Model-Based Learning for Network Clock Synchronization in Half-Duplex TDMA Networks

Itay Zino, Ron Dabora, Senior Member, IEEE, and H. Vincent Poor, Fellow, IEEE

Abstract

Supporting increasingly higher rates in wireless networks requires highly accurate clock synchronization across the nodes. Motivated by this need, in this work we consider distributed clock synchronization for half-duplex (HD) TDMA wireless networks. We focus on pulse-coupling (PC)based synchronization as it is practically advantageous for high-speed networks using low-power nodes. Previous works on PC-based synchronization for TDMA networks assumed full-duplex communications, and focused on correcting the clock phase at each node, without synchronizing clocks' frequencies. However, as in the HD regime corrections are temporally sparse, uncompensated clock frequency differences between the nodes result in large phase drifts between updates. Moreover, as the clocks determine the processing rates at the nodes, leaving the clocks' frequencies unsynchronized results in processing rates mismatch between the nodes, leading to a throughput reduction. Our goal in this work is to synchronize both clock frequency and clock phase across the clocks in HD TDMA networks, via distributed processing. The key challenges are the coupling between frequency correction and phase correction, and the lack of a computationally efficient analytical framework for determining the optimal correction signal at the nodes. We address these challenges via a deep neural network (DNN)-aided nested loop structure in which the DNNs are used for generating the weights applied to the loop input for computing the correction signal. This loop is operated in a sequential manner which decouples frequency and phase compensations, thereby facilitating synchronization of both parameters. Performance evaluation shows that the proposed scheme significantly improves synchronization accuracy compared to the conventional approaches.

I. INTRODUCTION

Clock synchronization is critical for the implementation of high-rate communications over wireless networks operating in a time division multiple access (TDMA) regime, as higher throughput requires stricter temporal coordination between the nodes. The common approach for clock synchronization in ad-hoc wireless networks is based on exchanging packets carrying timing information. While this approach is relatively simple to implement, it is susceptible to random queuing delays at the medium access control (MAC) layer as well as to random processing delays at the nodes, which limits its accuracy. Moreover, the processing associated with packet-based synchronization entails a higher power consumption at the nodes [1].

An alternative approach for network clock synchronization is based on pulse-coupling (PC), in which the nodes transmit signature sequences, and each node applies processing based on the time stamps it assigns to the signatures received from the other nodes. Commonly, a clock update signal is computed by weighting the received time stamps according to their relative received power w.r.t. to the received powers from the other nodes, see, e.g., [1]. Such weighting leads to good performance when all clocks have the same frequency as long as the propagation delays between the nodes are negligible. The major challenges thus follow as the accuracy of PC-based algorithms is strongly dependent on the weights, yet the optimal weights for practical scenarios, in which there are frequency differences between the clocks as well as propagation delays, are unknown. This has motivated our work [2], which proposed a deep neural network (DNN)-aided synchronization scheme in which the DNN is trained to compute the weights at the nodes. The algorithm, presented in [2], improves the accuracy by two orders of magnitudes compared to the classic weights of [1].

While previous works, [1], [2], [3], have proposed distributed algorithms which achieve different clock synchronization accuracy across the nodes, they all share a common limitation: In all these works, the correction signal is applied to the clock's phase, *without synchronizing the clock's frequency*. The main benefit of this approach is simplicity as only the clock phase is updated, and when applied in networks operating in the full-duplex (FD) regime, it can indeed attain good synchronization performance. However, when applied in the common scenario of half-duplex (HD) communications, rendering the frequencies of the clocks at the nodes unsynchronized results in significant drifts in the clock phase between updates across the nodes in the network, which decreases the throughput of the network. As the clocks drive the processing

at the nodes, then, when the clocks' frequencies remain unsynchronized, different nodes carry out processing at different rates, which will lead to loss of information even with perfect clock phase synchronization between the nodes. In order to mitigate these issues, *clock frequency synchronization has to be achieved along with clock phase synchronization* in HD TDMA networks, which is the focus of this work. We note that such network architectures are relevant to multiple network and application scenarios, including aerial networks [4], cooperative navigation in wireless networks [5], and sensor networks [6].

