Abstract. A theory of the absorption of a laser field by an atomic or condensed matter medium is presented for the case where the medium is also interacting with a strong electromagnetic field. The rotating wave approximation is not assumed for the latter. It is shown that in the weak probe limit the Lindblad master equation reduces to a smaller system of linear equations for the relevant steady state coherences. In this limit, the complex susceptibility of the medium can be expressed in terms of individual contributions of decaying dressed states, the latter being eigenstates of a non-Hermitian Floquet Hamiltonian.

1. Introduction

This article primarily concerns the theory of the absorption of a weak laser beam by an atomic or condensed matter medium also interacting with another or several other electromagnetic fields, when at least one of these other fields is too strong to be taken into account within the rotating wave approximation. In the applications we have in mind, this strong field would typically be a microwave or radio frequency field; however, the theory is not limited to this particular case. The relevance of the Floquet theory of linear differential equations with periodic coefficients in this context and in other areas of quantum optics has long been recognised [1, 2, 3]. It is easily appreciated from the fact that the Hamiltonian describing the interaction of a quantum system with a CW monochromatic electromagnetic field is periodic in time, barring other time-dependent interactions. However, the theory also applies to stationary multi-frequency fields [4, 5, 6] and helps understand the dynamics of quantum systems interacting with non stationary fields, e.g., the dynamics of atoms in intense laser pulses [7, 8, 9].

A full Floquet description is often unnecessary for the relatively weak, near resonant fields typically used in spectroscopic measurements. The rotating wave approximation can usually be made for such fields, which simplifies the theory considerably [6, 10]. However, making this approximation is not always possible. For instance, going beyond the rotating wave approximation is normally essential in applications of Floquet theory to the modelling of multiphoton ionisation and other multiphoton processes driven by a strong laser field [5, 6, 7, 9, 11, 12], to the measurement of low frequency fields using atoms in Rydberg states [13, 14, 15, 16, 17], and of course for understanding how the properties of atomic or other systems can be manipulated through Floquet engineering — e.g., [18, 19, 20, 21, 22, 23, 24].

Floquet calculations involves replacing the time-dependent Hamiltonian of the system of interest by a time-independent Hamiltonian acting in a larger Hilbert space, the “Floquet Hamiltonian” [1, 2]. This Floquet Hamiltonian is non-Hermitian in some cases, for example in the cases considered in [25] or in [26]. In particular, it is non-Hermitian in the complex dilation approach to multiphoton ionisation in a strong laser field [11, 12]: the radial variable r is replaced by $r \exp(i\theta_r)$ for a well-chosen value of the angle θ_r , which transforms the Floquet Hamiltonian into a non-Hermitian operator. Doing so yields complex quasienergies, whose imaginary parts, within a factor $(-2/\hbar)$, give the ionisation rates of the states of interest [27]. This approach to multiphoton ionisation has been shown to be mathematically rigorous [28, 29, 30].

The Floquet Hamiltonian is also non-Hermitian in the case considered in the present work, but for a different reason. Here we assume that the medium can be modelled as an ensemble of individual systems with a finite number of bound energy eigenstates, and that some of these bound states may decay radiatively or otherwise. For example, the methods outlined in the present article have recently been applied to the calculation of the absorption of a weak probe beam by a sample of cuprous oxide (Cu_2O) driven by a strong microwave field [31]. In that system, the probe beam couples the valence

band (treated as a single bound state) to broad Rydberg excitons decaying through interaction with phonons. These methods could also be applied, e.g., to the spectroscopy of a strongly driven atomic vapour for which the excited atoms decay radiatively. The quantum state of such media can usually be described by a density matrix satisfying the Lindblad master equation. Floquet approaches to this issue have been discussed in the literature — e.g., [32, 33, 34, 35] and, in regard to the optical properties of the medium, [36, 37, 38, 39, 40, 41, 42]. However, and as shown in this article, the Lindblad master equation reduces to a set of simpler equations when the probe field is weak enough to be treated in first order of perturbation theory, with each decaying bound state being associated with a complex energy. I.e., the real energies $\hbar\omega^{(i)}$, $i = 0, 1, 2, \dots$, of the different states included in the model are replaced by the complex energies $\hbar\omega^{(i)} - i\hbar\Gamma^{(i)}/2$, $i = 0, 1, 2, \dots$, where $\Gamma^{(i)}$ is the decay rate of state i . The properties of the medium can then be described in terms of the eigenstates of a non-Hermitian Floquet Hamiltonian, this Hamiltonian being non-Hermitian because of the non-zero imaginary parts of these complex energies. In particular, the calculation yields the linear susceptibility of the medium as a sum of contributions from the decaying dressed states of the Floquet Hamiltonian. We stress that the imaginary parts of these energies are rigorously derived from the master equation, here, and are not *ad hoc* additional phenomenological decay widths.

For simplicity, we only consider the case of a homogeneous single species medium interacting with two monochromatic electromagnetic fields, namely a weak probe field and a strong coupling field, both polarised linearly in the same direction. The theory can be easily generalised to multi-species media and to more complex excitation pathways as long as the rotating wave approximation and the Beer-Lambert law apply for the probe field. The general theory is developed in section 2 and its weak probe and long time limits in section 3. The theory simplifies significantly in this double limit, as the relevant coherences can then be obtained by solving a system of linear equations of reduced size, equation (40) below. Moreover, the susceptibility can also be expressed as a sum of contributions of dressed excited states spawned by the coupling field, in these limits, in the same way as the susceptibility can be expressed as a sum of contributions of bare excited states in the absence of the coupling field. A numerical illustration of the theory can be found in section 4.

