Abstract. Finding and characterizing gravitational waves from individual supermassive black hole binaries is a central goal of pulsar timing array experiments, which will require analysis methods that can be efficient on our rapidly growing datasets. Here we present a novel approach built on three key elements: i) precalculating and interpolating expensive matrix operations; ii) analytically marginalizing over the gravitational-wave phase at the pulsars; iii) numerically marginalizing over the pulsar distance uncertainties. With these improvements the recent NANOGrav 15yr dataset can be analyzed in minutes after an  $\mathcal{O}(1 \text{ hour})$  setup phase, instead of an analysis taking days-weeks with previous methods. The same setup can be used to efficiently analyze the dataset under any sinusoidal deterministic model. In particular, this will aid testing the binary hypothesis by allowing for efficient analysis of competing models (e.g. incoherent, monopolar, or dipolar sine wave model) and scrambled datasets for false alarm studies. The same setup can be updated in minutes for new realizations of the data, which enables large simulation studies.

## 1. Introduction

With recent pulsar timing array (PTA) datasets [1, 2, 3] showing evidence for a stochastic gravitational-wave (GW) background (GWB) [4, 5, 6, 7], the nHz GW sky promises to be an exciting discovery space in the next decades. An important next milestone will be determining the source of the GWB. The most obvious candidate is a superposition of signals from supermassive black hole binaries (SMBHBs) [8, 9], but more exotic sources cannot be ruled out at this point [10, 9].

If the GWB is coming from SMBHBs, we can expect to individually resolve the loudest of those binaries within the next decade [11, 12, 13, 14, 15]. This will not only help us unequivocally pinpoint the source of the GWB, but these sources would be of great interest in their own right. They are expected to be rich multi-messenger sources, and they could help us better understand the formation and evolution of massive black holes [16, 17, 18]. To realize these sources' potential we need efficient and robust analysis methods to search for their signals, characterize them, and distinguish them from other potential noise sources and signals. These are challenging tasks due to the large data volumes, and unevenly sampled datasets that necessitate a time-domain analysis.

Several previous searches have been carried out to look for these sources, setting increasingly stringent upper limits over the years [19, 20, 21, 22, 23, 24, 25, 26, 27]. Most recently, Ref. [26] and Ref. [27] searched for individual binaries in the NANOGrav 15-year [1] and EPTA DR2 [2] datasets, respectively. While these found no strong evidence for a resolvable binary, they uncovered interesting candidates. This highlights the importance of rigorous model selection and additional checks if we want to reliably vet such candidates in the future.

As our datasets grew, and the presence of a stochastic background became more clear, analyses had to be improved to be efficient and allow for searching for an individual binary in the presence of a background. Numerous Bayesian analysis techniques have been developed to search for and characterize GWs from individual SMBHBs (see e.g. [28, 29, 30, 31, 32]). Most recently, the QuickCW pipeline [32] introduced a new formulation of the likelihood that allows more expensive calculations to be done less frequently, thus providing an overall speedup of about a factor of 100. While this is sufficient to carry out a search in a few days (instead of months) on the most recent PTA datasets, it is still not fast enough to allow for other analyses requiring more complicated setups or many independent runs, e.g.: i) simulation studies on thousands of realizations; ii) false alarm estimation of candidates via scrambled datasets similar to techniques used for the GWB (see e.g. Refs. [33, 34]); iii) comparing an individual binary model with alternative sinusoidal models (e.g. incoherent, monopolar, or dipolar sine models); iv) multiple binaries [35, 36]; v) non-circular binaries [37, 38, 39, 40]; vi) beyond-general-relativity binaries [41]; etc.

In this paper we present a method implemented in the FürgeHullám package‡§ that is an additional factor of 10-100 times faster than Ref. [32], as long as the noise parameters are fixed. This can be sufficient for many of the use cases, and can potentially be relaxed in a future implementation. However, this means that QuickCW can be thought of as a search pipeline, while FürgeHullám is a parameter estimation and model selection tool. This speedup is achieved via the combination of three different techniques:

- (i) Precalculating and interpolating expensive matrix operations (see Section 2.1);
- (ii) Analytically marginalizing over the gravitational-wave phase at the pulsars (see Section 2.2);
- (iii) numerically marginalizing over the pulsar distance uncertainties (see Section 2.3).

Note that (ii) and (iii) are similar to techniques presented in Ref. [31]. For their main results they use numerical phase marginalization, which our results improve upon by deriving analytic expressions, which are much faster. In addition, they also derive an analytic phase marginalization similar to ours. However, their derivation makes several assumptions that we relax in this paper, for example that there is no frequency evolution and that the filter functions are orthogonal. We relax these assumptions, which promotes

<sup>‡</sup> https://github.com/bencebecsy/FurgeHullam

<sup>§</sup> The name comes from Hungarian words "fürge" (meaning quick) and "hullám" (meaning wave).

the analytic marginalization technique from a quick but biased analysis to an efficient and accurate one.