Main Contributions: In this work, we propose a new PC-based DNN-aided synchronization algorithm that synchronizes both the frequencies and the phases of the clocks, which makes it particularly suitable for HD TDMA wireless networks. As coupling between phase correction and frequency correction may result in frequency differences also after convergence, we implement a staggered update rule which decouples the phase updates from the frequency updates. We then propose an unsupervised and distributed training scheme for obtaining the weights. The main novelty here is facilitating the training of both the frequency and the phase detectors overcoming the above mentioned coupling. The proposed DNN-aided algorithm implements a model-based learning approach, which benefits from the stability and convergence properties of the loop architecture, see, e.g., [2]. As training is carried out online with the actual deployment, the learned DNN coefficients result in superior synchronization performance compared to other distributed approaches. The proposed scheme is compared with a direct extension of the classic algorithm [1] to HD operation and frequency synchronization, as well as with an adapted version of [7]. The comparison shows that the synchronization accuracy of the DNN-aided scheme is considerably higher than that of analytical scheme [3], while the adapted scheme of [7] is not able to synchronize either the frequency or the phase.

Organization: The rest of this work is organized as follows: In Section II the clock model and the baseline network model are described and the classic algorithm [3] is extended to operate in the HD regime and to achieve frequency synchronization. The performance of the extended scheme is then demonstrated to motivate the current work; Section III details the proposed algorithm and Section IV details the associated training scheme; Section V presents simulation tests and discussion; Lastly, Section VI concludes the work.

II. PRELIMINARIES: DISTRIBUTED PULSE-COUPLED TIME SYNCHRONIZATION FOR WIRELESS NETWORKS

A. A Baseline Scenario

1) Network and Clock Models: We consider a network with N nodes, indexed by $i \in \{1, 2, ..., N\} \triangleq \mathcal{I}_N$. Each node *i* has a clock oscillator with its own inherent period, denoted by T_i . Ignoring phase noise (see, e.g., [7, Sec. V], [1]), then, at update index $k \in \mathcal{Z}$ the clock time at node *i*, $\phi_i[k]$, can be expressed as

$$\phi_i[k] = \phi_i[0] + k \cdot T_i,\tag{1}$$

where $\phi_i[0]$ denotes the clock time at index k = 0.

2) Scenario Parameters: As a baseline example, we set the network size to N = 16 nodes, deployed in a square area with a side-length of 10 [Km]. We assume 2-ray propagation with antenna height 1.5 [m], transmit power of 33 [dBm], and a reception threshold of $P_{th} = -114$ [dBm]. With the node deployment depicted by the circles in Fig. 1, it follows that 30% of the links carry signals that are received at their respective destinations above the reception threshold. These links are marked by the lines in Fig. 1. The nominal value of the TDMA period is set to 5 [msec] and the respective nominal TDMA frequency is $f_{\text{nom}} = 200$ [Hz]. We model clock uncertainty by generating the initial TDMA frequency f_i at each node *i* randomly, according to a uniform distribution $f_i \sim \mathbb{U}[f_{\text{nom}}(1-150\cdot 10^{-6}), f_{\text{nom}}(1+150\cdot 10^{-6})]$, which corresponds to clock accuracy of 150 [ppm]. The initial TDMA period at node i is obtained as $T_i = \frac{1}{f_i}$. Each node is then assigned an initial phase $\phi_i[0]$ uniformly distributed over $[0, T_i]$. After startup, the nodes begin to transmit their signatures, such that at time k, node $i = (k \mod N) + 1$ transmits and the remaining N-1 nodes receive. Each receiving node assigns a time stamp and a received signal power value to each received signature. At time indices k such that (k mod N = N - 1, each node independently processes its received time stamps and received signal power values to generate correction signals applied to update its TDMA clock period and clock phase. Accordingly, in the following we let $T_i[k]$ denote the period of the clock at node i at time index k, and $T_i[0]$ denote the initial period value.

Fig. 1. Nodes placement for the baseline scenario (nodes are denoted by circles). Links over which the signal is received at the respective destination above the reception threshold are denoted by lines.

