore how the jet composition affects the neutrino emission across the allowed jet parameter space.

6.1 The role of the jet composition in kinetic and Poynting flux dominated jets

In order to facilitate a comparison, we consider the neutrino fluence obtained for a jet loaded with protons (p -jet) and a jet loaded with ^{56}Fe (Fe-jet) for the internal shock, photospheric and ICMART jet models. Jets with mixed composition or loaded with intermediate isotopes would have a neutrino fluence falling in between these two extreme cases. We also note that it is highly unlikely to have a jet mostly composed by iron, yet we investigate this case in order to explore the largest variability of the expected neutrino signal according to the jet composition. We otherwise assume identical jet properties (cf. Table 1); in particular, the total energy fraction going into accelerated protons is the same as the one going into accelerated iron. This implies that the same power law index is chosen for both accelerated protons and iron nuclei (see Sec. 6.2 for an extensive discussion about this hypothesis).

We note that the survival of nuclei up to the region of neutrino production may be unlikely for our benchmark model, especially for kinetic dominated jets [31]. Yet, we rely on this benchmark jet to assess the impact of the jet composition for illustrative purposes.

For the internal shock model, in order to test our NCMC approach, we compare our results with the three benchmark cases presented in Ref. [32]. In all cases, we find excellent agreement (results not shown here). We also find comparable neutrino fluences using the Single Particle Model, yet we prefer to employ the more accurate photohadronic model in the rest of this paper (see Sec. 5.2).

Figure 4 shows the spectral energy density of nuclei (left panels) and the neutrino fluence (right panels) for the internal shock model, the photospheric model and the ICMART model, from top to bottom respectively. Comparing Fe-jet (ochre line) with the p -jet (indigo line), we can see that the neutrino fluence is lower for Fe-jet than for the p -jet up to one order of magnitude, independent of the jet model. For the internal shock case, the density of nuclei is larger than the one of nucleons (cf. blue/green vs. red curves in the left panels), but neutrino production from nuclei is comparable to the one driven by protons/neutrons. Indeed, since the meson production from nuclei is not so efficient as the one from protons or neutrons, the neutrino fluence is smaller than what could be expected given the associated nuclei densities. The shape of the neutrino fluence is overall the same for jets, independent of the composition. In particular, the maximum of $E_\nu^2 F_{\nu_\mu + \bar{\nu}_\mu}$ is achieved at about the same energy $E_\nu^M \simeq 5 \times 10^7$ GeV.

For the photospheric model, cascades are more efficient than in the internal shock model, due to the larger photon luminosity which makes nuclear cascades more efficient, leading to larger proton and neutron densities (cf. Fig. 3 which displays the fraction of the total energy carried by lighter isotopes and nucleons for Fe-jet). The ICMART model shows efficient nuclear cascades, as shown in Fig. 3, which lead to the largest neutrino fluence across all three jet models. However, compared to the photospheric model, the maximum fluence is achieved at the same energy for both p - and Fe-jets, and no sharp cutoff at high energies is observed. This is explained because the crossing between the acceleration and cooling timescales happens at larger energies in the ICMART model since the magnetic field is stronger than in the photospheric model. Hence, the acceleration processes are more efficient and the maximum energy per nucleon inside an iron nucleus is similar to the maximum energy found for protons.

Our findings are in general agreement with the ones presented in Fig. 7 of Ref. [32], our internal shock case would correspond to their “empty cascade” scenario, while our photospheric and ICMART models would correspond to their “populated cascade” scenario.