The rest of the paper is organized as follows. In Section 2 we review the signal model and describe the methods used in this new analysis. In Section 3 we validate this approach on simulated datasets. Finally, we offer concluding remarks and discuss future directions enabled by this work in Section 4.

# 2. Methods

It has been recognized in previous studies, that the GW signal of a circular SMBHB in PTA data can be decomposed into a sum over four filter functions: a sine and cosine describing the GW signal at the observer's location (*Earth term*) and a sine and cosine describing the signal at the pulsar location (*Pulsar term*). Here we give a brief overview of the signal model in this formulation (for more details see Ref. [32]). The signal in the  $\alpha$ th pulsar is:

$$s_{\alpha} = \sum_{i=1}^{4} b_{i\alpha} S_{\alpha}^{i},\tag{1}$$

where  $S_{\alpha}^{i} = [\sin(2\pi f_{\rm E}t); \cos(2\pi f_{\rm E}t); \sin(2\pi f_{\alpha}t); \cos(2\pi f_{\alpha}t)]$  are the four necessary filter functions at the Earth-term  $(f_{\rm E})$  and pulsar-term  $(f_{\alpha})$  frequencies. Here we make the realistic assumption that there is no frequency evolution during the  $\mathcal{O}(10 \text{ year})$  observing window, but there can be significant frequency evolution during the  $\mathcal{O}(10^{3} \text{ year})$  light-travel time between the Earth and the pulsar. The reason we need both a sine and a cosine is to be able to combine these to get any possible phase shift. The  $b_{i\alpha}$  coefficients can be written as:

$$b_{1\alpha} = A, (2a)$$

$$b_{2\alpha} = B, (2b)$$

$$b_{3\alpha} = \left(\frac{f_{\rm E}}{f_{\alpha}}\right)^{1/3} \left[ -A\cos\Phi_{\alpha} - B\sin\Phi_{\alpha} \right] , \qquad (2c)$$

$$b_{4\alpha} = \left(\frac{f_{\rm E}}{f_{\alpha}}\right)^{1/3} \left[ -B\cos\Phi_{\alpha} + A\sin\Phi_{\alpha} \right] , \qquad (2d)$$

where  $\Phi_{\alpha}$  are is the phase of the pulsar at the  $\alpha$ th pulsar's location, and:

$$A = F_{\alpha}^{+} a_1 + F_{\alpha}^{\times} a_3 \,, \tag{3a}$$

$$B = F_{\alpha}^{+} a_2 + F_{\alpha}^{\times} a_4 \,, \tag{3b}$$

where  $F_{\alpha}^{+/\times}$  are the antenna patterns for the  $\alpha$ th pulsar (defined e.g. in Eq. (7) and (8) in Ref. [32]), and  $a_i$  are coefficients defined as:

$$a_1 = -A_{\rm e}(2\pi f_{\rm E})^{-1} \left[\cos 2\Phi_0(1+\cos^2\iota)\cos 2\psi - 2\sin 2\Phi_0\cos\iota\sin 2\psi\right],$$
 (4a)

$$a_2 = -A_e(2\pi f_E)^{-1} \left[ \sin 2\Phi_0 (1 + \cos^2 \iota) \cos 2\psi + 2\cos 2\Phi_0 \cos \iota \sin 2\psi \right], (4b)$$

$$a_3 = A_e (2\pi f_E)^{-1} \left[ \cos 2\Phi_0 (1 + \cos^2 \iota) \sin 2\psi + 2 \sin 2\Phi_0 \cos \iota \cos 2\psi \right], \quad (4c)$$

$$a_4 = A_e (2\pi f_E)^{-1} \left[ \sin 2\Phi_0 (1 + \cos^2 \iota) \sin 2\psi - 2\cos 2\Phi_0 \cos \iota \cos 2\psi \right], \quad (4d)$$

where  $A_{\rm e} = \mathcal{M}^{5/3} d_L^{-1} (2\pi f_{\rm E})^{2/3}$  is the Earth-term signal amplitude, which is determined by the chirp mass of the binary  $(\mathcal{M})$ , the luminosity distance to the source  $(d_L)$  and the Earth term GW frequency  $(f_{\rm E})$ . The  $a_i$  coefficients are also influenced by the initial phase of the Earth-term signal  $(\Phi_0)$ , the inclination angle of the binary's orbit  $(\iota)$  and the GW polarization angle  $(\Psi)$ . In addition,  $F_{\alpha}^{+/\times}$  depends on the sky location of the binary  $(\theta$  and  $\Phi)$ , and the pulsar terms are influenced by the GW phase  $(\Phi_{\alpha})$  and GW frequency  $(f_{\alpha})$  at the pulsar's location. These together result in a total of  $8 + 2N_{\rm PSR}$ parameters that describe the signal, where  $N_{\rm PSR}$  is the number of pulsars in the array.