B. Phase and Frequency Synchronization with Current State-of-the-Art

As mentioned in Sec. I, the classic scheme of [1] operates to achieve network clock synchronization by updating only the clock phase leaving the frequencies of the clocks at the nodes unsynchronized. Fig. 2 depicts the clock phases obtained with the classic algorithm [1] in the HD regime, where the phase correction is applied at times k s.t. $(k \mod N) = N - 1$. The phase is plotted as the offset w.r.t. to the mean instantaneous phase, defined as $\overline{\phi}[k] \triangleq \frac{1}{N} \sum_{i=1}^{N} \phi_i[k]$. We observe that the lack of frequency synchronization induces significant phase drifts across the nodes. We measure the network synchronization accuracy via the normalized phase difference (NPD) range (NPDR), which is the maximal clock phase difference between any pair of clocks in the network, normalized to the instantaneous mean period, defined as $\overline{T}[k] \triangleq \frac{1}{N} \sum_{i=1}^{N} T_i[k]$:

$$\mathbf{NPDR}[k] \triangleq \left(\max_{i_1 \in \mathcal{I}_N} \phi_{i_1}[k] - \min_{i_2 \in \mathcal{I}_N} \phi_{i_2}[k] \right) / \bar{T}[k].$$
(2)

Fig. 2. Clock phases in an HD-TDMA network without period update. Each line depicts the clock phase at one node.

A straightforward approach for achieving clock phase and frequency synchronization in HD networks is to generalize the model of [1] by adding a frequency synchronization loop, using the same power-dependent weights. Before stating the generalization we recall the clock phase update rule at node i, as stated in [1, Eqn. (16)]:

$$\phi_i[k+1] = \phi_i[k] + T_i[0] + \varepsilon_0 \sum_{j \in \mathcal{N}(i)} \alpha_{i,j} \cdot (\phi_j[k] + q_{i,j} - \phi_i[k]),$$
(3)

where ε_0 denotes the loop gain, $q_{i,j}$ is the propagation delay between nodes *i* and *j*, and $\mathcal{N}(i)$ is the neighborhood set of node *i*, consisting of all the nodes whose signals are received at node *i* with power higher than P_{th} . Note that here the clock period is fixed at $T_i[0]$ as this value is not updated by the algorithm [1]. Let $P_{i,j}[k]$ denote the power of the signal received at node *i* from node *j* at time index *k*, and denote by $t_{i,j}[k] \triangleq \phi_j[k] + q_{i,j}$ the time stamp node *i* assigns to the signature received from node *j*. At startup, note *i* initializes the storage variables

 $\Delta \phi_{i,j}^{\text{prev.}} = \Delta \phi_{i,j} = P^{(i)}[j] = 0$. At time index k, node $j = (k \mod N) + 1$ transmits and nodes $i \in \mathcal{I}_N \setminus j$ receive. Then, for any node $i \in \mathcal{I}_N \setminus j$ for which $P_{i,j}[k] > P_{th}$, the node first updates $\mathcal{N}(i)$ to include j, and then computes and stores $\Delta \phi_{i,j}^{\text{prev.}} \leftarrow \Delta \phi_{i,j}, \Delta \phi_{i,j} \leftarrow t_{i,j}[k] - \phi_i[k]$, and $P^{(i)}[j] \leftarrow P_{i,j}[k]$. At times k s.t. $(k \mod 3N) = 2N - 1$, the weights at node i are set to [1, Eqn. (8)]

$$\alpha_{i,j} = P^{(i)}[j] / \sum_{m \in \mathcal{N}(i)} P^{(i)}[m].$$

In the following we generalize the algorithm of [1] to include period synchronization by introducing a nested loop designed to synchronize $T_i[k]$ across the different nodes. The generalized scheme, referred to in this work as the extended Simeone-Spagnolini-BarNess-Strogatz (ESSBS) algorithm, operates as follows:

$$\begin{aligned}
\phi_{i}[k+1] &= \phi_{i}[k] + T_{i}[k] + Q_{\phi,i}[k] \\
Q_{\phi,i}[k] &= \begin{cases} 0 & , (k \mod 3N) \neq 3N - 1 \\
\varepsilon_{\phi} \sum_{m \in \mathcal{N}(i)} \alpha_{i,m} \cdot \Delta \phi_{i,m} , (k \mod 3N) = 3N - 1 \end{cases} \tag{4} \\
T_{i}[k+1] &= T_{i}[k] + Q_{T,i}[k]/N \\
Q_{T,i}[k] &= \begin{cases} 0 & , 0 \leq (k \mod 3N) < 2N - 1 \\
\varepsilon_{T} \sum_{m \in \mathcal{N}(i)} \alpha_{i,m} & (\Delta \phi_{i,m} \\
m \in \mathcal{N}(i) & -\Delta \phi_{i,m}^{\text{prev.}}), (k \mod 3N) = 2N - 1 \\
Q_{T,i}[k-1] & , 2N \leq (k \mod 3N) < 3N - 1 \end{cases}
\end{aligned}$$

Fig. 3 presents a schematic depiction of the ESSBS algorithm. In Sec. III we elaborate on the factor of 3 included in the modulo operations in (4) and (5). Fig. 4 depicts the clock periods and the NPDR achieved by the ESSBS algorithm for the baseline scenario detailed in Sec. II-A. Observe that ESSBS is not able to achieve accurate clock synchronization, and in fact, as time increases the clocks' phases drift farther apart. *This motivates the introduction of a DNN-based weight computations*, considered in the next section.