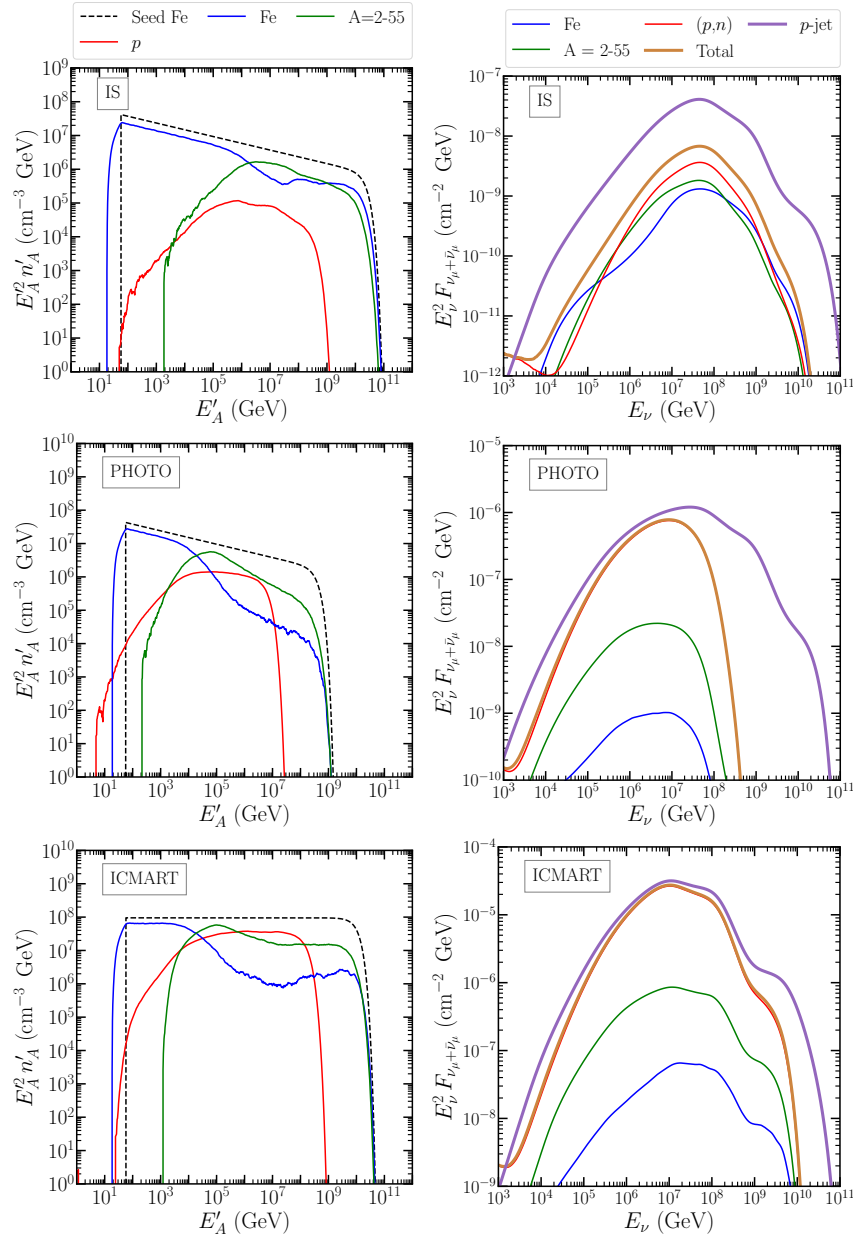

Figure 4. *Left:* Spectral energy density of nuclei as a function of the particle energy for our benchmark GRB (cf. Table 1) in the case of Fe-jet, for the internal shock, photospheric, and ICMART models, from top to bottom respectively. *Right:* $\nu_\mu + \bar{\nu}_\mu$ neutrino fluence as a function of the neutrino energy for our benchmark GRB, in the case of a p -jet (indigo curve) and Fe-jet (the ochre curve represents the total neutrino emission). The relative contributions to the neutrino fluence from iron, all other lighter nuclei and nucleons are plotted in blue, green and red respectively (cf. spectra of the corresponding parent particles in the left panels). If the density of iron nuclei is larger than the one of all other nuclei, neutrinos are produced mostly through iron photohadronic interactions. Since meson production from nuclei is less efficient than the one from protons and neutrons, the neutrino fluence for Fe-jet is smaller than for p -jet, independent of the jet model. Nuclear cascades are more efficient for the photospheric and ICMART models than for the internal shock one; this leads to larger neutrino fluence than in the internal shock model for Fe-jet.

However, our results differ for their “inefficient cascade” scenario because of the empirical cross-section model adopted in this work (vs. the Single Particle Model adopted in Ref. [32]).

Figure 5. Nuclear cascade efficiency in the plane spanned by the radius (R_{IS}) of the interaction region and the isotropic luminosity (\tilde{L}_{iso}) for the photospheric model. *Left:* The contours represent the region where the related isotopes (iron in black, any other lighter nucleus in magenta, and protons and neutrons in yellow) contribute the most to the total density. *Right:* Same as the left panel, but it represents the dominant contribution to the total neutrino fluence. Dashed orange lines indicate isocontours of $E_{\nu}^2 F_{\nu_{\mu} + \bar{\nu}_{\mu}}$ (in units of GeV cm^{-2}). For low luminosity and/or large radius, nuclear cascades are not efficient and iron dominates both the energy density of nuclei and the neutrino fluence. As the luminosity increases and/or the radius decreases, nuclear cascades are more efficient, and intermediate isotopes can dominate the nuclear energy density with a resulting larger neutrino fluence. However, protons and neutrons are responsible for most of the total neutrino fluence despite their lower density.

Figure 5 highlights the variation of nuclear cascade efficiency in the plane spanned by the radius of interaction and the GRB luminosity. For illustrative purposes, the photospheric model is adopted as a proxy since the overall structure would be the same for the internal shock model as well, while the ICMART model would correspond to a slice in this plot drawn for constant radius. For low luminosity and/or large radius, nuclear cascades are not efficient and iron dominates both the particle density and the neutrino fluence. As discussed earlier (see Fig. 4), we expect that the total neutrino fluence in this region is approximately reduced by one order of magnitude compared to a p -jet. As the luminosity increases and/or the radius decreases, nuclear cascades become more efficient, and we reach a region where intermediate isotopes dominate the nuclear energy density. However, except for a thin region (cf. the right panel of Fig. 5, magenta region), protons and neutrons are responsible for most of the total neutrino fluence despite their lower density. This is because nucleons are more efficient at producing neutrinos from photohadronic interactions than nuclei.

6.2 Dependence of the neutrino fluence on the injection spectral index of the parent nuclei and the jet Lorentz factor

We now extend our investigation of the dependence of the neutrino emission on the jet composition beyond our benchmark GRB jet, considering the variation of the neutrino fluence as a function of the bulk Lorentz factor (Γ) and the injection spectral index of the seed accelerated particle spectra (k). We choose to compute the neutrino fluence for $\Gamma = 10$ –1000. Regarding the power law index, for relativistic shocks (internal shock and photospheric

Figure 6. Dependence of the neutrino fluence on the injection spectral index of the accelerated parent nucleus/nucleon spectra. *Top:* $\nu_\mu + \bar{\nu}_\mu$ neutrino fluence as a function of the neutrino energy for $k = 2.0\text{--}3.0$, using our benchmark Fe-jet (cf. Table 1) for the internal shock, photospheric, and ICMART jet models; the other jet parameters are defined as in Table 1, in particular $\Gamma = 300$ is fixed. *Bottom:* Ratio between the Fe-jet neutrino fluence and the p -jet one as a function of the neutrino energy. A smaller k allows for a larger neutrino fluence, because it favors larger densities of seed nuclei; such trend holds independent of the jet composition.

