# On The Effectiveness of Program Reduction Techniques in Automated Program Repair

Omar I. Al-Bataineh Jordan University of Science and Technology

Abstract—Repairing a large-scale buggy program using current automated program repair (APR) approaches can be a difficult time-consuming operation that requires significant computational resources. We describe a program repair framework that effectively handles large-scale buggy programs of industrial complexity. The framework exploits program reduction in the form of program slicing to eliminate parts of the code irrelevant to the bug being repaired without adversely affecting the capability of the repair system in producing correct patches.

Observation-based slicing is a recently introduced, languageindependent slicing technique that shows a good effectiveness in a wide range of applications. In this work, we show how ORBS can be effectively integrated with APR to improve all aspects of the repair process including the fault localisation step, patch generation step, and patch validation step. The presented repair framework indeed enhances the capability of APR by reducing the execution cost of a test suite and the search cost for the appropriate faulty statement corresponding to the bug being repair. Our empirical results on the widely used Defects4J dataset reveal that a substantial improvement in performance can be obtained without any degradation in repair quality.

# I. INTRODUCTION

Automated program repair (APR) is an active research area with expanding tool support [1], [2]. However, APR has struggled with scalability and grows time-consuming and resource-intensive for larger programs. This paper aims to enhance APR performance by exploiting program reduction in the form of program slicing to reduce both the search time for the faulty statement and validation times for candidate patches.

APR consists of three steps: fault localization, patch generation, and patch validation. Poor performance of the first phase, fault localization (FL) can lead to poor overall performance when the actual faulty statement is found far down the list of suspicious statements [3], [4]. Poor ranking impacts APR performance by increasing the number of failed patch attempts. Another aspect that contributes to the poor performance of APR tools is the cost of patch validation, which is heavily reliant on the test suite size. Experience has shown that much of a test suite is irrelevant to fixing a given bug. The expense of running these tests decrease APR's efficiency. This paper experiments with test suite reduction and suspicious list optimisation that make use of the program slice.

To demonstrate the effectiveness of combining slicing with APR, we apply TBar [5], a state-of-the-art template-based APR tool, to selected bugs form the widely used Defects4J dataset [6]. We use template-based APR because it is one of the most effective approaches to generating patches [3]. We use the bugs from Defects4J to illustrate the effectiveness

results reveal that a substantial improvement in performance can be obtained without any degradation in repair quality. The need for accelerating APR: Real-world programs grow ever larger. For example, the modern vehicles include millions of lines of code. In spite of the successes of APR in fixing a wide variety of bugs in real-world programs, additional research is needed to handle programs of industrial complexity. Current APR approaches simply take too long. For example, in the benchmarks we study even a single line repair can take hours and in several cases the search fails because of the patch space is too large. While we study template-based repair, recent NN-based approaches are even slower [7]. For example, the recent NN-based tool recoder consumes more than 4 hours on average to fix the bugs of Defects4J. The main reason for this slow running time is APR tools commonly must consider a large number of patch candidates before finding a valid patch. To expedite the APR process, acceleration approaches based on the concepts of program reduction techniques are needed. Demonstrating example: As a preliminary illustration, consider the repair of Defects4J [6] bug Lang-10 using the stateof-the-art template-based APR tool TBar [5]. TBar takes seven hours to generate a plausible patch. The long processing time can be explained by the following observations. First, TBar spends a significant time mutating suspicious statements that are not the actual faulty statement responsible for the bug: the fault localization results for Lang-10 are a ranked list of 287 suspicious statements, in which the faulty has rank 70. Second, the test suite for bug Lang-10 consists of 2196 passing tests and 2 failing tests where most of the tests are irrelevant to Lang-10 and thus can be skipped without adversely affecting the quality of generated patches. A minimised test suite obtained by removing irrelevant tests using a slicing-based test reduction approach consists of only 52 tests. Using the minimised test suite we discover the same patch is produced after examining 1476 patches in approximately 40 minutes.

of our approach and to consider its scalability. The empirical

**Contribution:** We show how slicing can be *effectively* integrated with APR to improve all aspects of the repair process including the FL step, the patch generation step (the number of examined patch candidates), and the patch validation step. We show first how ORBS slicer [8] can be used to optimise FL by improving the suspiciousness rank of the actual faulty statement corresponding to the target bug, which in turn reduces the number of examined patch candidates. We also show how slicing can be used to reduce the size of test suites by eliminating irrelevant tests without adversely affecting the

quality of produced patches. We demonstrate the effectiveness of our repair framework approach that combines the ORBS program slicing with APR across the widely used Defects4J benchmark [6], demonstrating promising results using ORBS to improve fault localization effectiveness, as well as the patch generation and patch validation steps of APR.