This decomposition can be used to form a maximum-likelihood estimator, called the F-statistic [42]. The same decomposition is also used in the QuickCW pipeline to separate parameters that change the  $S^i_{\alpha}$  filter functions (expensive to update shape parameters) and ones only changing the  $b_{i\alpha}$  coefficients (cheap to update projection parameters) [32]. Note that the decomposition described above is slightly different from the one used in QuickCW in that it does not include frequency evolution within the observing timespan, while QuickCW does.

# 2.1. Inner product spline interpolation

Central to any Bayesian analysis is the log likelihood function, which in this case can be written as:

$$\ln L = \sum_{\alpha=1}^{N_{\text{PSR}}} (d_{\alpha} - s_{\alpha}|d_{\alpha} - s_{\alpha}) = \sum_{\alpha=1}^{N_{\text{PSR}}} \left[ \sum_{i=1}^{4} b_{i\alpha} N_{\alpha}^{i} - \frac{1}{2} \sum_{i=1}^{4} \sum_{j=1}^{4} b_{i\alpha} b_{j\alpha} M_{\alpha}^{ij} \right], (5)$$

where  $d_{\alpha}$  is the data from the  $\alpha$ th pulsar,  $N_{\alpha}^{i} = (d_{\alpha}|S_{\alpha}^{i})$ , and  $M_{\alpha}^{ij} = (S_{\alpha}^{i}|S_{\alpha}^{j})$ , and  $(a|b) = a^{T}C^{-1}b$  denotes the inner product between two vectors with some C covariance matrix that includes all the information about the noise model for the given pulsar. Note that as long as there are no noise processes correlated between pulsars, the log likelihood factorizes as a sum over terms for different pulsars. We can also see that the log likelihood is a sum of various inner products between the data and the filter functions  $(N_{\alpha}^{i})$  and between filter functions  $(M_{\alpha}^{ij})$ . By far the most expensive operation in calculating the likelihood is evaluating these inner products, after which we get the likelihood with just a couple of additions and multiplications. QuickCW makes use of this fact by only occasionally updating the parameters of the signal model that affect the filter functions (half of the parameters). This allows extremely quick exploration of parameters that only affect the coefficients, and thus speeds up the entire search.

Here we introduce a different way of utilizing this structure of the likelihood, by precalculating these inner products on a grid and using interpolation to get their value at any location in parameter space. This approach was used in Ref. [43] for analyzing a signal from a burst with memory. However, the binary signal model has more parameters, thus a grid in those parameters would be prohibitively expensive. However, we can notice that while half the signal parameters affect  $N^i_{\alpha}$  and  $M^{ij}_{\alpha}$ , they only do so by changing the frequency of these filter functions. Thus fundamentally,  $N^i_{\alpha}$  and  $M^{ij}_{\alpha}$  are only functions of the Earth term and pulsar term frequencies, which

are in turn functions of other model parameters, like the pulsar distances, chirp mass, and sky location. This means that we can precalculate these inner products on a grid and interpolate between them whenever we need  $N_{\alpha}^{i}$  and  $M_{\alpha}^{ij}$  at particular frequencies. While  $N_{\alpha}^{i}$  has 4 components for each pulsar, the Earth term and pulsar term filters are the same except they are at different frequencies. So in practice we only need two interpolations, one for a sine and one for a cosine with various frequencies. Figure 1 shows the inner products of sine with the data as a function of frequency (blue dots) for simulated data made to resemble the data of PSR B1855+09 from the NANOGrav 15yr dataset [1]||. We also show a local cubic interpolation (orange dashed curve), which is based on a grid evenly sampled in frequency with a spacing of  $1/(10T_{\rm obs})$ , where  $T_{\rm obs}$  is the total observing timespan. We found this spacing to be the least number of points needed for reliable results. The the absolute error of the interpolation (green points) is also shown in Figure 1. All of these were evaluated on a grid 10 times finer than the one used for the interpolation. Note that the errors are typically orders of magnitudes smaller than the actual values¶.

Figure 1: Inner products of a sine with various frequencies with the data (blue dots) for a simulated dataset made to resemble the data of PSR B1855+09 from the NANOGrav 15yr dataset. Also shown are the local cubic interpolant (orange dashed curve) and the absolute error of the interpolation (green dots).