models), theoretical work predicts $k \simeq 2.2$ [88] and particle-in-cell simulations find $k \simeq 2.0\text{--}2.5$ [58, 59]; for magnetized jets, particle-in-cell simulations suggest $k \simeq 2.0$ [60, 61]. It is crucial to highlight that most of the existing work does not consider populations of heavier nuclei because particle-in-cell simulations with heavier nuclei are computationally intensive. In Ref. [59], it has been found that the power law index does not depend strongly on the mass of the ion for ion masses ranging from $m_i = 25 m_e$ to $m_i = 1600 m_e \simeq m_p$. Thus, we extrapolate from this result, and consider that the power law index for an iron population would be similar to the one of a proton population and explore the efficiency of neutrino production for $k = 2.0\text{--}3.0$ for p - and Fe-jets.

The top panels of Fig. 6 show the neutrino fluence for varying k for the internal shock, photospheric and ICMART models; all other jet parameters are kept fixed as indicated in Table 1. Decreasing the power law index tends to increase the neutrino fluence, because it allows for larger densities of seed nuclei. We can also note that decreasing k slightly increases

Figure 7. Same as Fig. 6, but for investigating the dependence of the neutrino fluence on Γ ($k = 2.2$ is fixed for both the internal shock and the photospheric models, while $k = 2.0$ is used for the ICMART case). Decreasing Γ increases the neutrino fluence, with the larger spread occurring for the internal shock and photospheric jet models. In fact, for these models, the interaction radius scales as Γ^2 , which implies that for larger Γ , internal shocks happen at a radius where both photon and seed nuclei have lower densities. However, this is not the case for the ICMART model, for which the radius of interaction is independent of the bulk Lorentz factor. This explains the milder variation of the neutrino fluence on Γ in the internal shock model. A strong variation of the neutrino fluence as a function of Γ occurs according to the composition.

the energy E_ν^M corresponding to the maximum neutrino fluence. For our benchmark jet, we also observe that k mostly scales the neutrino fluence in a similar fashion for p - and Fe-jets, as evident from the bottom panels of Fig. 6.

Figure 7 explores the impact of Γ on the neutrino emission. For fixed composition, from the top panels of Fig. 7, we can see that decreasing Γ tends to increase the neutrino fluence, in a way that depends on the jet model. For the internal shock and photospheric models, changes in Γ affect the radius of interaction ($R_{\text{IS}} = 2\Gamma^2 c \tilde{t}_{\text{var}}$); when Γ decreases, internal shocks happen at a radius where both photon and seed nuclei have larger densities. However, this is not the case for the ICMART model, for which the radius of interaction is independent of the bulk Lorentz factor (internal shocks trigger magnetic reconnection events assumed to happen at a nearly constant radius). This explains the milder dependence of

the neutrino fluence on Γ in the internal shock model. The energy corresponding to the maximum neutrino fluence (E_ν^M) is strongly shifted to lower energies as Γ decreases; this is because higher photon densities are achieved as Γ decreases, hence the photodisintegration timescale increases and crosses the acceleration timescale at lower energies. This implies that the cutoff energy of the parent spectrum decreases, which also forces the neutrino fluence to peak at lower energies. This effect is less prominent in Poynting-flux jets than in kinetically-dominated jets since the acceleration process is more efficient in the former thanks to the larger magnetic fields.

The bottom panels of Fig. 7 also highlight a strong variation of the neutrino fluence as a function of Γ according to the composition. The ratio between the neutrino fluence of Fe-jet and p -jet is a direct measurement of the efficiency of nuclear cascades. For large Γ , this ratio saturates near 10^{-1} because of the less efficient production of neutrinos from ^{56}Fe nuclei; then, there is a transition from inefficient to efficient cascades as Γ decreases due to higher photon densities. This transition is more or less sharp depending on the model, following the dependence on the interaction radius on Γ . For small Γ , the ratio saturates around 1, which is consistent with the fact that the Fe-jet with highly efficient cascades of iron into nucleons is equivalent to the p -jet (disintegrated ^{56}Fe leads to 26 protons and 30 neutrons; photohadronic interactions are equivalent for protons and neutrons as long as no distinction between neutrino and antineutrino is considered).

Figure 8 quantifies the dependence of the neutrino energy (E_ν^M) at which the fluence peaks in Fe-jets and p -jets in the parameter space spanned by k and Γ . In order to avoid degeneracies in the computation of E_ν^M for the cases where the neutrino fluence reaches a plateau around the spectral peak, we compute the two energies ($E_\nu^{90\%,1}$ and $E_\nu^{90\%,2}$) where the fluence is 90% of its maximum. Then, the maximum energy is computed as $\log_{10}(E_\nu^M) = 1/2 [\log_{10}(E_\nu^{90\%,1}) + \log_{10}(E_\nu^{90\%,2})]$. The contours of the ratio of E_ν^M for the Fe-jet and p -jet in Fig. 8 highlight that E_ν^M does not change much as a function of the jet composition. However, E_ν^M has non-trivial dependencies on the jet parameters according to the jet model. We note that the normalization of the neutrino fluence does strongly depend on the jet composition, as illustrated in Figs. 6 and 7.