III. A DISTRIBUTED DNN-AIDED FREQUENCY AND PHASE SYNCHRONIZATION SCHEME FOR THE HD REGIME

We propose to improve upon the current state-of-the-art FD algorithms [1] (which uses weights computed analytically) and [2] (which uses weights generated via a DNN) by incorporating three

Fig. 3. Schematic description of the ESSBS algorithm (Eqns. (4)-(5)).

new elements: (1) A DNN-aided *frequency synchronization loop* which operates together with the phase synchronization loop; (2) Modification of the operation of the overall synchronization scheme, adapting it to the *HD regime*; and (3) Introduction of an *unsupervised* and *distributed* training scheme that facilitates training of both DNNs without requiring the exchange of feedback information between the nodes. Next, we elaborate on the operation of the proposed combined frequency and phase synchronization scheme in the HD regime.

By analyzing (this original analysis, reported in [8], is not included here due to space constraints) the impact of propagation delays on the phase update rule in the ESSBS algorithm

Fig. 4. Performance of the ESSBS algorithm: (a) The evolution of the clock periods $T_i[k]$ vs. k, where each line represents the evolution of the clock period at a different node in the network; (b) The NPDR of the network vs. k.

(4) it was concluded that these delays induce a drift in the frequency synchronization loop. Accordingly, our proposed synchronization scheme, referred to as the *phase and frequency DNN-aided synchronization algorithm (PFDSA)*, is designed to guarantee that both the clock phases and periods are simultaneously synchronized. We employ learning only of the weights, keeping the other elements of the loop structure of the ESSBS algorithm (4)-(5) unchanged, see Fig. 3. This approach, known as a *model-based* approach, benefits from the desired convergence and stability properties associated with the loop structure, while optimizing only the element whose analytical determination is suboptimal.

Let $\psi_{T,i}^{(\boldsymbol{\theta}_{T,i})}(\cdot)$ and $\psi_{\phi,i}^{(\boldsymbol{\theta}_{\phi,i})}(\cdot)$ denote the DNNs used for computing the weights for the period and for the phase update loops at node $i \in \mathcal{I}_N$, respectively, where $\boldsymbol{\theta}_{T,i}$ and $\boldsymbol{\theta}_{\phi,i}$ denote their respective DNN parameters. In the HD regime, a node requires N time slots to collect the timing information from all of its neighbors (received above the reception threshold), which is a significantly slower rate than in the FD regime, in which timing information from all received nodes is collected at *every* time slot. Accordingly, at time indices k such that $(k \mod N) \neq N - 1$, node $i \in \mathcal{I}_N$ updates its clock phase and frequency via

$$\phi_i[k+1] = \phi_i[k] + T_i[k] + \Omega_i[k]$$
(6a)

$$T_i[k+1] = T_i[k] + A_i[k]/N,$$
(6b)

where $A_i[k]$ denotes the period correction term at node i at time k, and $\Omega_i[k]$ is the corresponding phase correction term. In addition to updating their clocks, at time slot k the node with index $j = (k \mod N) + 1$ transmits its synchronization signature while the remaining N - 1 nodes, $i \in \mathcal{I}_N \setminus j$ are set to receive. Let $X_{\phi}^{(i)}[j]$ denote the phase difference between nodes j and i, stored at node i at the *previous* update cycle. Upon reception, each node $i \in \mathcal{I}_N \setminus j$ for which $P_{i,j}[k] > P_{th}$, stores $P^{(i)}[j] \leftarrow P_{i,j}[k]$, otherwise it sets $P^{(i)}[j] = 0$. A node i for which $P^{(i)}[j] > 0$ computes and stores the period difference w.r.t. node j, defined as $X_T^{(i)}[j] \leftarrow \frac{1}{N}(t_{i,j}[k] - \phi_i[k] - X_{\phi}^{(i)}[j])$. Node i then proceeds to store the new receive phase difference $X_{\phi}^{(i)}[j] \leftarrow t_{i,j}[k] - \phi_i[k]$. If $P^{(i)}[j] = 0$, then node i sets $X_{\phi}^{(i)}[j] = X_T^{(i)}[j] = 0$.