2. The probe absorption spectrum

As already mentioned, this article primarily concerns experiments in which a strong microwave or some other electromagnetic field (the “coupling field”) is applied to a homogeneous sample addressed by a laser beam (the “probe field”), in circumstances where the latter is sufficiently weak that its attenuation is well described by Beer-Lambert law. We thus assume that

$$I(x) = \exp(-Kx)I(x = 0), \quad (1)$$

where $I(x)$ is the laser beam intensity at a distance x inside the medium and K , the absorption coefficient, is a constant. For simplicity, we assume that these two fields are monochromatic and polarised in the z -direction, that the probe field can be modelled as a plane wave propagating in the x -direction and that the coupling field is homogeneous. We also assume that these fields are turned on at $t = 0$. The details of the turn on are not important in so far as the state of the medium in the $t \rightarrow \infty$ limit is concerned, which is the focus of this work. Accordingly, we write their electric field components as follows,

$$\mathbf{E}_p(x, t) = \frac{1}{2} \hat{\mathbf{z}} [\mathcal{E}_p(x) \exp(-i\omega_p t) + \mathcal{E}_p^*(x) \exp(i\omega_p t)] H(t), \quad (2)$$

$$\mathbf{E}_c(t) = \frac{1}{2} \hat{\mathbf{z}} [\mathcal{E}_c \exp(-i\omega_c t) + \mathcal{E}_c^* \exp(i\omega_c t)] H(t), \quad (3)$$

where $\hat{\mathbf{z}}$ is a unit vector in the z -direction and $H(t)$ is the Heaviside step function. The probe and coupling fields polarise the medium, resulting in a polarisation field $\mathbf{P}(x, t)$. In terms of the density operator $\hat{\rho}(x, t)$ describing the state of the medium at position x and time t ,

$$\mathbf{P}(x, t) = N_d \text{Tr}[\hat{\rho}(x, t) \hat{D}_z] \hat{\mathbf{z}}, \quad (4)$$

where \hat{D}_z is the z -component of the dipole operator and N_d is the number density of atoms or other individual systems whose state is described by $\hat{\rho}(x, t)$. Assuming that t is large enough for the medium to have evolved into a stationary state,

$$\mathbf{P}(x, t) = \frac{1}{2} \hat{\mathbf{z}} [\mathcal{P}_p(x) \exp(-i\omega_p t) + \mathcal{P}_p^*(x) \exp(i\omega_p t) + \dots], \quad (5)$$

where \dots stands for contributions oscillating at angular frequencies other than ω_p . The complex polarisation amplitude $\mathcal{P}_p(x)$ is proportional to $\mathcal{E}_p(x)$ for the weak probe fields considered here: in terms of a frequency-dependent susceptibility $\chi(\omega_p, \omega_c, \mathcal{E}_c)$,

$$\mathcal{P}_p(x) = \epsilon_0 \chi(\omega_p, \omega_c, \mathcal{E}_c) \mathcal{E}_p(x). \quad (6)$$

It follows from the above [43] that

$$K = 2(\omega_p/c) \text{Im} [1 + \chi(\omega_p, \omega_c, \mathcal{E}_c)]^{1/2}. \quad (7)$$

The absorption coefficient K does not depend on x and can therefore be calculated at any position within the medium. Accordingly, we no longer specify the spatial dependence of $\mathcal{E}_p(x)$, $\mathcal{P}_p(x)$ and $\hat{\rho}(x, t)$.

We use a finite basis of \mathcal{N} orthonormal eigenstates of the medium's field-free Hamiltonian, \hat{H}_0 , namely a basis $\{|i\rangle, i = 0, \dots, \mathcal{N} - 1\}$ such that $\langle i|j\rangle = \delta_{ij}$ and

$$\hat{H}_0|i\rangle = \hbar\omega^{(i)}|i\rangle, \quad i = 0, \dots, \mathcal{N} - 1. \quad (8)$$

We describe the interaction between the medium and the applied fields within the electric dipole approximation. The Hamiltonian of the system can therefore be written

in the following way in terms of the Rabi frequencies $\Omega_{p;ij} = \mathcal{E}_p \langle i | \hat{D}_z | j \rangle / \hbar$ and $\Omega_{c;ij} = \mathcal{E}_c \langle i | \hat{D}_z | j \rangle / \hbar$:

$$\hat{H}(t) = \sum_i \hbar \omega^{(i)} |i\rangle \langle i| - \frac{\hbar}{2} \sum_{i,j} \{ [\Omega_{p;ij} \exp(-i\omega_p t) + \Omega_{c;ij} \exp(-i\omega_c t)] |i\rangle \langle j| + \text{h.c.} \}. \quad (9)$$