**Notations:** Throughout the paper we use the following notations. We write P to refer to the original program containing bug b,  $P_S$  to refer to the corresponding sliced version of P, T a test suite for P,  $T_R \subseteq T$  a reduced test suite obtained by eliminating irrelevant tests of T w.r.t. bug b, SL the list of suspicious statements obtained by running an FL technique using P and T, and  $SL_R$  is a reduced suspicious list obtained for bug b using P and  $T_R$ . Finally, we refer to R(P, T, SL) as a *standard repair setup* in which the original program P, the entire test suite T, and the list SL are used when running the repair system R to produce a patch for bug b.

# II. BACKGROUND

This section introduces APR's efficiency metrics that we use in this work and observation-based slicing (ORBS).

**Efficiency metrics for APR:** We use two efficiency metrics to measure the efficiency gain brought on by the use of slicing: (i) the repair time (RT) or the time it takes the APR tool to generate a patch, and (ii) the number of patches examined before a valid patch is found (known as the NPC score [9]). While reducing the size of the test suite is expected to improve the RT but not the NPC, improving the suspiciousness rank of the faulty statement is expected to improve both RT and NPC. The effectiveness impact of slicing on the performance of APR tools needs therefore to be assessed using both metrics.

**Observation-based slicing:** The following description of Observation-Based Slicing (ORBS) is taken from existing work on the technique [8], [10], [11].

The key to ORBS is *observation*. ORBS takes as input a source program P, a slicing criterion identified by a program variable  $\nu$ , a program location l, a set of inputs  $\mathcal{I}$ , and a maximum window size  $\delta$ . The resulting slice preserves the values of  $\nu$  at l for the inputs of  $\mathcal{I}$ .

ORBS *observes* behavior by instrumenting P with a sideeffect free line that tracks the value of variable  $\nu$  immediately before line l. Then, starting with P, ORBS repeatedly forms candidate slices by deleting a sequence of one to  $\delta$  lines from the current slice. The candidate is rejected if it fails to compile or produces different values for  $\nu$ . Otherwise, the candidate becomes the current slice. ORBS systematically forms candidates until no more lines can be deleted.

# **III. APR AND REDUCTION TECHNIQUES**

The program reduction strategy we study in this paper is dynamic program slicing. A dynamic slice of program P is a syntactic subset of P that preserves the behavior of a given part of the code called a *slicing criteria* on a select set of P's tests. Slicing's goal is to produce the simplest such program. Applied in the context of APR, slicing is useful as it abstracts away code irrelevant to the bug being repaired and thus reduces the effort required by the APR tool. We next formalize the requirements that a slice must satisfy to be useful in APR.

Definition 1: Feasible slices. Let P be a program that contains a statement s which is the location of bug b and let P' be a slice of P taken with respect to s and the variables used in b (i.e., s and the variables used in b form the slicing criterion). Program P' is a repair-feasible slice of P iff

- 1) P' is a smaller executable version of P, and
- 2) all runs of P that exhibit bug b have a corresponding run of P' that also exhibits b.

The first property of Definition 1 concerns the *efficiency* of the APR process: it is essential that repairing the sliced program will be faster than repairing the original program. The second property concerns the *accuracy* of the applied slicing method: if the slicing method skips some of the erroneous behaviors in the original program then the resultant slice is no longer feasible for repairing the target bug.

# A. Reducing Test Suites by Eliminating Irrelevant Tests

Most state-of-the-art APR tools use test suites to localize the faulty statement of the bug under repair, and then generate and validate the resulting candidate patches. Tests used by APR typically consists of two parts: (i) failing tests  $T_F$  used to trigger the defective behavior in the program, and (ii) passing tests  $T_P$  used to model the expected correct behavior of the program. The number of failing and passing tests employed in the APR process affects not only the quality of the generated patches but also the accuracy of the fault localization step.