7 Dependence of the diffuse neutrino flux on the jet composition

In this work, we do not explore the detection prospects of neutrinos, since we are interested in assessing the model dependence on the jet composition. On the other hand, in order to gauge the variation of the neutrino signal as a function of the jet composition for different jet models, we consider the diffuse emission of neutrinos from HL- LL- and sGRBs. The diffuse neutrino emission is defined as follows:

$$F_{\nu_\beta}^d(E_{\nu_\beta}) = \int_{z_{\min}}^{z_{\max}} \frac{c}{4\pi H_0 \Gamma} \frac{1}{\sqrt{\Omega_\Lambda + (1+z)^3 \Omega_M}} R_{\text{GRB}}(z) \frac{4\pi \Gamma d_L(z)^2}{(1+z)^3} F_{\nu_\beta}(E_{\nu_\beta}, z) dz, \quad (7.1)$$

where $R_{\text{GRB}}(z)$ is the cosmological rate (in units of $\text{Gpc}^{-3} \text{ yr}^{-1}$), which is different for HL-GRBs, LL-GRBs and sGRBs. For HL-GRBs, we model the rate following Ref. [89, 90], for

Figure 8. Contour plots of the ratio between the neutrino energy at which the neutrino fluence peaks for the Fe-jet and the p-jet in the plane spanned by k and Γ . From left to right, the contour plots for the internal shock, photospheric, and ICMART models are illustrated, respectively. The energy at which the neutrino fluence peaks does not depend on the jet composition strongly for all considered jet models, however the normalization of the spectral energy distribution does (cf. Figs. 6 and 7).

Table 2. Jet parameters assumed for HL-GRBs [54, 94], LL-GRBs [91, 95, 96] and sGRBs [95, 97, 98]. All other jet parameters are modeled as specified in Table 1 according to the jet model.

	HL-GRB	LL-GRB	sGRB
\tilde{E}_{iso}	4.5×10^{54} erg	1.5×10^{52} erg	1.05×10^{53} erg
Γ	300	10	300
t_{dur}	30 s	1000 s	1 s
t_{var}	0.5 s	100 s	0.01 s

LL-GRBs we consider Refs. [91, 92], and for sGRBs we follow Ref. [93]:

$$R_{\text{HL-GRB}}(z) = \rho_{0,\text{HL-GRB}} \begin{cases} (1+z)^{2.1} & \text{for } z < z_{\star}^{\text{HL-GRB}} \\ (1+z_{\star}^{\text{HL}})^{2.1+0.7} (1+z)^{-0.7} & \text{for } z > z_{\star} \end{cases}, \quad (7.2)$$

$$R_{\text{LL-GRB}}(z) = \rho_{0,\text{LL-GRB}} \left[(1+z)^{-34.0} + \left(\frac{1+z}{5000} \right)^{3.0} + \left(\frac{1+z}{9} \right)^{35.0} \right]^{-1/10}, \quad (7.3)$$

$$R_{\text{sGRB}}(z) = \begin{cases} 10^{\alpha} z^3 - \beta z^2 + \gamma z + \delta & \text{for } z < z_{\star}^{\text{sGRB}} \\ 10^{-\eta z + \mu} & \text{for } z > z_{\star}^{\text{sGRB}} \end{cases} \text{ Gpc}^{-3} \text{ yr}^{-1}, \quad (7.4)$$

with $\rho_{0,\text{HL-GRB}} = 200\text{--}2000 \text{ Gpc}^{-3} \text{ yr}^{-1}$, $\rho_{0,\text{LL-GRB}} = 0.5\text{--}0.8 \text{ Gpc}^{-3} \text{ yr}^{-1}$, $z_{\star}^{\text{HL-GRB}} = 3.6$, and $z_{\star}^{\text{sGRB}} = 6.0$. We have $\alpha = [0.049, 0.047, 0.048]$, $\beta = [0.636, 0.609, 0.586]$, $\gamma = [1.9, 1.9, 2.0]$, $\delta = [0.01, 0.49, 0.98]$, $\eta = [0.6, 0.53, 0.23]$, and $\mu = [3.0, 3.6, 3.6]$. For each of the parameters of R_{sGRB} , we indicate fit values corresponding to the lower, average, and higher redshift rate.

As for the jet parameters entering the neutrino fluence, we differentiate among the three GRB types as summarized in Table 2 and otherwise use the parameters in Table 1. For each GRB type, we compute the diffuse emission considering p -jet and Fe-jet.