Typically, the relevant states form two groups differing considerably in energy, namely a low energy group A and a higher energy group B . We will assume that the coupling field strongly couples the states of group B to each other, but does not directly couple the states of group A to each other or to those of group B , while the probe field only couples states of group A to states of group B . Neglecting the far-detuned transitions, we thus set

$$\begin{aligned} \hat{H}(t) = & \sum_i \hbar \omega^{(i)} |i\rangle \langle i| - \frac{\hbar}{2} \sum_{i \in A} \sum_{j \in B} [\Omega_{p;ij} \exp(-i\omega_p t) |i\rangle \langle j| + \text{h.c.}] \\ & - \frac{\hbar}{2} \sum_{i \in B} \sum_{j \in A} [\Omega_{p;ij} \exp(-i\omega_p t) |i\rangle \langle j| + \text{h.c.}] \\ & - \frac{\hbar}{2} \sum_{i \in B} \sum_{j \in B} [\Omega_{c;ij} \exp(-i\omega_c t) |i\rangle \langle j| + \text{h.c.}]. \end{aligned} \quad (10)$$

Given this Hamiltonian, the density operator $\hat{\rho}(t)$ is governed by the Lindblad master equation

$$\frac{d\hat{\rho}}{dt} = -\frac{i}{\hbar} [\hat{H}, \hat{\rho}] + \frac{1}{2} \sum_n \left(2\hat{C}_n \hat{\rho} \hat{C}_n^\dagger - \hat{C}_n^\dagger \hat{C}_n \hat{\rho} - \hat{\rho} \hat{C}_n^\dagger \hat{C}_n \right), \quad (11)$$

where the \hat{C}_n 's are the collapse (or jump) operators accounting for decoherence and relaxation. The \hat{C}_n 's should include the operator $\sqrt{\Gamma_{ij}} |i\rangle \langle j|$ if state j relaxes to state i at a rate Γ_{ij} , e.g., by spontaneous decay.

We will also assume that the energies are measured with respect to a given reference energy $\hbar\omega^{\text{ref}}$ chosen so that the differences $|\omega^{(i)} - \omega^{\text{ref}}|$ are much smaller for the states of group A than for those of group B . Conversely, the differences $|\omega_p - (\omega^{(i)} - \omega^{\text{ref}})|$ are much smaller for the states of group B than for those of group A . We can thus pass to slowly varying variables by transforming state vectors and density operators by the unitary transformation

$$\hat{U}(t) = \exp(i\omega^{\text{ref}} t) \sum_{i \in A} |i\rangle \langle i| + \exp[i(\omega^{\text{ref}} + \omega_p) t] \sum_{j \in B} |j\rangle \langle j|. \quad (12)$$

In particular, the operator $\hat{U}(t)$ transforms $\hat{\rho}(t)$ into the density operator

$$\hat{\rho}^{\text{tr}}(t) = \hat{U}(t) \hat{\rho}(t) \hat{U}^\dagger(t), \quad (13)$$

and

$$\langle i | \hat{\rho}(t) | j \rangle = \begin{cases} \langle i | \hat{\rho}^{\text{tr}}(t) | j \rangle & \text{if } i \text{ and } j \in A, \\ \exp(i\omega_p t) \langle i | \hat{\rho}^{\text{tr}}(t) | j \rangle & \text{if } i \in A \text{ and } j \in B, \\ \exp(-i\omega_p t) \langle i | \hat{\rho}^{\text{tr}}(t) | j \rangle & \text{if } i \in B \text{ and } j \in A, \\ \langle i | \hat{\rho}^{\text{tr}}(t) | j \rangle & \text{if } i \text{ and } j \in B. \end{cases} \quad (14)$$

A short calculation shows that $\hat{\rho}^{\text{tr}}(t)$ evolves in time according to the equation

$$\frac{d\hat{\rho}^{\text{tr}}}{dt} = -\frac{i}{\hbar} [\hat{H}^{\text{tr}}, \hat{\rho}^{\text{tr}}] + \frac{1}{2} \sum_n \left(2\hat{C}_n \hat{\rho}^{\text{tr}} \hat{C}_n^\dagger - \hat{C}_n^\dagger \hat{C}_n \hat{\rho}^{\text{tr}} - \hat{\rho}^{\text{tr}} \hat{C}_n^\dagger \hat{C}_n \right), \quad (15)$$

where

$$\begin{aligned} \hat{H}^{\text{tr}}(t) = & \hbar \sum_{i \in A} \delta\omega^{(i)} |i\rangle\langle i| - \hbar \sum_{i \in B} \Delta_p^{(i)} |i\rangle\langle i| - \frac{\hbar}{2} \sum_{i \in B} \sum_{j \in A} (\Omega_{p;ij} |i\rangle\langle j| + \text{h.c.}) \\ & - \frac{\hbar}{2} \sum_{i \in A} \sum_{j \in B} [\Omega_{p;ij} \exp(-2i\omega_p t) |i\rangle\langle j| + \text{h.c.}] \\ & - \frac{\hbar}{2} \sum_{i \in B} \sum_{j \in B} [\Omega_{c;ij} \exp(-i\omega_c t) |i\rangle\langle j| + \text{h.c.}] \end{aligned} \quad (16)$$