In order to decouple the period update and the phase update, such that both period and phase will converge, the update takes place in a sequence of 3 alternating actions, and therefore, a cycle of frequency and phase updates spans 3N times indices. We denote the interval for which $(k \mod 3N) \in \{0, 2N - 2\}$ as a "collection-only" interval, at which the clocks are updated via Eqns. (6) where the correction terms are set to $\Omega_i[k] = A_i[k] = 0$. The "period update" action takes place at k such that $(k \mod 3N) \in \{2N - 1, 3N - 2\}$. In this interval each node updates its period via a correction signal computed by weighting all the estimated period differences between its own period and the periods of the other nodes with weights computed by the DNN $\psi_{T,i}^{(\Theta_{T,i})}(\cdot)$, which replace the weights $\alpha_{i,m}$'s used in the rule (5), while $\Omega_i[k] = 0$. The period correction signal at node *i* is given by

$$A_{i}[k] = \varepsilon_{T} \sum_{\substack{j=1, \\ j \neq i}}^{N} \left[\psi_{T,i}^{(\boldsymbol{\theta}_{T,i})} \left(\left\{ \left(X_{T}^{(i)}[j'], P^{(i)}[j'] \right) \right\}_{\substack{j'=1, \\ j' \neq i}}^{N} \right) \right]_{j} X_{T}^{(i)}[j].$$
(7)

Finally, a phase correction update is applied when $(k \mod 3N) = 3N - 1$, by weighting the received clock phase differences with weights generated by the DNN $\psi_{\phi,i}^{(\theta_{\phi,i})}(\cdot)$, which replace

Fig. 5. Schematic description of the proposed PFDSA.

the weights $\alpha_{i,m}$'s used Eqn. (4), while $A_i[k] = 0$. The phase correction signal at node *i* is given by

$$\Omega_{i}[k] = \varepsilon_{\phi} \sum_{\substack{j=1, \\ j \neq i}}^{N} \left[\psi_{\phi,i}^{(\boldsymbol{\theta}_{\phi,i})} \left(\left\{ \left(X_{\phi}^{(i)}[j'], P^{(i)}[j'] \right) \right\}_{\substack{j'=1, \\ j' \neq i}}^{N} \right) \right]_{j} X_{\phi}^{(i)}[j].$$
(8)

The proposed algorithm is schematically depicted in Fig. 5.

A. Data Acquisition and Training Set Generation

Typically, DNNs are trained offline with data collected a-priori. However, as was already noted in [2], achieving high accuracy clock synchronization in wireless networks requires that the training data corresponds to the actual parameters of the network deployment, i.e., the actual clock frequency differences, clock phases, propagation delays, and network topology. This requires collecting the training data *after deployment*.

The data acquisition step takes place after startup and spans N_T TDMA frames, each consisting of N transmissions, one from each node in the network. During this step, each node i uses its initial, randomly generated DNN parameters, $\theta_{\phi,i}$ and $\theta_{T,i}$, to generate its clock times via the PFDSA, while concurrently storing all its measured time stamps and received signal powers. For example, at time k, following the TDMA time-slot assignment, node $j = (k \mod N) + 1$ transmits, and each node $i \in \mathcal{I}_N \setminus j$ stores its receive time stamp $t_{i,j}[k]$ and received powers $P_{i,j}[k]$ (if $P_{i,j}[k] < P_{th}$, then both stored parameters are set to 0). Thus, for every time k, node istores the pair $\mathcal{D}^{(i)}[k] \triangleq \{t_{i,j}[k], P_{i,j}[k]\}$, where $j = (k \mod N) + 1$, $j \neq i$. Note that during the entire acquisition step, the parameters of both DNNs remain fixed. Due to the HD transmission protocol, the acquisition step spans $N \cdot N_T$ time indices k.