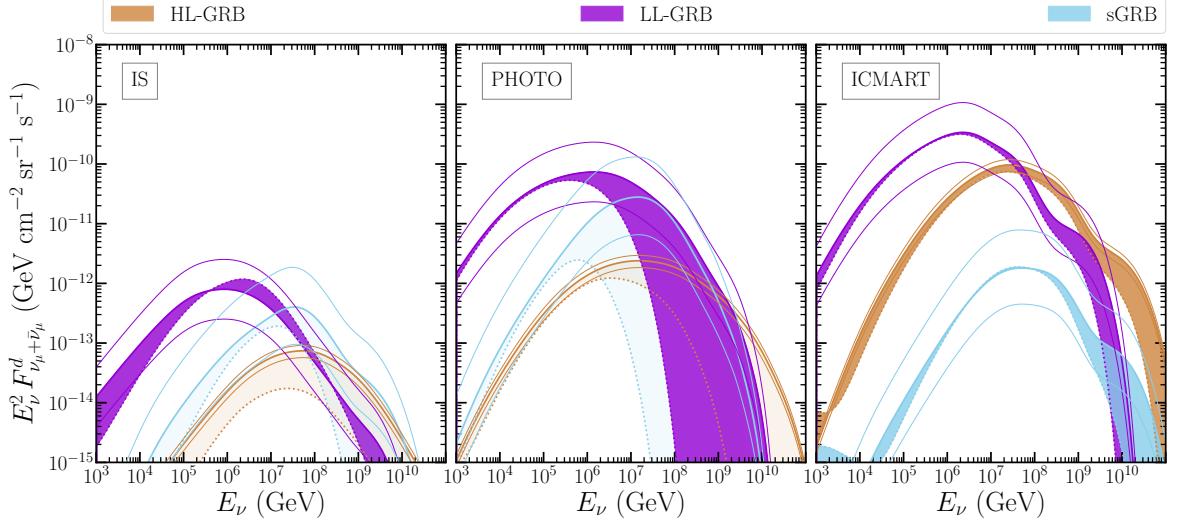

Figure 9. Diffuse $\nu_\mu + \bar{\nu}_\mu$ emission for HL-GRBs (ochre), LL-GRBs (purple) and sGRBs (light blue) for the internal shock, photospheric and ICMART models, from left to right, respectively, computed assuming the average redshift rate. For each jet model and GRB type, the band marks the uncertainty due to the jet composition (p -jets are plotted as solid lines and Fe-jets as dotted lines; any mixed composition is represented by the color band). For each GRB type, the color band is shadowed for the cases where nuclear contamination is expected to be disfavored. The uncertainty due to the jet composition is smaller or at most comparable to the uncertainty due to redshift rate. The latter is represented by solid lines for the p -jet. Independent of the GRB type, the diffuse neutrino flux is expected to be lower for the internal shock model.

Figure 9 shows the expected diffuse emission for HL-GRBs, LL-GRBs and sGRBs, for the three jet models, from left to right, respectively. For fixed jet model, for each GRB type, the band represents the uncertainty due to the jet composition (with the lower emission corresponding to p -jet and the larger one to Fe-jet). In order to compare the uncertainty due to the jet composition with the one due to the redshift rate, we plot three solid lines for each GRB type, representing the diffuse flux of a p -jet assuming the lowest, average and highest GRB rate. Independent of the GRB type, the diffuse neutrino emission is expected to be smaller for the internal shock model.

In order to allow for a comparison across different jet models, we use the same jet parameters (e.g. isotropic energy and total duration of the burst) for the internal shock, photospheric and ICMART models. This implies that, due to the smaller microphysical parameters typical of the internal shock model, the overall gamma-ray luminosity predicted within the internal shock model is smaller than the one of the other two models, and about two orders of magnitude below the peak of the luminosity function for each GRB family [94, 98–100]. While this choice might seem conservative, we are interested in exploring the variation of the neutrino signal across jet models and composition relying on the same benchmark jet parameters.

While we refrain from an exploration of the detection prospects, that would require a dedicated exploration of the GRB population and survival of nuclei according to the jet properties, it is interesting to note that the uncertainty on the GRB rate is generally larger or at most comparable to the uncertainty due to the composition. Magnetically dominated jets and low-luminosity ones are the most likely to guarantee the survival of heavy nuclei

up to the interaction region [31]. For this reason, we use darker (lighter) shaded bands to distinguish between the GRB types that are likely (unlikely) to be loaded with heavier nuclei at the interaction region.

8 Discussion and outlook

It is likely that the GRB jet is not only composed by composed of protons, but also heavier nuclei, either synthesized or entrained in the jet [30, 31]. In this paper, we have explored the impact of the jet composition on the neutrino emission for kinetic dominated jets (according to the internal shock and photospheric models) as well as for Poynting flux dominated jets (considering the ICMART model). To this purpose, we have built a Monte-Carlo algorithm that simulates nuclear cascades for any nucleus with $A \leq 56$.

We find that the nuclear composition affects the neutrino fluence in quantitatively different ways according to the jet model, although the overall qualitative trend is similar across models. The neutrino fluence can be lower up to one order of magnitude for the Fe-jet case with respect to the p -jet scenario because the production of mesons from nuclei is less efficient than the one from protons. The efficiency of neutrino production is linked to the jet model; the ICMART model, because of its fixed particle interaction radius, guarantees efficient nuclear cascades leading to an overall larger neutrino fluence across all three jet models, even for the Fe-jet case.

Independent of the jet model, the survival of nuclei and inefficient nuclear cascades lead to a lower neutrino fluence due to the lower efficiency of nuclear photohadronic interactions. Conversely, if nuclei are disintegrated, the neutrino fluence may be similar to the one from a jet loaded with protons. The sketch in Fig. 10 summarizes how the jet luminosity and the radius of neutrino production, within a one-zone jet model, affect the nuclear cascade efficiency and therefore the neutrino production (left and right panels, respectively); see also Fig. 5.

Exploring the jet parameter space, we showed that the power law index of the seed spectra of nuclei mostly affects the normalization of the spectral energy distribution of neutrinos, without altering its shape. On the other hand, the bulk Lorentz factor of the jet is important to assess the efficiency of nuclear cascades and is thus highly correlated with both the composition and the GRB model. Our work focuses on neutrinos only, complementing dedicated work in this direction centered on ultra-high-energy cosmic rays, e.g. Refs. [32, 34].

We have explored two extreme cases in terms of composition: either assuming that the jet is fully made out of protons or pure ^{56}Fe . Any other mixed composition, involving nuclei lighter than ^{56}Fe is expected to fall in between the two extreme scenarios considered here. However, it is important to keep in mind that, according to the jet luminosity and Lorentz boost factor, heavier nuclei may not survive in the jet [31, 101]; we do not explore the conditions for survival of nuclei in this paper, rather focus on assessing the uncertainty linked to the jet composition across jet models. Further work should be dedicated to explore the neutrino and cosmic ray emission from jets with mixed composition, guided by self-consistent simulations of the source and their ejecta composition. Nuclear cascades from GRBs could also contribute to the spectrum of ultra-high-energy cosmic rays [32, 37, 101, 102].