with $\delta\omega^{(i)} = \omega^{(i)} - \omega^{\text{ref}}$ and $\Delta_p^{(i)} = \omega_p - (\omega^{(i)} - \omega^{\text{ref}})$. We make the rotating wave approximation for the probe field, which is to neglect the rapidly oscillating terms in $\exp(\pm 2i\omega_p t)$ appearing in equation (16). Accordingly, we set

$$\hat{\rho}(t) = \hat{U}^\dagger(t) \hat{\rho}^{\text{rw}}(t) \hat{U}(t) \quad (17)$$

where $\hat{\rho}^{\text{rw}}(t)$ satisfies the equation

$$\frac{d\hat{\rho}^{\text{rw}}}{dt} = -\frac{i}{\hbar} [\hat{H}^{\text{rw}}, \hat{\rho}^{\text{rw}}] + \frac{1}{2} \sum_n \left(2\hat{C}_n \hat{\rho}^{\text{rw}} \hat{C}_n^\dagger - \hat{C}_n^\dagger \hat{C}_n \hat{\rho}^{\text{rw}} - \hat{\rho}^{\text{rw}} \hat{C}_n^\dagger \hat{C}_n \right) \quad (18)$$

with

$$\begin{aligned} \hat{H}^{\text{rw}}(t) = & \hbar \sum_{i \in A} \delta\omega^{(i)} |i\rangle\langle i| - \hbar \sum_{i \in B} \Delta_p^{(i)} |i\rangle\langle i| - \frac{\hbar}{2} \sum_{i \in B} \sum_{j \in A} (\Omega_{p;ij} |i\rangle\langle j| + \text{h.c.}) \\ & - \frac{\hbar}{2} \sum_{i \in B} \sum_{j \in B} [\Omega_{c;ij} \exp(-i\omega_c t) |i\rangle\langle j| + \text{h.c.}]. \end{aligned} \quad (19)$$

The density operator $\hat{\rho}^{\text{rw}}(t)$ is represented by the matrix $[\rho_{ij}^{\text{rw}}(t)]$ in the basis $\{|0\rangle, \dots, |\mathcal{N}-1\rangle\}$, with

$$\rho_{ij}^{\text{rw}}(t) = \langle i | \hat{\rho}^{\text{rw}}(t) | j \rangle. \quad (20)$$

Arranging the matrix elements $\rho_{ij}^{\text{rw}}(t)$ into a column vector $\mathbf{r}(t)$ makes it possible to recast equation (18) into a more standard form, namely

$$\frac{d\mathbf{r}}{dt} = \mathbf{L}(t) \mathbf{r}(t), \quad (21)$$

where $\mathbf{L}(t)$ is a $\mathcal{N}^2 \times \mathcal{N}^2$ matrix.

We note, at this point, that $\mathbf{L}(t)$ can be written in terms of three constant matrices, \mathbf{L}_0 , \mathbf{L}_+ and \mathbf{L}_- , in the following way:

$$\mathbf{L}(t) = \mathbf{L}_0 + \exp(i\omega_c t) \mathbf{L}_- + \exp(-i\omega_c t) \mathbf{L}_+. \quad (22)$$

The time-periodicity of $\mathbf{L}(t)$ suggests to seek a solution of equation (21) of the form

$$\mathbf{r}(t) = \sum_N \exp(-iN\omega_c t) \mathbf{r}_N(t), \quad (23)$$

the $\mathbf{r}_N(t)$ being time-dependent column vectors such that

$$\frac{d\mathbf{r}_N}{dt} = \mathbf{A}_N \mathbf{r}_N(t) + \mathbf{L}_+ \mathbf{r}_{N-1}(t) + \mathbf{L}_- \mathbf{r}_{N+1}(t), \quad N = 0, \pm 1, \pm 2, \dots, \quad (24)$$

where $\mathbf{A}_N = \mathbf{L}_0 + iN\omega_c \mathbf{l}$ with \mathbf{l} denoting the $\mathcal{N}^2 \times \mathcal{N}^2$ unit matrix. In practice, this infinite system can be truncated to a finite number of equations and the index N restricted to a certain interval $[N_{\min}, N_{\max}]$. equation (24) can be expressed in matrix form as

$$\frac{d}{dt} \begin{pmatrix} \vdots \\ r_{-2}(t) \\ r_{-1}(t) \\ r_0(t) \\ r_1(t) \\ r_2(t) \\ \vdots \end{pmatrix} = \begin{pmatrix} & & & \vdots & & & \\ \mathbf{L}_+ & \mathbf{A}_{-2} & \mathbf{L}_- & & & & \\ & \mathbf{L}_+ & \mathbf{A}_{-1} & \mathbf{L}_- & & & \\ & & \mathbf{L}_+ & \mathbf{A}_0 & \mathbf{L}_- & & \\ & & & \mathbf{L}_+ & \mathbf{A}_1 & \mathbf{L}_- & \\ & & & & \mathbf{L}_+ & \mathbf{A}_2 & \mathbf{L}_- \\ & & & & & \vdots & \end{pmatrix} \begin{pmatrix} \vdots \\ r_{-2}(t) \\ r_{-1}(t) \\ r_0(t) \\ r_1(t) \\ r_2(t) \\ \vdots \end{pmatrix}, \quad (25)$$