Based on the N_T TDMA frames received during data acquisition, each node *i* generates a training set containing N_T samples, where each sample consists of N-1 pairs, $\mathcal{D}^{(i)}[k]$, containing the receive time stamp and received power.

$$\mathcal{D}_{i} = \left\{ t_{i,(k \mod N)+1}[k], P_{i,(k \mod N)+1}[k] \right\}_{\substack{k=0, \\ (k \mod N) \neq i-1}}^{N \cdot N_{T}-1}$$

B. Training Procedure

Once the acquisition step is completed, node *i* processes the stored training data at sample $k \ge N$ as follows: Let $j = (k \mod N) + 1$. Then, if $P_{i,j}[k] > 0$, node *i* computes

$$\Delta \phi_{i,j}[k] = t_{i,j}[k] - \phi_i[k] \tag{9}$$

$$T_{i,j}[k] = t_{i,j}[k] - t_{i,j}[k - N + 1].$$
(10)

Using the definition of $t_{i,j}[k]$ and the update rules (6) in (10) we can express $T_{i,j}[k]$ via the period and the phase correction signals as follows:

$$\begin{split} T_{i,j}[k] &= \sum_{l=k-N+1}^{k} (\frac{A_j[l]}{N} + \Omega_j[l]) + N \cdot T_j[k-N+1] \\ &= \frac{A_j[k-N+1]}{N} \cdot (N-j+1) + \frac{A_j[k]}{N} \cdot (j-1) \\ &+ \Omega_j \bigg[\bigg\lfloor \frac{k}{N} \bigg\rfloor N - 1 \bigg] + N \cdot T_j[k-N+1]. \end{split}$$

Observe that $T_{i,j}[k]$ represents node *i*'s estimate of the TDMA frame duration of node *j*, at time k. Note that this estimate will have an offset at some values of k due to the phase correction term, which is non-zero only at values of k for which $(k \mod 3N) = 3N - 1$, and to the change in $A_j[k]$ within a set of N - 1 samples at node *i*, which occurs when $(k \mod 3N) = 2N - 1$. Recall also that $A_j[k]$ is non-zero only for k s.t. $(k \mod 3N) \in \{2N - 1, 3N - 2\}$.

Next, the features used for computing the outputs of the DNNs $\psi_{T,i}^{(\theta_{T,i})}(\cdot)$ and $\psi_{\phi,i}^{(\theta_{\phi,i})}(\cdot)$ are obtained in the following order

$$X_T^{(i)}[j] \leftarrow \frac{1}{N} \left(\Delta \phi_{i,j}[k] - X_{\phi}^{(i)}[j] \right)$$
$$X_{\phi}^{(i)}[j] \leftarrow \Delta \phi_{i,j}[k]$$
$$P^{(i)}[j] \leftarrow P_{i,j}[k].$$

Subsequently, the DNNs compute the weights for the phase loop and the frequency loop for generating the error signals at node *i*, using the respective 2(N-1) features at each DNN according to the time regime, i.e., when $(k \mod 3N) = 2N-1$, the DNN $\psi_{T,i}^{(\theta_{T,i})} \left(\left\{ \left(X_T^{(i)}[j'], P^{(i)}[j'] \right) \right\}_{\substack{j'=1, \ j'\neq i}}^N \right)$ is used for computing $A_i[k]$ via (7). Then, $A_i[k]$ is applied for period update when $(k \mod 3N) \in \{2N-1, 3N-2\}$. When $(k \mod 3N) = 3N-1$, a phase correction is applied using (8) with $\Omega_i[k]$ obtained using the DNN $\psi_{\phi,i}^{(\theta_{\phi,i})} \left(\left\{ \left(X_{\phi}^{(i)}[j'], P^{(i)}[j'] \right) \right\}_{\substack{j'=1, \ j'\neq i}}^N \right)$. Letting $\mathbb{1}_{(\mathcal{X})}$ denote the indicator function for the event \mathcal{X} , the loss functions are computed as follows:

$$\mathcal{L}_{\mathcal{D}_i}(\boldsymbol{\theta}_{i,\phi}) = \sum_{k=1}^{N_T \cdot N - 1} \mathbb{1}_{(P^{(j)}[j] > 0)} \log(k+1) (t_{i,j}[k] - \phi_i[k])^2$$
(11)

$$\mathcal{L}_{\mathcal{D}_{i}}(\boldsymbol{\theta}_{i,T}) = \sum_{k=1}^{N_{T} \cdot N - 1} \mathbb{I}_{(P^{(j)}[j] > 0)} \log(k+1) \left(\frac{T_{i,j}[k]}{N} - T_{i}[k]\right)^{2}$$
(12)

By the structure of the loss functions (11) and (12), it follows that the gradient of the loss

with respect to the weights can be computed via backpropagation through time. Moreover, the loss functions can be computed in an unsupervised manner by each node locally, facilitating unsupervised local training via conventional first-order based optimizers. The training algorithm is summarized in Algorithm 1. Observe that at each training batch, first, only the frequency loop