However, test suites written for large-scale programs are often constructed without developing sufficient knowledge about the dependency relationships between the different components of the program under repair. Thus, a test suite may contain tests that are irrelevant to the bug being repaired. The repeated execution of these irrelevant tests during patch validation can significantly degrade the performance of APR tools. There is, therefore, a need to identify and eliminate irrelevant test cases in an test suite (see Definition 2).

Definition 2: Identifying irrelevant tests. Let P be a program containing a bug b and  $S_f$  be the set of faulty statements responsible for the occurrence of b and T be a test suite for program P. We say that a test  $t \in T$  is an irrelevant test w.r.t. bug b if t tests behaviors in P (i.e. a sequence of statements S) that are semantically independent from  $S_f$ . That is, the computations of  $S_f$  and S are mutually irrelevant.

# B. Optimising Suspicious Lists by Reducing False-Positives

Despite significant advances [12], [13], [14], [15], [16], [17], [18], [19], [20], FL still suffers from accuracy issues [3], [4]. For example, the top ranked suspicious statements are often false positives. This poor ranking of faulty statements directly affects APR performance by increasing the number of patch candidates that are needlessly considered. Therefore, valid optimisation and reduction techniques must be applied to reduce the number of false-positives in the suspicious lists produced by current FL techniques (see Definition 3).

Definition 3: Valid suspicious list optimisation. Let P be a program containing bug b,  $S_f$  be the set of faulty statements responsible for the occurrence of b, and  $T = (T_F \cup T_P)$  be a test suite developed for testing P. Let also  $P_S = ORBS(P, T_F)$ be a program slice of P computed by running the set of failing tests  $T_F$ , and  $T_R \subseteq T$  be a reduced test suite obtained as described at Definition 2. For an FL algorithm F, we say that  $SL_R = F(P, T_R)$  is a valid optimised suspicious list of P iff:

- 1) the reduced suspicious list  $SL_R$  contains  $S_F$ , and
- 2) the setup  $R(P,T,SL_R)$  produces a valid patch for b or one that is identical to that created by R(P,T,SL), and
- 3) NPC score of  $R(P,T,SL_R)$  is smaller than that of R(P,T,SL). That is, R examines a fewer number of patches before finding a valid one using the list  $SL_R$ .

In Subsection VI-B, we empirically evaluate the effectiveness of ORBS in identifying and eliminating irrelevant tests, as well as lowering false-positives in generated suspicious lists.

## IV. OPTIMISED TEMPLATE-BASED REPAIR ALGORITHM

Our repair algorithm (see Algorithm 1) aims to improve all aspects of APR including the fault location step, the patch generation step, and the patch validation step. We do this using slicing, which typically reduces the size of the test suite and suspicious list as well. Statements that are not part of the slice can be removed from the original suspicious list thus reducing the number of false positives. This in turn helps reduce the number of irrelevant patches considered. Additionally, slicing can help identify and eliminate irrelevant tests from the test suite, which reduces the cost of the patch validation step.

More formally, our algorithm consists of the following phases applied to buggy program P and its test suite T.

- 1) Program reduction phase. This phase produces a slice  $P_S$  of P by eliminating code irrelevant to the bug.
- 2) Test suite reduction phase. This phase constructs a reduced test suite  $T_R$  by removing all tests from T that test parts of P not found in  $P_S$ .
- 3) Suspicious list optimisation phase. This phase runs GZoltar [21] on P using  $T_R$  to produce the list  $SL_R$ .
- 4) Repair phase. This phase applies R to P,  $T_R$ , and  $SL_R$ .

The effectiveness of test suite and suspicious list reduction is relative to the soundness of the generated slice corresponding to the original buggy program. The number of deleted irrelevant statements and deleted irrelevant tests depends directly on the effectiveness of the employed reduction technique.

### V. RESEARCH QUESTIONS

During the analysis we consider the following questions: RQ1 – How effective is ORBS at reducing test suites? RQ2 – How effective is ORBS in improving FL results? RQ3 – Does improving FL improve the performance of TBar? RQ4 – Does reducing test suites improve TBar's efficiency?