or, in a more compact notation, as

$$\frac{d\mathbf{R}}{dt} = \mathbf{M}\mathbf{R}(t). \quad (26)$$

The density matrix describing the state of the medium can therefore be obtained in terms of the eigenvalues and eigenvectors of the non-Hermitian constant matrix \mathbf{M} , unless this matrix would be defective. Let us denote the eigenvalues of \mathbf{M} by $w^{(k)}$, its right eigenvectors by $\mathbf{c}^{(k)}$ and its left eigenvectors by $\mathbf{d}^{(k)}$, so that $\mathbf{M}\mathbf{c}^{(k)} = w^{(k)}\mathbf{c}^{(k)}$ and $\mathbf{d}^{(k)\dagger}\mathbf{M} = w^{(k)}\mathbf{d}^{(k)\dagger}$ (the $\mathbf{c}^{(k)}$'s and the $\mathbf{d}^{(k)}$'s are column vectors). Assuming that these eigenvectors form a basis and are bi-orthogonal (i.e., that $\mathbf{d}^{(k)\dagger}\mathbf{c}^{(k')} = 0$ if $k \neq k'$),

$$\mathbf{R}(t) = \sum_k \alpha_k \mathbf{c}^{(k)} \exp(w^{(k)}t) \quad (27)$$

with

$$\alpha_k = \frac{\mathbf{d}^{(k)\dagger}\mathbf{R}(t=0)}{\mathbf{d}^{(k)\dagger}\mathbf{c}^{(k)}}. \quad (28)$$

It is worth noting that the right eigenvectors of \mathbf{M} define solutions of equation (21) in the Floquet form, namely

$$\mathbf{r}(t) = \exp(w^{(k)}t) \sum_N \exp(-iN\omega_c t) \mathbf{c}_N^{(k)}. \quad (29)$$

The eigenvectors for which $w^{(k)} = 0$ may describe steady states of the system, i.e., states for which $d\mathbf{r}_N/dt = 0$. However, the solutions with $w^{(k)} \neq 0$ do not correspond

to density operators of constant unit trace and therefore do not represent physically meaningful quantum states.

Since the column vector $r(t)$ is formed by the matrix elements $\rho_{ij}^{\text{rw}}(t)$, the elements of the vectors $r_N(t)$ are the functions $\rho_{ij;N}^{\text{rw}}(t)$ such that

$$\rho_{ij}^{\text{rw}}(t) = \sum_N \exp(-iN\omega_c t) \rho_{ij;N}^{\text{rw}}(t). \quad (30)$$

As will be illustrated by a numerical example in Section 4, the functions $\rho_{ij;N}^{\text{rw}}(t)$ normally converge to constant values in the $t \rightarrow \infty$ limit. In the ensuing steady state, the density matrix contains terms oscillating at the angular frequencies ω_p , $\omega_p \pm \omega_c$, $\omega_p \pm 2\omega_c$, etc. Only the terms oscillating at the angular frequency ω_p contribute to the complex polarisation amplitude $\mathcal{P}_p(x)$. Combining equations (4), (5), (6), (12), (17) and (30) yields

$$\chi(\omega_p, \omega_c, \mathcal{E}_c) = \frac{N_d}{\epsilon_0 \mathcal{E}_p} \sum_{i \in B} \sum_{j \in A} \langle j | \hat{D}_z | i \rangle \rho_{ij;N=0}^{\text{rw}}(t \rightarrow \infty). \quad (31)$$

Having calculated $\chi(\omega_p, \omega_c, \mathcal{E}_c)$, the probe absorption spectrum can then be deduced from equation (7).

3. The weak probe limit

3.1. General theory

It is often the case, in experiments, that the medium can be taken to be initially in its ground state or in an incoherent superposition of low energy states, and that the probe laser is too weak for producing significant optical pumping over the relevant time scales. This common situation can be modelled by assuming, (1) that the probe field is weak enough that $\hat{\rho}^{\text{rw}}(t)$ only needs to be calculated to first order in \mathcal{E}_p , and (2) that the states of group B are initially unpopulated, so that

$$\sum_{i \in A} \rho_{ii}^{\text{rw}}(t = 0) = 1 \quad (32)$$

and $\rho_{ij}^{\text{rw}} = 0$ if state i or state j belongs to group B . We will further assume that $\Gamma_{ij} = 0$ and $\rho_{ij \neq i}^{\text{rw}}(t = 0) = 0$ if states i and j both belong to group A , which is normally the case in applications. The density operator $\hat{\rho}^{\text{rw}}(t)$ reduces to a density operator $\hat{\rho}^{\text{wp}}(t)$ in this weak probe approximation:

$$\rho_{ij}^{\text{rw}}(t) \approx \rho_{ij}^{\text{wp}}(t) \quad (33)$$

with $\rho_{ij}^{\text{wp}}(t = 0) = \rho_{ij}^{\text{rw}}(t = 0)$. One finds, after a straightforward calculation, that

$$\frac{d\rho_{ij}^{\text{wp}}}{dt} = 0 \quad (34)$$

if state i and state j both belong to group A or both belong to group B , and that