Modeling the diffuse neutrino emission from HL-GRBs, LL-GRBs and sGRB, for our three jet models and varying jet composition, we find that also for Fe-jets, the diffuse neutrino flux from LL-GRBs may dominate the overall GRB diffuse emission, consistently with the findings of Refs. [95, 103] for p -jets. Our results on the diffuse neutrino emission are in

Figure 10. *Left:* Sketch of the efficiency of nuclear cascades for our one-zone jet model in the plane spanned by the radius of neutrino production and the jet luminosity. The nuclear species dominating the particle density are highlighted in color (protons and neutrons in red, any nucleus lighter than iron in green, and iron in light blue). *Right:* Same as the left panel, except for the fact that the different regions are colored depending on which isotopes contribute the most to the total neutrino fluence. The efficiency of nuclear cascades is the largest for small interaction radii and larger jet luminosity. Notably, when nuclear cascades are efficient, the neutrino production is driven by proton and neutrons in a larger region of the parameter space (cf. green band that is smaller for the right panel).

overall good agreement with Ref. [38], which predicted that the neutrino production from nuclei should be up to one order of magnitude lower in the limit of inefficient nuclear cascades. However, the uncertainty on the jet composition is generally smaller or at most comparable with the one associated to the GRB cosmological rate.

Acknowledgments

A Details on the Monte Carlo simulation of nuclear cascades

In this appendix, we present details on the modeling of the photonuclear cross section for any nuclei with mass number $A \leq 56$, as well as the half-life and radioactive decay channels of unstable isotopes. We also describe the method adopted to construct the particle spectral energy distributions and the modeling of the nuclear photohadronic interactions.

A.1 Modeling of the nuclei photonuclear cross section

In order to model the photonuclear cross sections we distinguish among three different energy regimes:

Figure 11. Comparison among different models of the ^{56}Fe photonuclear inelastic cross section. The blue, orange and green curves refer to the models presented in Refs. [86], [85] and [79], respectively. The dashed vertical lines highlight the different energy ranges considered in this work (GDR1, GDR2, and PM).

Giant Dipole Resonance 1. We consider the energy range between 0 and 30 MeV as being the Giant Dipole Resonance 1 (GDR1) one; it coincides with the GDR peak. We use the fit from Ref. [85] to compute the total inelastic cross-section for any nucleus of mass number $A \leq 56$ in this energy region:

$$\sigma_{A\gamma}(E_{\gamma,r}, A) = \sum_{i=1,2,4,8} \frac{e^{i(\rho_i - z)}}{1 + e^{3i(\tau_i - z)}} + f_r(r_H + r_\Delta) + s_p f_p h_p, \quad (\text{A.1})$$

with $z = \ln(E_{\gamma,r}/1 \text{ MeV})$, and the fit parameters ρ_i , τ_i , f_r , r_H , r_Δ , s_p , f_p , and h_p being defined as in Ref. [85]. Figure 11 compares this fit to the GDR model presented in Ref. [86], displaying a satisfactory agreement in the GDR1 energy range.

In the GDR1 energy range, the emission of only one or two nucleons is possible. The fit of Ref. [85] does not provide this information, hence the data from Ref. [86] are used to compute the branching ratio $P_{\mathcal{N}}$ for $\mathcal{N} = Z + N$ nucleons emission. The branching ratio P is a function of the number (Z, N) of protons and neutrons emitted and is computed as follows:

$$P(Z, N) = P_{\mathcal{N}}(Z + N) \binom{Z + N}{Z} \frac{1}{2^{Z+N}}, \quad (\text{A.2})$$

where the binomial distribution is equivalent to the hypothesis that protons and neutrons have the same probability of being emitted and all emission channels are independent.

Giant Dipole Resonance 2. The second energy range is the Giant Dipole Resonance 2 (GDR2) one, which spans from 30 to 150 MeV. This range coincides with the transition between the GDR peak and the photomeson range. The fit in Eq. (A.1) is still used to compute the cross-section in this energy range and is displayed in Fig. 11. A notable improvement on the modeling of the cross section in this energy range has been achieved in Ref. [85], with respect to Ref. [86]. An estimation of the branching ratios $P_{\mathcal{N}}$ can be found in Ref. [86] (see Eq. (A.2)).

Photomeson regime. The photomeson energy range (PM) is defined for energies above 150 MeV, where the production of mesons is possible thanks to interactions with photons. Ref. [79] provides the cross-section and the estimation of the branching ratio in the PM range. We have performed a polynomial fit of the total inelastic cross-section (in microbarn):

$$\sigma_{A\gamma}^{PM}(E_{\gamma,r}, A) = A \left(\frac{A}{56} \right)^{\alpha(E_{\gamma,r})-1} \begin{cases} \sigma_{\text{low}}(E_{\gamma,r}) & \text{if } 0.18 \text{ GeV} \leq E_{\gamma,r} \leq 1 \text{ GeV} \\ \sigma_{\text{mid}}(E_{\gamma,r}) & \text{if } 1 \text{ GeV} \leq E_{\gamma,r} \leq 10^4 \text{ GeV} \\ \sigma_{\text{high}}(E_{\gamma,r}) & \text{if } E_{\gamma,r} \geq 10^4 \text{ GeV} \end{cases} \quad (\text{A.3})$$