Now consider  $M_{\alpha}^{ij}$ , which is a 4-by-4 symmetric matrix for each pulsar, thus having 10 independent components. However, all of these fall into 3 different categories: i) sinesine; ii) cosine-cosine; iii) sine-cosine. Thus we only need three distinct 2-dimensional interpolants. These are constructed similarly to those for  $N_{\alpha}^{i}$ , but on a 2-dimensional

<sup>||</sup> The corresponding plot for the inner product between cosine and data looks qualitatively the same. || The green points along zero correspond to points where the interpolant was evaluated at the same point where it was precalculated, so the error is at much smaller scales and corresponds to numerical precision.

grid, using a 2-dimensional local cubic interpolation. Figure 2 shows the sine-sine and sine-cosine interpolants<sup>+</sup>. Note that as expected, the sine-sine term is maximal when the frequencies are the same, and shows a sinc-function-like decay for different frequencies. Similarly, the sin-cos term is close to zero for equal frequencies and shows a periodic decaying pattern as the frequency difference increases. However, the uneven sampling and non-stationary noise results in non-trivial modification of these simple expectations. For example, frequencies close to zero and  $1/yr \simeq 32$  nHz show inner products close to zero, as the timing model fit down-weights frequencies covariant with the timing model. There is also an overall upward trend as frequency increases, due to red noise that reduces the noise-weighted inner products at low frequencies. Also note that the sine-cosine inner products are comparable in magnitude to the sine-sine inner products, and depending on the frequencies they can even be larger. This highlights that these cross-terms cannot be ignored in this case, even though they would be zero if the data were evenly sampled and we were only looking at multiples of the fundamental  $1/T_{\rm obs}$ frequency. Similar to the  $N^i_{\alpha}$  interpolants,  $M^{ij}_{\alpha}$  interpolants typically show relative errors of less than 1%.

Figure 2: Inner products between sine and sine (a) and sine and cosine (b) as a function of frequency for a simulated dataset made to resemble the data of PSR B1855+09 from the NANOGrav 15yr dataset. Dashed lines show  $f_{\rm GW,1} = f_{\rm GW,2}$ .

Thus we can see that in total we need two 1-dimensional, and three 2-dimensional interpolants. We found the reliable results can be achieved with 10 grid points per

<sup>&</sup>lt;sup>+</sup> The cosine-cosine interpolant looks qualitatively similar to the sine-sine interpolant shown.

 $1/T_{\rm obs}$ -wide frequency bin. So if we want to analyze up to a frequency of  $N/T_{\rm obs}$ , we need 10N inner product calculations for each 1-dimensional grids,  $100N^2$  inner products for the sine-cosine inner products, and 5N(1+10N) for the sine-sine and cosine-cosine grids each, because those are symmetric. Thus in total, we need  $30N + 200N^2$  inner product calculations. For the realistic scenario where we want to search up to a frequency of 1/yr in a 16 yr long dataset (N=16), the interpolation setup requires  $\sim 52$  thousand inner product calculations. Note however, that one can save on the 2-dimensional grids by first calculating and storing  $C^{-1}b$  for all 10N b vectors and then contracting that with the  $10N \ a^T$  vectors. Thus in practice the setup is about as costly as 20 thousand likelihood calls, which is much faster than a naive Markov-chain Monte Carlo (MCMC) that calculates the likelihood from scratch each time. We can see in Table 1 that this setup on a simulated dataset with the same data volume as the NANOGrav 15yr dataset takes about 4.5 hours on a modest 16-core CPU. In addition, unlike a serial MCMC, this setup is trivially parallelizable, since we already know each inner product we wish to calculate. Thus a setup time of <1 hour is easily possible, but utilizing the high parallel-computing capabilities of GPUs could reduce the setup time to a few minutes (see e.g. [44] for a recent effort to parallelize PTA computations on GPUs). Also note that the majority of the setup is spent on the 2-dimensional interpolants, which do not depend on the data. Thus if we want to analyze many realizations of simulated datasets, where the data changes, but the covariance matrix and observing epochs stay the same, the setup only costs 20N inner products, or about 3.5 minutes instead of 4.5 hours in the above example.

Table 1: Representative evaluation times of different variants of the likelihood on a NANOGrav 15yr-like dataset (67 pulsars, 674,683 TOAs) with an AMD Ryzen Threadripper 3970X 32-core processor (restricted to use only 16 cores).