$$\begin{aligned} \frac{d\rho_{ij}^{\text{wp}}}{dt} &= i[\omega^{(j)} + \omega_p - \omega^{(i)} + i\Gamma^{(i)}/2]\rho_{ij}^{\text{wp}}(t) + \frac{i}{2}\Omega_{p;ij}\rho_{jj}^{\text{wp}}(t) \\ &\quad + \frac{i}{2}\sum_{l \in B} [\Omega_{c;il} \exp(-i\omega_c t) + \Omega_{c;li}^* \exp(i\omega_c t)]\rho_{lj}^{\text{wp}}(t) \end{aligned} \quad (35)$$

if $i \in B$ and $j \in A$. In this last equation, $\Gamma^{(i)}$ denotes the total decay rate of state i :

$$\Gamma^{(i)} = \sum_n \Gamma_{ni}. \quad (36)$$

Our main aim is to solve equation (35) in the long time limit, in view of equation (31). Proceeding as above, we seek a solution of equation (35) of the form

$$\rho_{ij}^{\text{wp}}(t) = \sum_N \exp(-iN\omega_c t)\rho_{ij;N}^{\text{wp}}(t), \quad (37)$$

with

$$\begin{aligned} \frac{d\rho_{ij;N}^{\text{wp}}}{dt} &= i[\omega^{(j)} + \omega_p - \omega^{(i)} + i\Gamma^{(i)}/2 + N\omega_c]\rho_{ij;N}^{\text{wp}}(t) + \frac{i}{2}\Omega_{p;ij}\rho_{jj;N}^{\text{wp}}(t) \\ &\quad + \frac{i}{2}\sum_{l \in B} [\Omega_{c;il}\rho_{lj;N-1}^{\text{wp}}(t) + \Omega_{c;li}^*\rho_{lj;N+1}^{\text{wp}}(t)]. \end{aligned} \quad (38)$$

Since the populations of the different states remain constant in this weak probe approximation,

$$\rho_{jj;N}^{\text{wp}}(t) \equiv \rho_{jj;0}^{\text{wp}} \delta_{N,0} = \rho_{jj}^{\text{wp}}(t=0). \quad (39)$$

The steady state solution of equation (38) can be obtained by setting the time derivatives to zero and solving the resultant system of linear equations, namely

$$\begin{aligned} [\omega^{(j)} + \omega_p - \omega^{(i)} + i\Gamma^{(i)}/2 + N\omega_c]\rho_{ij;N}^{\text{wp}} \\ + \frac{1}{2}\sum_{l \in B} [\Omega_{c;il}\rho_{lj;N-1}^{\text{wp}} + \Omega_{c;li}^*\rho_{lj;N+1}^{\text{wp}}] = -\frac{1}{2}\Omega_{p;ij}\rho_{jj;0}^{\text{wp}}\delta_{N,0}, \end{aligned} \quad (40)$$

where $i \in B$, $j \in A$, $N_{\min} \leq N \leq N_{\max}$ and $\rho_{ij;N}^{\text{wp}} \equiv \rho_{ij;N}^{\text{wp}}(t \rightarrow \infty)$. Calculating the absorption spectrum in the weak probe limit thus reduces to solving this system of equations for each state of group A and obtaining the absorption coefficient from equation (31) with $\rho_{ij;0}^{\text{fw}}(t \rightarrow \infty)$ replaced by $\rho_{ij;0}^{\text{wp}}$ — i.e., from the equation

$$\chi(\omega_p, \omega_c, \mathcal{E}_c) = \frac{N_d}{\epsilon_0 \mathcal{E}_p} \sum_{i \in B} \sum_{j \in A} \langle j | \hat{D}_z | i \rangle \rho_{ij;N=0}^{\text{wp}}. \quad (41)$$

Because $\Omega_{p;ij} \propto \mathcal{E}_p$, $\rho_{ij;N=0}^{\text{wp}} \propto \mathcal{E}_p$ and the susceptibility does not depend on \mathcal{E}_p in this approximation.

We note that only the total dephasing rates $\Gamma^{(i)}/2$ appear in this formulation of the optical Bloch equations, rather than the individual relaxation rates Γ_{ij} . Contrary to

equation (15), equation (40) therefore applies even to cases where the states of group B decay to other states than those of group A , which makes it well suited for describing systems with complex de-excitation pathways.

We also note that the equations forming this system decouple from each other in the absence of the coupling field (i.e., for $\mathcal{E}_c = 0$); equation (40) then yields

$$\rho_{ij;0}^{\text{wp}} = -\frac{\Omega_{p;ij}/2}{\omega^{(j)} + \omega_p - \omega^{(i)} + i\Gamma^{(i)}/2} \rho_{jj;0}^{\text{wp}}, \quad (42)$$

in agreement with well known theory — see, e.g., [44].