Using $z = \log_{10}(E_{\gamma,r}/1\text{GeV})$, the expressions for the cross section above in the three energy ranges are respectively:

$$\sigma_{\text{low}}(E_{\gamma,r}) = 2720.9z^5 - 1979.5z^4 - 1139.4z^3 + 902.4z^2 - 165.1z + 139.1 \quad (\text{A.4})$$

$$\sigma_{\text{mid}}(E_{\gamma,r}) = -2.02z^5 + 25.32z^4 - 112.23z^3 + 212.91z^2 - 188.22z + 156.26 ; (\text{A.5})$$

$$\sigma_{\text{high}}(E_{\gamma,r}) = 39.1 \quad (\text{A.6})$$

while the function $\alpha(E_{\gamma,r})$ is defined as follows

$$\alpha(E_{\gamma,r}) = \begin{cases} 1 & \text{if } E_{\gamma,r} \leq 0.2 \text{ GeV} \\ 0.004z^5 - 0.023z^4 + 0.019z^3 + 0.018z^2 - 0.043z + 0.97 & \text{if } 0.2 \text{ GeV} \leq E_{\gamma,r} \leq 10^3 \text{ GeV} \\ 2/3 & \text{if } E_{\gamma,r} \geq 10^3 \text{ GeV} \end{cases} \quad (\text{A.7})$$

This PM parametrization of the cross section is displayed in Fig. 11.

The cross-sections of each process averaged over the PM energy range are used to compute the branching ratios for the five types of photonuclear reactions: direct proton production, direct neutron production, multi neutron production, spallation and pion production. The branching ratio of a process is estimated as the ratio of its cross-section over the total cross-section.

A.2 Radioactive decay of unstable isotopes

For each isotope, we extract the mean lifetime (or half-life) and decay channel from the International Atomic Energy Agency database [87]. Figure 12 shows the half-life (left panel) and decay type (right panel) for isotopes of mass number $A \leq 56$. We can see that the lifetimes can vary by orders of magnitudes. Moreover, the isotope stability decreases exponentially as the isotope position in the plane spanned by N and Z strays from the valley of stability (which corresponds to $Z = N = A/2$). An unstable isotope can undergo five types of radioactive decays: β^+ decay, β^- decay, α decay, single proton emission and single neutron emission. Single proton and neutron emission are unusual decay types that describe the behavior of the most proton-rich/neutron-rich isotopes. Such isotopes are so unstable that they emit a proton/neutron almost instantaneously. No precise measurement of their lifetime is available; this explains why they are not highlighted in color in the left panel of Fig. 12. Consequently, if a nucleus arrives in the proton/neutron emission region, the emission of single nucleons can be integrated out until the isotope reaches a β^+ , β^- , α or stable state (as indicated in the contour scale of the right panel).

Figure 12. Contour plots of the half-life (left panel) and radioactive decay channels (right panel) for nuclei of mass number $A \leq 56$ [87] in the plane spanned by N and Z . The lifetime of different isotopes can largely vary. The isotope stability decreases exponentially as the isotope strays from the valley of stability ($Z = N = A/2$; corresponding to the black region on the right panel); in this case, the isotope can undergo five different types of radioactive decays: β^+ decay, β^- decay, α decay, single proton emission and single neutron emission.

A.3 Spectral energy distributions

In order to generate the spectral energy distribution for each nucleon, we first select the seed isotope energy randomly out of a logarithmic distribution:

$$\log_{10}(E'_0) = \log_{10}(E'_{\min}) + (\log_{10}(E'_{\max}) - \log_{10}(E'_{\min})) U(0, 1) , \quad (\text{A.8})$$

with $U(0, 1)$ being the uniform probability density function between 0 and 1, E'_{\min} and E'_{\max} the minimum and maximum energies.

The spectral density $n'_A(E'_A)$ is a set of N_s points located at energies $E'_{s,i}$ with $0 \leq i \leq N_s - 1$. Hence, to each nucleus with initial energy E'_0 , we can associate a number density:

$$d_0(E'_0) = \int_{E'_{s,i_0}}^{E'_{s,i_0+1}} n'_A(E') dE' \approx n'_A(E'_{s,i_0}) (E'_{s,i_0+1} - E'_{s,i_0}) , \quad (\text{A.9})$$

with i_0 such that $E'_{s,i_0} \leq E'_0 \leq E'_{s,i_0+1}$. If a test nucleus undergoes a photonuclear reaction that generates (N_p, N_n) free protons and neutrons, this creates the nucleon density $d_{\mathcal{N}} = N_{\mathcal{N}} d_0(E'_0)$, with $\mathcal{N} = (p, n)$ representing a proton or a neutron. Note that these particle densities are independent of the energy at which the test nucleus interacts with a photon and the energy of the produced nucleons.

We then add these nucleons together to populate the spectral energy distribution for each species. Nucleons have an energy E'_f at the end of the Monte-Carlo run. Their density is computed as

$$d_{\mathcal{N}}(E'_f) = \int_{E'_{s,i_f}}^{E'_{s,i_f+1}} n'_{\mathcal{N}}(E') dE' \approx n'_{\mathcal{N}}(E'_{s,i_f}) (E'_{s,i_f+1} - E'_{s,i_f}) , \quad (\text{A.10})$$

Figure 13. Ratio of the function f_{π^+}/f_{π^0} and multiplicity ratio M_{π^+}/M_{π^0} in the nuclear photo-hadronic interaction model as functions of y .

with i_f such that $E'_{s,i_f} \leq E'_f \leq E'_{s,i_f+1}$. Using $d\mathcal{N} = N_{\mathcal{N}} d(E'_0)$ and Eqs. (A.9) and (A.10), we get

$$n'_{\mathcal{N}}(E'_{s,i_f}) = N_{\mathcal{N}} n'_A(E'_{s,i_0}) \frac{E'_{s,i_0+1} - E'_{s,i_0}}{E'_{s,i_f+1} - E'_{s,f_0}}. \quad (\text{A.11})$$

We note that these calculations presented in this section can be easily generalized to compute the spectrum of the associated photodisintegrated nuclei.