Enterprise likelihood	1.4 s
QuickCW fast step	$15 \ \mu s$
QuickCW slow step	500  ms
Unparallelized setup time	4.5 h
Setup update with new data	3.5 min
Splined likelihood	$350~\mu\mathrm{s}$
Phase-marginalized splined likelihood	$500~\mu \mathrm{s}$
Phase-and-distance-marginalized splined likelihood	$3.5 \mathrm{\ ms}$

We tested the accuracy of the log likelihood calculated with these interpolated likelihoods on a simulated dataset made to resemble the NANOGrav 15yr dataset. We injected an individual binary signal and analyzed it with QuickCW. Then we randomly drew samples from the posterior and calculated the log likelihood at these points with the interpolated inner products. The absolute difference between the directly computed and interpolated likelihoods was always less than 3%, and most of the time less than 1%. These are larger than the expected numerical errors ( $\sim 10^{-5}$ ), but they are small enough

not to affect results appreciably (see Section 3 for more consistency tests). Table 1 also shows the average time it takes to calculate this interpolated likelihood. It is interesting to compare this evaluation time with the traditional enterprise [45] likelihood call and fast and slow QuickCW likelihood calls, which are also shown in Table 1. We can see that the splined likelihood is  $\sim 4,000$  times faster than enterprise,  $\sim 1,500$  times faster than a QuickCW slow step, and  $\sim 25$  times slower than a QuickCW fast step. So we can expect an analysis using this splined likelihood not only to be vastly faster than enterprise, but also to be significantly faster than QuickCW, since it can make relatively fast steps in all parameters.

The current implementation uses a local cubic interpolant based on the fast\_interp package\*, which utilizes just-in-time compilation with Numba[46, 47] to make these really fast. As we have seen this achieves reasonable accuracy and speed based on a moderately high number of interpolation points. However, it is possible that more advanced interpolation methods would result in better accuracy and speed or require fewer evaluations for a setup. One promising approach could be using Gaussian processes, which potentially could match the intrinsic periodic variability we see on Figures 1 and 2. Another promising avenue would be using machine-learning-based interpolation approaches. We leave these investigations of potential further improvements to future work.

# 2.2. Analytic phase marginalization

The phases of the GW at the locations of the pulsars  $(\Phi_{\alpha})$  are nuisance parameters that carry no physical information about the GW source‡. Thus it could be beneficial to marginalize over them explicitly, instead of including them in the list of parameters sampled via MCMC. A similar approach was suggested for ground-based GW detectors [48]. PTAs could potentially see even more benefits, due to the large number of pulsar phase parameters. In addition, since a given pulsar phase parameter only affects the given pulsar, each pulsar phase can be integrated out via a 1-dimensional integral. So by explicitly integrating these parameters out, we are calculating a 1-dimensional integral  $N_{PSR}$  times, instead of a single  $N_{PSR}$ -dimensional integral that the MCMC is doing when we leave these parameters to sample over. This suggests that even a naive numerical integral of these phase parameters is better than sampling over them with MCMC. This argument has been made in Ref. [31], where they numerically marginalize over phase parameters. However, as it turns out the required integral can be done analytically.

The integral in question for the  $\alpha$ th pulsar has the following form:

$$I_{\alpha} = \int_{0}^{2\pi} \exp L(\Phi_{\alpha}) = \int_{0}^{2\pi} \exp \left[ \sum_{i=1}^{4} b_{i\alpha} N_{\alpha}^{i} - \frac{1}{2} \sum_{i=1}^{4} \sum_{j=1}^{4} b_{i\alpha} b_{j\alpha} M_{\alpha}^{ij} \right] d\Phi_{\alpha}.$$
 (6)

<sup>\*</sup> https://github.com/dbstein/fast\_interp

<sup>#</sup> At least in the current situation where the error on the pulsar distances is much larger than a GW wavelength.

Using Eq. (2d) we can rewrite the log likelihood in the integrand to highlight its  $\Phi_{\alpha}$  dependence:

$$L(\Phi_{\alpha}) = L_0 + L_1 \sin(\Phi_{\alpha}) + L_2 \cos(\Phi_{\alpha}) + L_3 \sin(2\Phi_{\alpha}) + L_4 \cos(2\Phi_{\alpha}), \quad (7)$$

where (dropping the  $\alpha$  indices):

$$L_0 = AN^1 + BN^2 - \frac{A^2}{2}M^{11} - \frac{B^2}{2}M^{22} - ABM^{12} - \frac{\chi^2}{4}(A^2 + B^2)(M^{33} + M^{44}), \quad (8a)$$

$$L_1 = \chi \left[ -BN^3 + AN^4 + ABM^{13} - A^2M^{14} + B^2M^{23} - ABM^{24} \right], \tag{8b}$$

$$L_2 = \chi \left[ -AN^3 - BN^4 + A^2M^{13} + ABM^{14} + ABM^{23} + B^2M^{24} \right], \tag{8c}$$

$$L_3 = \frac{\chi^2}{2} \left[ AB \left( M^{44} - M^{33} \right) + \left( A^2 - B^2 \right) M^{34} \right], \tag{8d}$$

$$L_4 = \frac{\chi^2}{4} \left[ \left( A^2 - B^2 \right) \left( M^{44} - M^{33} \right) - 4ABM^{34} \right], \tag{8e}$$