Data: Data set \mathcal{D}_i consisting of N_T tuples, each of length $2 \cdot (N-1)$; learning rate μ ; initial weights $(\theta_{\phi,i}, \theta_{T,i})$, number of epochs E_s and E_{loop} , number of epochs for each loop E_{loop} , initial phases, $\{\phi_i[k]\}_{k=0}^{N-1}$. 1 for epoch₁ = 1 to E_s do **Initialize:** for any j = 1, 2, ..., N, $j \neq i$: 2 **Read** $\{t_{i,j}[j-1], P_{i,j}[j-1]\} \in \mathcal{D}_i$ 3 if $P_{i,j}[j-1] > 0$ then 4 Set $X_{\phi}^{(i)}[j] = t_{i,j}[j-1] - \phi_i[j-1];$ 5 for m = 1 to $2 \cdot E_{loop}$ do 6 for k' = N to $N \cdot N_T - 1$ do 7 Set current Tx node $j = (k' \mod N) + 1$ 8 **Read** $\{t_{i,j}[k'], P_{i,j}[k']\} \in \mathcal{D}_i$ 9 if $P_{i,j}[k'] > 0$ and $j \neq i$ then 10 Compute $\Delta \phi_{i,j}[k'] = t_{i,j}[k'] - \phi_i[k']$ 11 Store $X_T^{(i)}[j] \leftarrow (\Delta \phi_{i,j}[k'] - X_{\phi}^{(i)}[j])/N$ 12 Store $X_{\phi}^{(i)}[j] \leftarrow \Delta \phi_{i,j}[k']$ Store $P^{(i)}[j] \leftarrow P_{i,j}[k']$ 13 14 Forward pass $P^{(i)}[j]$, $X_T^{(i)}[j]$ and $X_{\phi}^{(i)}[j]$ to compute $\phi_i[k'+1]$ and 15 $T_i[k'+1]$ via Eqns. (6), (7), and (8), according to update action selected by the value of $(k \mod 3N)$ if $m \leq E_{loop}$ then 16 **Compute loss** $\mathcal{L}_{\mathcal{D}_i}(\boldsymbol{\theta}_{i,T})$ via Eqn. (12) using the computed $T_i[k']$ and the 17 stored $t_{i,j}[k']$'s (from which $T_{i,j}[k']$ is computed via (10)); **Compute gradient** $\nabla_{\theta_i} \mathcal{L}_{\mathcal{D}_i}(\theta_{i,T})$ using backpropagation through time; 18 Update weights via $\boldsymbol{\theta}_{i,T} \leftarrow \boldsymbol{\theta}_{i,T} - \mu \cdot \nabla_{\boldsymbol{\theta}_{i,T}} \mathcal{L}_{\mathcal{D}_i}(\boldsymbol{\theta}_{i,T}).$ 19 else 20 **Compute loss** $\mathcal{L}_{\mathcal{D}_i}(\boldsymbol{\theta}_{i,\phi})$ via Eqn. (11) using the computed $\phi_i[k']$ and the 21 stored $t_{i,j}[k']$; **Compute gradient** $\nabla_{\theta_i} \mathcal{L}_{\mathcal{D}_i}(\theta_{i,\phi})$ using backpropagation through time; 22 Update weights via $\theta_{i,\phi} \leftarrow \theta_{i,\phi} - \mu \cdot \nabla_{\theta_{i,\phi}} \mathcal{L}_{\mathcal{D}_i}(\theta_{i,\phi}).$ 23

is trained, and then only the phase loop is trained. This is done to avoid the phase loop compensating for frequency errors, which would decrease the accuracy of frequency synchronization across the nodes. We note that as training is local at each node, based only on its received inputs with fixed DNNs parameters during training data acquisition, then the proposed approach is flexible and scales with the size of the network without requiring any modifications.

C. Discussion and Complexity Analysis

The DNNs used in the frequency synchronization loop and in the phase synchronization loop have the same structure, each consisting of a total of six layers, including two linear layers, each followed by a sigmoid layer, and a third linear layer followed by a softmax layer, which is the output of the DNN. The output of the DNN is then passed to a selector which outputs only the weights corresponding to nodes whose signal was received above the reception threshold. These weights are then normalized such that their sum is one and are then applied in the loop. The number of inputs and outputs of each layer are summarized in Table I.