#### VI. EVALUATION

The evaluation makes use of a spectrum-based fault localization (SBFL) technique in the latest version (v1.7.2) of GZoltar, the ORBS slicer, and the Ochiai ranking strategy,

```
1: Inputs: The project to be repaired P and its test cases T
2: Output: the patch candidate pt that passes all test cases
3: pt := NULL
4: P_S := ORBS(P,T)
5: T_R := TestMinimisation(P_S, T)
6: SL_R := fault\_localisation(P, T_R)
7: for each loc \in SL_R do
       for each ft \in fix\_templates do
8:
           donor\_code\_list := search\_donor\_code(loc, ft)
9:
10:
          for each item \in donor\_code\_list do
11:
              candidate := patch_generate(loc, ft, item)
              if validate(candidate, T_R) then
12:
                  pt := candidate
13:
                  return pt
14:
15:
              end if
          end for
16:
17:
       end for
18: end for
19: return pt
```

Algorithm 1: Optimised template-based repair process

which is one of the most effective ranking strategies in objectoriented programs [22], [23]. Among the available repair tools, we choose TBar, a template-based APR tool, because this approach is more effective at generating correct patches than other APR approaches. However the approach suffers from efficiency issues making TBar highly sensitive to the quality of the fault localisation algorithm and the size of test suite [3].

# A. Benchmark Dataset and Repair Setups

Our experiments use the Defects4J (v1.2.0) benchmark [6], which is widely used for APR tasks [24], [5]. The benchmark contains a diversity of bug types [25]. For each of the examined subjects, we run TBar using the reduced test suites and suspicious lists and report the resultant RT and NPC values.

#### B. Experimental Results

**RQ1: How effective is ORBS at removing irrelevant tests? Setup:** We use the number of tests in a suite as a proxy for the cost of executing the test suite. This enables us to compute a *reduction rate* as the ratio of the number of tests in the reduced suite to the number of tests in the original suite.

**Results:** Table I shows the difference in the number of passing and failing test cases before and after reduction. Several interesting patterns are evident in the Table I. First, as expected slicing does not affect the number of failing tests. Thus all executions of the original program that exhibit bug *b* have a corresponding execution of program slice that also exhibits *b*.

Second, the test suites that accompany Defects4J are designed to comprehensively test all functionalities of the corresponding software project. This is indeed useful when generating a patch of a large software project, because we typically do not know which parts of the project are affected by the repair and thus need to validated it against the entire test suite to ensure the program still satisfies its specification. However, our analysis shows that a large number of tests in test suites examine parts of the code that are irrelevant to the bug being repaired. Thus, slicing can be an effective test suite minimisation technique to identify and remove irrelevant tests.

	Complete test suites		Reduced test suite	
BugID	Passing tests	Failing tests	Passing tests	Failing tests
Lang-10	2196	2	50	2
Lang-39	1617	1	76	1
Lang-44	1784	1	19	1
Lang-45	1782	1	15	1
Lang-51	1630	1	43	1
Lang-58	1594	1	53	1
Lang-59	1592	1	30	1

 TABLE I

 The impact of ORBS on the size of test suites

Answer to RQ1: ORBS is effective in identifying tests that are irrelevant to the bug being repaired. The integration of ORBS with APR reduces the size of test suites without eliminating any relevant passing or failing test. In addition, the patch generated for each bug by the setup  $R(P, T_R, SL)$  is identical to the one produced by R(P, T, SL). This increases confidence in the soundness of test reduction provided by ORBS.

# **RQ2:** How effective is the ORBS at improving FL?

Setup: APR tools are typically fed a ranked list of suspicious statements to be potentially mutated in turn. Thus, fault localization's accuracy has a direct impact on the performance of an APR tool. To evaluate the effectiveness of ORBS in improving the accuracy of the fault localization, we run GZoltar under two setups: (i) using original programs with complete test suite, and (ii) using original programs with reduced test suites. **Results:** Table II summarizes the results. First, for all seven versions the actual faulty statement is included in the slice. This is crucial as it shows that slicing does not adversely affect the capability of fault localization to localise the faulty statement. Second, the table shows that ORBS improved the suspiciousness rank of the faulty statement for six of the seven bugs. The reduction is roughly proportional to the rank of the faulty statement. For example, for Lang-10 the suspiciousness rank improves 13 positions from 71 to 58, while for Lang-59 it improves only one position from 6 to 5.