where  $\chi = (f_{\rm E}/f_{\alpha})^{1/3}$ . Note that the non-vanishing double-angle terms ( $L_3$  and  $L_4$ ) come from the fact that  $M^{34} \neq 0$  and  $M^{33} \neq M^{44}$  due to the uneven sampling of the dataset and the fact that frequencies are not necessarily integer multiples of  $1/T_{\rm obs}$ . This is unlike the situation in ground-based detectors, where these terms do vanish, thus the resulting integral is simply a 0th order modified Bessel function of the first kind [49, 48, 50]. Note that a phase-marginalized likelihood was also derived for PTAs under the assumption that  $M^{34} = 0$  and  $M^{33} = M^{44}$  (see Appendix A in Ref. [31]). However, as we can see on Figure 2,  $M^{34}$  can be comparable to  $M^{11}$  and  $M^{22}$ , so this is not a particularly accurate approximation in realistic scenarios.

Since an overall phase does not change the integral, we can get rid of the  $\sin(2\Phi_{\alpha})$  term and can rewrite the integral as:

$$I_{\alpha} = e^{L_0} \int_0^{2\pi} \exp\left[f(\Phi_{\alpha})\right] d\Phi_{\alpha} = e^{L_0} \int_0^{2\pi} \exp\left[x \sin(\Phi_{\alpha}) + y \cos(\Phi_{\alpha}) + z \cos(2\Phi_{\alpha})\right] d\Phi_{\alpha}, (9)$$
 where

$$x = -\sqrt{L_1^2 + L_2^2} \sin \Delta \Phi \,, \tag{10a}$$

$$y = \sqrt{L_1^2 + L_2^2} \cos \Delta \Phi \,, \tag{10b}$$

$$z = \sqrt{L_3^2 + L_4^2}, (10c)$$

and  $\Delta\Phi = \tan^{-1}(-L_1/L_2) - \tan^{-1}(-L_3/L_4)/2$  is the phase difference between the single and double angle terms. Using the Jacobi–Anger expansion for all three terms in the integrand, we get a triple sum. Gathering the non-vanishing terms the integral solution can be written as:

$$I_{\alpha} = e^{L_{0}} + I_{0}(x)I_{0}(y)I_{0}(z) + 2I_{0}(x)\sum_{n=1}^{\infty} I_{n}(z)I_{2n}(y) + 2I_{0}(z)\sum_{n=1}^{\infty} I_{2n}(y)I_{2n}(x)(-1)^{n} + 2I_{0}(y)\sum_{n=1}^{\infty} I_{n}(z)I_{2n}(x)(-1)^{n} + 2\sum_{n=1}^{\infty} I_{2n}(z)I_{2n}(y)I_{2n}(x)(-1)^{n} + 2\sum_{n=1}^{\infty} I_{n}(z)I_{4n}(y)I_{2n}(x)(-1)^{n} + 2\sum_{n=1}^{\infty} I_{n}(z)I_{2n}(y)I_{4n}(x),$$

$$(11)$$

where  $I_n$  are modified Bessel functions of the first kind. The first non-trivial term comes from when we gather the constants from all three sums. The next three terms are from combinations when we pick the constant from one of the sums and  $\cos(n\Phi_{\alpha})$  from the other two, which results in a non-vanishing integral of cosine squared. The last three terms are from when two  $\cos(n\Phi_{\alpha})$  terms are combined with a  $\cos(2n\Phi_{\alpha})$ . While the sums go to infinity, these can be well approximated by just the first few terms for relatively low signal amplitudes. Using fast implementations of the Bessel functions†† makes the calculation of the phase marginalized likelihood cost less than two times more than a single non-marginalized likelihood (see Table 1). For large amplitudes, the series oscillates and convergence cannot be achieved due to numerical errors. However, in this regime, the integral can be approximated with the Laplace method [52]:

$$I_{\alpha} \simeq \frac{\exp\left[L_{0} + f_{0}\right]}{\sqrt{2\pi|f_{2}|}} \left(1 + \frac{f_{4}}{8|f_{2}|^{2}} + \frac{5f_{3}^{2}}{24|f_{2}|^{3}} + \frac{f_{6}}{48|f_{2}|^{3}} + \frac{35f_{4}^{2}}{384|f_{2}|^{4}} + \frac{7f_{3}f_{5}}{48|f_{2}|^{4}} + \frac{35f_{3}^{2}f_{4}}{64|f_{2}|^{5}} + \frac{385f_{3}^{4}}{1152|f_{2}|^{6}}\right), \tag{12}$$

where  $f_n$  is the *n*th derivative of  $f(\Phi)$  w.r.t.  $\Phi$ . The first term is the usual Gaussian integral, while terms in the parentheses account for non-vanishing higher order derivatives of the function. The maximum is found by searching for a root of  $f_1$  on both the  $(0,\pi)$  and  $(\pi,2\pi)$  intervals using Brent's method [53] as implemented in scipy.optimize.brentq [51]. Then the real maximum can be picked from the two by requiring that  $f_2 < 0$ .