3.2. Complex energies

Equation (40) was derived from the Lindblad master equation in the above, starting from the Hermitian Hamiltonian $\hat{H}(t)$ of equation (9). However, it is easy to see that the same result would also be obtained, in the weak probe approximation, if the density operator was instead calculated by solving the equation

$$\frac{d\hat{\rho}}{dt} = -\frac{i}{\hbar} [\hat{H}', \hat{\rho}] \quad (43)$$

with $\hat{H}'(t)$ taken to be the non-Hermitian Hamiltonian

$$\begin{aligned} \hat{H}'(t) = & \sum_{i \in A} \hbar \omega^{(i)} |i\rangle\langle i| + \sum_{i \in B} \hbar (\omega^{(i)} - i\Gamma^{(i)}/2) |i\rangle\langle i| \\ & - \frac{\hbar}{2} \sum_{i,j} \{ [\Omega_{p;ij} \exp(-i\omega_p t) + \Omega_{c;ij} \exp(-i\omega_c t)] |i\rangle\langle j| + \text{h.c.} \}. \end{aligned} \quad (44)$$

In this alternative approach, the states of group B are given a phenomenological width $\hbar\Gamma^{(i)}$ and the steady state of the system is derived solely from the effective Hamiltonian $\hat{H}'(t)$ by integrating the von Neumann equation. The two approaches are equivalent in the weak probe approximation in so far as they predict the same results. However, they would generally lead to different results beyond that approximation, in which case energy relaxation needs to be taken into account through the Lindblad master equation rather than through complex energies.

3.3. Dressed states

Equation (40) has a close similarity with the equation defining the dressed states of the system in the absence of the probe field, as we now discuss. By dressed states, we mean, here, the quasistationary solutions of the equation

$$\left[i\hbar \frac{d}{dt} - \sum_{i \in B} \hbar (\omega^{(i)} - i\Gamma^{(i)}/2) |i\rangle\langle i| + \mathbf{E}_c(t) \cdot \hat{\mathbf{D}} \right] |\Psi(t)\rangle = 0, \quad (45)$$

where $\hat{\mathbf{D}}$ is the dipole operator. The dressed states in question are solutions of the Floquet form,

$$|\Psi^{(q)}(t)\rangle = \exp(-i\epsilon^{(q)}t/\hbar) |\Phi^{(q)}(t)\rangle, \quad (46)$$

where $\epsilon^{(q)}$ is a constant and the state vector $|\Phi^{(q)}(t)\rangle$ is time-periodic with period $2\pi/\omega_c$. We expand the latter in a Fourier series with time-independent harmonic components $|\psi_N^{(q)}\rangle$ and write

$$|\Psi^{(q)}(t)\rangle = \exp(-i\epsilon^{(q)}t/\hbar) \sum_N \exp(-iN\omega_c t) |\psi_N^{(q)}\rangle. \quad (47)$$

Since the field $\mathbf{E}_c(t)$ only couples states belonging to group B to other states of that group, we set

$$|\psi_N^{(q)}\rangle = \sum_{i \in B} a_{i;N}^{(q)} |i\rangle. \quad (48)$$

It is not difficult to show that the coefficients $a_{i;N}^{(q)}$ satisfy a system of equations similar (but not identical) to equation (40), i.e.,

$$[\epsilon^{(q)} - \hbar(\omega^{(i)} - i\Gamma^{(i)}/2) + N\hbar\omega_c] a_{i;N}^{(q)} + \frac{\hbar}{2} \sum_{l \in B} [\Omega_{c;il} a_{l;N-1}^{(q)} + \Omega_{c;li}^* a_{l;N+1}^{(q)}] = 0. \quad (49)$$

In matrix form,

$$[\epsilon^{(q)} \mathbf{I}_{\mathcal{F}_1} - \mathbf{F}] \mathbf{v}^{(q)} = 0, \quad (50)$$

where $\mathbf{v}^{(q)}$ is the column vector formed by the coefficients $a_{i;N}^{(q)}$, $\mathbf{I}_{\mathcal{F}_1}$ is the $\mathcal{N}_{\mathcal{F}_1} \times \mathcal{N}_{\mathcal{F}_1}$ unit matrix with $\mathcal{N}_{\mathcal{F}_1} = (N_{\max} - N_{\min} + 1)\mathcal{N}_B$, where \mathcal{N}_B is the number of states belonging to group B , and \mathbf{F} is a $\mathcal{N}_{\mathcal{F}_1} \times \mathcal{N}_{\mathcal{F}_1}$ non-Hermitian matrix. This matrix represents the Floquet Hamiltonian and describes how the states of group B are coupled to each other by the coupling field beyond the rotating wave approximation.

How these dressed states relate to the solutions of equation (40) may be best brought out by recasting the latter in terms of the matrix \mathbf{F} . For each state $j \in A$, we write equation (40) as

$$[(\omega^{(j)} + \omega_p) \mathbf{I}_{\mathcal{F}_1} - \mathbf{F}/\hbar] \mathbf{x}^{(j)} = \mathbf{b}^{(j)}, \quad (51)$$

where $\mathbf{I}_{\mathcal{F}_1}$ and \mathbf{F} are the matrices defined above (the same for all states j), $\mathbf{x}^{(j)}$ is the column vector formed by the coherences $\rho_{ij;N}^{\text{wp}}$ and $\mathbf{b}^{(j)}$ is the column vector formed by the right-hand sides of equation (40). We will assume that \mathbf{F} is not defective in view of the fact that this matrix would be Hermitian if the decay rates Γ_i were zero. The results outlined below do not apply if \mathbf{F} is defective. The coherences derived from Eq. (57) would be incorrect and would differ from those obtained by solving Eq. (40) in this case.