Answer to RQ2: combining GZoltar and ORBS proved generally effective. It reduced the size of suspicious lists and improved the suspiciousness rank of each relevant faulty statement. The advantage ORBS brings is more pronounced when the size of the suspicious list is large and rank of the faulty statement is low.

**RQ3:** Does improving FL improve TBar's performance? Setup: From RQ2 ORBS improves the result of fault localization. RQ3 asks if this improvement carries over to the performance of TBar. To do so, we first run TBar using each original program, the complete test suite, and the original suspicious lists generated by the Ochiai ranking strategy. We then rerun TBar but substitute the optimised suspicious lists. To isolate the impact of improved FL on the performance on

	Original program		Reduced program	
BugID	FL size	Fault rank	FL size	Fault rank
Lang-10	261	71	164	58
Lang-39	51	27	42	24
Lang-44	22	16	19	14
Lang-45	24	5	20	6
Lang-51	19	10	16	7
Lang-58	54	20	52	19
Lang-59	12	6	8	5

THE FL RESULTS USING ORIGINAL AND REDUCED TEST SUITES

APR, we hold the program P and the test suite T fixed while varying the list of suspicious lines.

**Results:** Table III compares the results of running TBar on the original buggy programs using first the complete suspicious list and then the reduced one.

In terms of NPC scores, combining ORBS and SBFL clearly helps. For example, the suspiciousness rank of the faulty statement for Lang-10 improved from position 71 to position 58, which caused the NPC score to drop from 2027 to 1489. Overall the reduction in NPC score varies depending on how many positions a faulty statement has been improved.

Recall that each suspicious statement in the generated suspicious list will be mutated using a number of fix templates, which varies depending on the syntactic structure of the statement. A reduction in the NPC score should lead to a reduction in the total number of patch candidates examined by TBar and thus a reduction on the time taken to find a valid patch. From the table the impact of the NPC reduction on the repair time is significant, dropping the total repair time by more than half, from 7 hours to 3 hours and 20 minutes.

Answer to RQ3: the efficiency of TBar is influenced heavily by the accuracy of the FL approach. Combining SBFL with ORBS we observed that the suspicious rank of each faulty statement improved and thus TBar's resultant NPC score was reduced.

BugID	Original NPC	Reduced NPC	Reduction value		
Lang-10	2027	1489	538		
Lang-39	1350	1187	163		
Lang-44	438	357	81		
Lang-51	340	107	233		
Lang-58	516	465	51		
Lang-59	4	4	0		
TABLE III					

THE EFFICIENCY OF TBAR USING NPC IN ORIGINAL AND REDUCED SLS

**RQ4:** Does reducing test suites improve TBar's efficiency? Setup: Test suite minimization attempts to reduce testing cost be removing irrelevant tests. When performing APR, test suite minimization aims to reduce the cost of repair by reducing the cost of patch validation. To address this, we run TBar under two different settings: (i) the original programs with complete tests, and (ii) original programs with reduced tests while keeping the size of the suspicious list unchanged.

**Results:** Table IV shows the repair time cost for running TBar using the complete and the reduced test suites. As noted previously, NPC is not a good choice here because changing the size of the test suite does not impact the number of patch candidates and thus the NPC score stays the same. Only the cost of patch validation where tests are run using generated patches is effected by changes in the test quite.

One clear trend in the data is that the performance of TBar is *inversely proportional* to the rank of the faulty statement responsible for the target bug. That is, the lower the suspiciousness rank of the faulty statement, the greater the impact of test suite reduction. Note that as the faulty statement is ranked lower in the suspicious list, the number of examined patch candidates increases, which in turn increases the number of patch compilations and test case executions. Thus, by reducing the size of the test suite we obtain a great reduction on the overall processing time. For example, the test suite for Lang-10 dropped from 2198 to 52 tests, which reduced the repair time from 26340 to 5400 seconds. This is mainly due to the faulty statement of Lang-10 being ranked in the 71th position in the original suspicious list.