Thus a combination of these two methods can provide an accurate and efficient integration of phase parameters over the entire prior range of signal amplitudes. We tested this method against a simple numerical integration and found that the error these methods introduce in the log likelihood is less than  $10^{-3}$ , thus smaller than the errors introduced by inner product interpolation discussed in Section 2.1. This is sufficient for current datasets, but if higher precision is required, the Laplace method in Eq. (12) can be continued to higher order.

Note also that while this phase integration is presented as part of this new approach that uses the interpolated inner products, the same marginalization could be introduced in any other method where the  $N^i_\alpha$  and  $M^{ij}_\alpha$  matrices are available, e.g. in QuickCW.

## 2.3. Numerical pulsar distance marginalization

After the analytic phase marginalization, we can also marginalize over pulsar distances numerically. This is relatively cheap, because the pulsar distance only affects the signal in the given pulsar, and even for moderate frequency ( $\sim 20$  nHz) and high chirp mass ( $\sim 10^9 M_{\odot}$ ) the likelihood is slowly changing and can be integrated out over just a few points (we default to 10). In addition, making 10 calls to the likelihood at different

 $\dagger\dagger$  We use the implementation in scipy [51] compiled in Numba [46, 47] via the numba-scipy package (https://github.com/numba-scipy)

pulsar distances (and thus pulsar frequencies) does not increase the cost 10-fold, since only part of the calculation needs to be repeated. To make best use of our likelihood calls, we can rewrite the integral as a sum over points evenly spaced according to the CDF of the Gaussian prior:

$$p(d|\theta) = \int_0^\infty p(d|\theta, L)p(L) \ dL = \int_0^1 p(d|\theta, L) \ dP(L)$$
$$\approx \frac{1}{N} \sum_{i=1}^N p\left(d\Big|\theta, L = P^{-1}\left[\frac{2i-1}{2N}\right]\right), \tag{13}$$

where L is the distance to the pulsar, p(L) is the PDF and P(L) is the CDF of the distance prior. We can see from Table 1 that doing this sum over 10 points makes the likelihood call about 7 times more expensive as the phase-marginalized likelihood. We argue that this is well-worth it, since now our likelihood costs 10 times the original interpolated likelihood (still  $\sim 400$  times faster than a regular enterprise likelihood call), but now we only need to sample over 8 parameters, instead of  $8+2N_{\rm PSR}$  parameters, which for recent PTA datasets with dozens of pulsars is a significant reduction in parameter dimension†. Note that this is essentially the same idea as in Ref. [31], except they draw values randomly from the prior of L instead of using a uniform-in-probability grid via the CDF.

## 3. Tests on simulated datasets

To validate the parameter estimation accuracy of this new algorithm, we tested it on simulated datasets made to resemble the NANOGrav 15yr dataset. In addition to white noise and red noise in each pulsar, we also added a simulated SMBHB with  $f_{\rm E}=20~{\rm nHz}$ ,  $\log_{10}\mathcal{M}=9.5,\ A_{\rm e}=4\times10^{-15},$  which resulted in a signal-to-noise ratio of SNR=11.4. Figure 3 shows the 1 and 2-dimensional posterior distributions via the FürgeHullám likelihood sampled with the Eryn [54] ensemble-sampler (black), and a standard QuickCW run for comparison (red). Green lines indicate the prior distributions, and blue shows the injected model parameters. QuickCW was run for 1 billion fast steps, 100 thousand slow steps, which took about 50 hours. Eryn was run with 100 walkers for 200 iterations after a 100 iteration burnin (initialized around the injected location), and took about 6 minutes to run (after the 4.5 hour setup discussed above). While QuickCW produces many more samples, due to the larger autocorrelation length, the two analyses resulted in roughly the same number of independent samples.

We can see on Figure 3 that even in this large-SNR highly-evolving signal limit, the two results are nearly identical. The most significant (but still minor) difference can be seen in the recovery of the GW frequency parameter. This is due to the fact that FürgeHullám ignores the frequency evolution of the signal within the observing timespan. Since the frequency is referenced at the first TOA, and the signal chirps up in frequency, FürgeHullám recovers a wider posterior centered slightly higher. We also

<sup>†</sup> E.g. for the NANOGrav 15yr dataset, this reduces the number of parameters from 142 to 8.