B Nuclear photohadronic model

In order to estimate the meson production, the function f (cf. Eq. (5.4)) should be identified for each energy interval $\Delta E = [y_{\min}, y_{\max}]$:

$$f^{\Delta E}(y) = \frac{1}{2y^2} \int_{E_{\gamma,r}^{\text{th},\Delta E}}^{2y} E_{\gamma,r} \sigma_{A\gamma \rightarrow \mathcal{M}}(E_{\gamma,r}) dE_{\gamma,r} \quad (\text{B.1})$$

To this purpose, we compute the total function (f^{tot}) using the total cross-section fit from Eq. (A.3).

The function f^{tot} does not only describe the meson production, but also all the other processes in this energy range. That is why it needs to be scaled by the branching ratios of meson production. Using data for the π^0 production cross-section [79], we compute an approximation of the product of the multiplicity and the branching ratio and find $M_{\pi^0} \sigma_{A\gamma \rightarrow \pi^0}^{\text{PM}} / \sigma_{A\gamma}^{\text{PM}} \approx 0.18$. Then, using data for $(p,n)-\gamma$ interactions from Ref. [78] and assuming that they are still valid for nuclei, we compute the ratios f_{π^+}/f_{π^0} and f_{π^-}/f_{π^0} as approximations of the multiplicity ratio M_{π^+}/M_{π^0} and M_{π^-}/M_{π^0} . This is shown in Fig. 13. We highlight that $M_{\pi^+}/M_{\pi^0} = M_{\pi^-}/M_{\pi^0}$ because 50% of interactions are expected to happen with a proton and the rest with a neutron of the nucleus. Indeed, the parameters describing $p\gamma$ and $n\gamma$ photohadronic interactions are the same, except that produced mesons have opposite charge [78]. As a consequence, we have symmetry between the production of π^+ and

Table 3. Multiplicities and fraction of the energy transferred to pions for the seven considered energy ranges.

Intervals ΔE	$y_{\min} = E_{\gamma,r}^{\text{th}}/2$	$y_{\max} = E_{\gamma,r}^{\text{max}}/2$	$M_{\pi^+}/M_{\pi^0} = M_{\pi^-}/M_{\pi^0}$	$\chi_{\pi} \times A$
1	0.1 GeV	0.25 GeV	0.25	0.22
2	0.25 GeV	1.75 GeV	0.6	0.2
3	1.75 GeV	2.5 GeV	0.86	0.25
4	2.5 GeV	25 GeV	0.95	0.18
5	25 GeV	250 GeV	0.91	0.25
6	250 GeV	2500 GeV	0.89	0.25
7	2500 GeV	$+\infty$	0.88	0.3

the one of π^- . Following Ref. [78], we also compute approximations of the fraction of energy transferred to the produced meson $\chi_{\mathcal{M}}$. Both M_{π} and $\chi_{\mathcal{M}}$ need to be constant as functions of the energy for a given energy range. Thus, we consider seven energy intervals ΔE , each associated to a range where the multiplicity and the energy fraction is approximately constant, as summarized in Table 3.

The product of the multiplicity and the function $f^{\Delta E}$, taking into account both branching ratio and multiplicity, is:

$$M_{\pi^+} f^{\Delta E}(y) \approx \left(\frac{M_{\pi^+}}{M_{\pi^0}} \right)^{\Delta E} \left(M_{\pi^0} \frac{\sigma_{A\gamma \rightarrow \pi^0}^{\text{PM}}}{\sigma_{A\gamma}^{\text{PM}}} \right) \left(f^{\text{tot}}(y) - f^{\text{tot}}(y_{\text{th}}^{\Delta E}) \left(\frac{y_{\text{th}}^{\Delta E}}{y} \right)^2 \right). \quad (\text{B.2})$$

On the right hand side of the equation above, the second term is subtracted from $f^{\text{tot}}(y)$ since the latter is an integral with lower limit equal to $E_{\gamma,r}^{\text{th,PM}} = 0.2$ GeV (and not from $E_{\gamma,r}^{\text{th},\Delta E}$):

$$\begin{aligned} f^{\text{tot}}(y) &= \frac{1}{2y^2} \int_{E_{\gamma,r}^{\text{th,PM}}}^{2y} E_{\gamma,r} \sigma_{A\gamma}(E_{\gamma,r}) dE_{\gamma,r} = f^{\text{tot}}(y_{\text{th}}^{\Delta E}) \left(\frac{y_{\text{th}}^{\Delta E}}{y} \right)^2 + \\ &+ \frac{1}{2y^2} \int_{E_{\gamma,r}^{\text{th},\Delta E}}^{2y} E_{\gamma,r} \sigma_{A\gamma}(E_{\gamma,r}) dE_{\gamma,r}. \end{aligned} \quad (\text{B.3})$$

Finally, knowing the parameters M_{π} , χ_{π} and $f^{\Delta E}$, we use Eq. (5.4) to compute the pion production.