Answer to RQ4: Size of the test suite has a direct effect on TBar's efficiency. This impact is proportional to the rank of the faulty statement responsible for the bug.

BugID	complete test suite	reduced test suite	<b>RTC Reduction</b>
Lang-10	26340	5400	21030
Lang-39	11400	8880	2520
Lang-44	360	143	217
Lang-45	4080	600	3480
Lang-51	2760	480	2280
Lang-58	1260	285	975
Lang-59	34	25	9

#### TABLE IV

TBAR'S EFFICIENCY (IN SECONDS) ON COMPLETE AND REDUCED SUITES

### C. Reliable setups for the combination of slicing and APR

This section provides a summary of empirically discovered reliable slicing-related repair setups. We consider a setup to be reliable if it produces a patch that is identical to the one produced by the setup R(P,T,SL) or a patch valid for program P. Identifying reliable slicing-related repair setups is crucial for APR because it allows us to draw conclusions about the correctness of the patches created by the implemented slicing-related repair setup without needing to consider the standard repair setup R(P,T,SL) with the complete test suite.

There are four setups to examine:  $R(P_S, T_R, SL_R)$ ,  $R(P, T_R, SL_R)$ ,  $R(P, T_R, SL_R)$ ,  $R(P, T_R, SL)$ , and  $R(P, T, SL_R)$ . However, during the analysis we observe cases where the setups  $R(P, T_R, SL_R)$ ,  $R(P, T_R, SL)$ , and  $R(P, T, SL_R)$  are able to produce valid patches for the analyzed bug while  $R(P_S, T_R, SL_R)$  fails to find a patch (e.g., bug Math-5 in Defects4J). This occurs, for instance, when the slicing operation deletes some expressions from the associated conditional branch, but the erroneous conditional statement itself is maintained in the generated slice. This indicates that ORBS may delete statements that are necessary for generating patches.

**Reliable repair setups:** Empirical results demonstrate that the setups  $R(P, T_R, SL_R)$ ,  $R(P, T, SL_R)$ , and  $R(P, T_R, SL)$  give the same patch as the standard setup R(P, T, SL) for all of the investigated defects. On the other hand, the setup  $R(P_S, T_R, SL_R)$  may fail to generate a valid patch for the original program.

#### VII. RELATED WORK

In this section, we discuss related work on template-based APR approaches and previous attempts on accelerating APR. **Template-based APR:** Template-based APR are widely used in the APR literature [26], [27], [24], [28], [29], [30], [31], [5], [32], [33], [34], [35], which utilize predefined fix templates to fix specific bugs. However, most of previous work on template-based APR has focused on maximizing the fix-rate by incorporating a large number of useful fix templates. Despite of these great achievements, modern template-based APR tools still suffer from the efficiency issue as demonstrated in [3] and this work. Combining slicing with APR would help not only in improving the efficiency of the repair process by reaching faulty statements earlier, but also increasing their capabilities in producing correct patches.

**Previous attempts on accelerating APR:** Several techniques have been developed to increase the performance of APR, including regression test selection [36], [37], patch filtering [38], [39], and on-the-fly patch generation [27] and validation [40], [41]. The goal of these techniques is to reduce the patch compilation and test case execution costs, which are the dominant contributors for APR runtime. While these techniques have the potential to reduce the repair cost of programs, they affect a particular step of the APR process. Combining slicing with APR has the potential to improve all aspects of APR, including the fault localization step, patch generation step, and patch validation step.

# VIII. CONCLUSION AND FUTURE WORK

Repairing large-scale programs is a time-consuming process. The most challenging parts of the APR process are finding faulty statements and verifying patches. Instead of examining the entire program without any useful hints, this work proposed to focus on a relatively small portion of the program containing suspicious statements that directly cause program bugs. This can be achieved by applying program slicing ahead of the repair process. The experiments show that the effect of slicing is mostly positive and can significantly improve the performance of APR tools. However, we need exhaustive experiments involving programs with various program sizes and bug types to confirm the general effectiveness of the approach. We aim to report on this in future work.

## ACKNOWLEDGEMENTS

The author would like to acknowledge Dave Binkley for providing the slices for the Lang project and Linas Vidziunas for the help with the experimental setup. The author completed this work while working at the Simula Research Laboratory.