Figure 3: Posterior comparison of analysis sampling the splined phase-and-distance-marginalized FürgeHullám likelihood with the Eryn ensemble sampler (6 min run, black) and a QuickCW analysis (50 hour run, red). Green lines indicate the prior distributions, and blue shows the injected model parameters. Orange shows the injected frequency if we reference that at the middle of the 16 year observing window instead of referencing it at the first TOA.

show the injected frequency if we reference that at the middle of the 16 year observing window, the offset of which is consistent with the shift in posterior. Ignoring the signal evolution within the observing window is expected to have the strongest effect for such a high-frequency high-chirp-mass and high-SNR signal as this one. Thus we can conclude that for all realistic scenarios, the accuracy is expected to be sufficient.

We also tested the model selection capabilities of this new approach. To do so we

analyzed the same dataset as above, except with a lower amplitude to achieve a more realistic SNR of 6.7. We then calculated the Bayes-factor in favor of a model including an individual binary in addition to pulsar noise with two different methods: i) with the FürgeHullám likelihood using nested sampling (NS, [55]) via dynesty[56]; ii) using a QuickCW run via the Savage-Dickey density ratio (SD, [57]). The former took 30 mins and resulted in the estimate of  $\ln BF_{NS} = 5.84 \pm 0.24$ , while the latter took 50 hours to run and resulted in the estimate of  $\ln BF_{SD} = 5.82 \pm 0.11$ . So we can see that the new likelihood with NS gives a consistent and comparably accurate Bayes factor as the frequently used SD method in a fraction of the time.

### 4. Conclusion and future work

In this paper we presented a new approach to analyzing signals from individual SMBHBs in PTA data, which provides superior speed compared to current analysis techniques as long as the noise models are held fixed. Thus in its current implementation this approach can be viewed as an efficient inference and model selection tool, which complements efficient search algorithms like QuickCW.

We demonstrated that after an initial setup this new approach can provide efficient parameter estimation and model selection 100-1000 times faster than current methods. The speedup is still a factor of 10-100 when taking into account the setup time. In addition, the same setup can be used for the analysis of any deterministic signal that can be expressed as a sum of sines and cosines. These will be explored in more details in future studies, but some possibilities include:

- Comparison with alternative sinusoidal models, like incoherent sine model, monopolar or dipolar sine model;
- Non-GW sinusoidal models like ultralight dark matter (see Ref. [10] and references therein);
- Repeated runs on sky scrambled/phase shifted datasets for false-alarm estimation similar to those used for the GWB (see e.g. Refs. [33, 34]);
- Eccentric binary analysis [37, 38, 39, 40];
- Alternative polarization modes [41];
- Multiple binaries [35, 36].

In addition, this new approach will particularly beneficial for large simulation studies, since only a small fraction of the setup needs to be repeated if only the data changes between realizations, but the observing epochs and covariance matrix stays the same.

While the current implementation only works if the noise is held fixed due to the inner product interpolation, the other two components of this approach could benefit search algorithms like QuickCW as well. In addition, there are potential ways to remedy the fixed-noise limitation of this pipeline to make it a full search algorithm in the future. One possibility would be to change the  $M_{\alpha}^{ij}$  interpolation from using a 2-dimensional

grid over all frequencies to a 1-dimensional one covering possible pulsar frequencies and recalculate them each time we change the Earth-term frequency. That would still require 100s of inner product calculations for each update, but potentially with GPU-based parallelization it can be done on the fly, which would also allow for changing the noise parameters. This can also be thought of as an extension of the QuickCW approach, where all parameters except the Earth-term frequency become fast projection parameters. This approach will be explored in more detail in a future study.

Another way to marginalize over parameters of the covariance matrix (in particular a common red noise process) would be to directly sample the Fourier coefficients instead of using the marginalized covariance matrices. This has been proposed before [58], but have not been used widely because the computation via the marginalized covariance matrix was more efficient. However, there have been recent developments in efficient sampling of these coefficients [59, 60], which could change this situation. In particular, the fact that we precalculate sine cosine inner product for the deterministic model anyway, would further help in combining these efforts. In addition, it has also been suggested, that this is the way forward for deterministic signal searches. this is because directly sampling the GWB Fourier coefficients allows us to keep the likelihood factorized even under a correlated background model (see details of the idea in Appendix A in Ref. [32] and a first implementation in Ref. [61]), which is a requirement for both QuickCW and the FürgeHullám approach presented in this paper.

#### Acknowledgments

The author thanks Neil Cornish and members of the OSU Gravity Group and the NANOGrav Collaboration for fruitful discussions throughout this project. We would also like to thank Bjorn Larsen for feedback on the manuscript. The author is also grateful to an anonymous contributor to Mathematics Stackexchange for the idea that helped identify the Laplace method as an appropriate approximation of the pulsar phase integral in the large-amplitude limit, see Eq. (12). We appreciate the support of the NSF Physics Frontiers Center Award PFC-2020265.