Operation	Inputs	Outputs	
Linear Layer 1	2(N-1)	30	
Sigmoid Layer 1	30	30	
Linear Layer 2	30	30	
Sigmoid Layer 2	30	30	
Linear Layer 3	30	N-1	
Softmax Layer	N-1	N-1	
Selection	N-1	N-1	
Normalization	N-1	N-1	

TABLE I SUMMARY OF THE LAYERS IN THE DNN IMPLEMENTATION.

For a network with N nodes, each DNN consists of $(3(N-1)+30)\cdot 30$ weights and $2\cdot 30+N-1$ biases. For a network with N = 16 nodes, we obtain 2250 weights and 75 biases, which corresponds to less than $2.5 \cdot 10^3$ products for inference per DNN. We note that each DNN is used for inference only once per $3 \cdot N$ time slots, thus the rate of computation at a node is less than 1700 products for inference per TDMA frame. As discussed in [2], such a computational burden is feasible on real-time modern micro-controllers.

V. PERFORMANCE EVALUATION

In the simulations we used the baseline setup described in Sec. II-A. In this section we shall depict the comparison only with the ESSBS algorithm described in Sec. II-B, as the algorithms based on skew and offset estimation, e.g., [7], achieve worse performance than ESSBS for the

scenarios tested in this section. In the learning phase of the simulations, the PFDSA algorithm was trained using $E_s = 6$ cycles with $E_{\text{loop}} = 5$. Thus, overall each DNN is trained over 30 epochs with a learning rate of $\mu = 0.1$. The information for training was collected over $N_T = 126$ TDMA frames. As each TDMA frame facilitates transmission of N = 16 nodes, then the overall time samples collected for training at a given node is 2016. In the testing phase, $N_T = 751$ TDMA frames were used in the evaluation.

The results for the proposed PFDSA algorithm for the network depicted in Fig. 1 are presented in Figs. 6 (synchronization of the period) and 7 (synchronization of the phase). Both figures present the quantities w.r.t. the respective instantaneous mean. The figures demonstrate that the proposed PFDSA algorithm is indeed able to achieve excellent frequency and phase synchronization performance, which is considerably better than that of the ESSBS algorithm. The main performance characteristics, namely, the NPDR, is depicted in Figure 8a. It is observed that the proposed PFDSA is able to achieve accurate synchronization while ESSBS is not able to synchronize the phase at all.

Next, we tested the impact of network parameters on the performance, by randomly generating 800 network scenarios in which the nodes were randomly placed in the network area, and the initial phases and periods were selected according to the statistics described in Sec. II-A. Only scenarios in which about 30% of the links are received above the detection threshold were considered. The histogram of the NPDR and of the mean period are depicted in Figs. 9 and 10, respectively. It is observed from the figure that both algorithms can typically be expected to achieve accurate frequency synchronization. Yet, the ESSBS would typically result in very high NPDR which implies that it is not able to achieve phase synchronization, and therefore does not facilitate communications over the network. In contrast, the proposed PFDSA would typically achieve very accurate phase synchronization and represents a major improvement both in the mean NPDR (a factor of 4.5) and in its standard deviation (STD) (a factor of 2).

VI. CONCLUSIONS

In this work we have considered the problem of clock synchronization in networks operating in the HD regime. Synchronization of both clock phase and clock frequency introduces several challenges: The first challenge is that phase correction can compensate for frequency differences, and thus, we proposed a scheme in which these two updates are decoupled. The second challenge is the stability and convergence of the synchronization scheme. In this work

Fig. 6. The evolution of the clock periods $T_i[k]$ vs. k, for the PFDSA for all nodes (each line represents the period at a different node in the network), $\varepsilon_T = \varepsilon_{\phi} = 0.3$.

we use a nested loop structure, where each loop is a first order loop. This structure benefits from the stability and convergence associated with such loops. The third challenge follows as facilitating accurate synchronization requires that the synchronization parameters correspond to the scenario parameters, however, to date, the optimal discriminator for a given scenario parameters is unknown. In particular, attempting to apply the classic weights of [1] results in very poor synchronization performance. We address this challenge by employing DNN-based phase and period discriminators for the HD regime. Combined with a temporal update regime that facilitates decoupling of the phase and the frequency updates, the proposed approach achieves significant improvement compared to the (generalized) classic approach of [1]. Future work will focus on further improving the performance of the DNN-based scheme by considering different initialization procedures, and evaluation of performance for different channel conditions relevant to wireless communications.