Clearly, the eigenvalues of \mathbf{F} are the complex quasienergies $\epsilon^{(q)}$ defined above and its right eigenvectors are the column vectors $\mathbf{v}^{(q)}$:

$$\mathbf{F} \mathbf{v}^{(q)} = \epsilon^{(q)} \mathbf{v}^{(q)}. \quad (52)$$

We denote the corresponding left eigenvectors by $\mathbf{u}^{(q)}$ and define them as being the column vectors such that

$$\mathbf{u}^{(q)\dagger} \mathbf{F} = \epsilon^{(q)} \mathbf{u}^{(q)\dagger}. \quad (53)$$

Let \mathbf{U} and \mathbf{V} be the matrices formed by the column vectors $\mathbf{u}^{(q)}$ and $\mathbf{v}^{(q)}$, respectively, with $\mathbf{u}^{(q)}$ and $\mathbf{v}^{(q)}$ normalised in such a way that $\mathbf{u}^{(q)\dagger}\mathbf{v}^{(q)} = 1$. Then $\mathbf{u}^{(q)\dagger}\mathbf{v}^{(q')} = \delta_{qq'}$ and $\mathbf{U}^\dagger\mathbf{V} = \mathbf{V}\mathbf{U}^\dagger = \mathbf{I}_{\text{Fl}}$ [45]. Therefore

$$\mathbf{U}^\dagger [(\omega^{(j)} + \omega_p) \mathbf{I}_{\text{Fl}} - \mathbf{F}/\hbar] \mathbf{V} = \mathbf{\Lambda}^{(j)} \quad (54)$$

where $\mathbf{\Lambda}^{(j)}$ is the diagonal matrix of elements $(\omega^{(j)} + \omega_p - \epsilon^{(q)}/\hbar) \delta_{qq'}$. It follows from equation (51) that

$$\mathbf{U}^\dagger [(\omega^{(j)} + \omega_p) \mathbf{I}_{\text{Fl}} - \mathbf{F}/\hbar] \mathbf{V} \mathbf{U}^\dagger \mathbf{x}^{(j)} = \mathbf{U}^\dagger \mathbf{b}^{(j)}, \quad (55)$$

and therefore[‡]

$$\mathbf{x}^{(j)} = \mathbf{V} [\mathbf{\Lambda}^{(j)}]^{-1} \mathbf{U}^\dagger \mathbf{b}^{(j)} = \sum_q \frac{\mathbf{u}^{(q)\dagger} \mathbf{b}^{(j)}}{\omega^{(j)} + \omega_p - \epsilon^{(q)}/\hbar} \mathbf{v}^{(q)}. \quad (56)$$

More explicitly,

$$\rho_{ij;N}^{\text{wp}} = \sum_q \frac{\mathbf{u}^{(q)\dagger} \mathbf{b}^{(j)}}{\omega^{(j)} + \omega_p - \epsilon^{(q)}/\hbar} \rho_{ij;N}^{(q)}, \quad (57)$$

where $\rho_{ij;N}^{(q)}$ is the component of the vector $\mathbf{v}^{(q)}$ corresponding to the coherence $\rho_{ij;N}^{\text{wp}}$. Calculating the coherences in this way is completely equivalent to solving equation (40). However, this alternative formulation makes it possible to identify the contribution of the different dressed states to the susceptibility $\chi(\omega_p, \omega_c, \mathcal{E}_c)$. It is also advantageous in calculations of $\chi(\omega_p, \omega_c, \mathcal{E}_c)$ over a range of probe frequencies since the eigenvalues $\epsilon^{(q)}$, the eigenvectors $\mathbf{v}^{(q)}$ and the inner products $\mathbf{u}^{(q)\dagger} \mathbf{b}^{(j)}$ do not depend on ω_p and can be calculated once and for all. In particular, this result makes it easier to average the susceptibility over a statistical distribution of values of ω_p , as may be required, e.g., for taking inhomogeneous broadening into account [50].

Finally, we note that these results must be corrected if the coherences ρ_{ij} also decay not only through energy relaxation but also through some pure dephasing mechanisms such as collisional broadening or phase fluctuation of the probe field. Denoting the corresponding additional dephasing rates by γ_{ij} , $\Gamma^{(i)}/2$ should then be replaced by $\Gamma^{(i)}/2 + \gamma_{ij}$ in equations (35), (38), (40) and (42), and $\omega^{(j)} + \omega_p - \epsilon^{(q)}/\hbar$ should be replaced by $\omega^{(j)} + \omega_p - \epsilon^{(q)}/\hbar + i\gamma_{ij}$ equations (56) and (57).

4. Numerical illustration

We now illustrate the theory developed in the previous section by a numerical calculations of an absorption spectrum for a simple toy model. An application to a much

[‡] This result can also be derived directly from the closure relation [45] $\sum_q \mathbf{v}^{(q)} \mathbf{u}^{(q)\dagger} = \mathbf{I}_{\text{Fl}}$ and from the spectral decomposition of the operator $(\omega^{(j)} + \omega_p) \mathbf{I}_{\text{Fl}} - \mathbf{F}/\hbar$, i.e., $(\omega^{(j)} + \omega_p) \mathbf{I}_{\text{Fl}} - \mathbf{F}/\hbar = \sum_q (\omega^{(j)} + \omega_p - \epsilon^{(q)}/\hbar) \mathbf{v}^{(q)} \mathbf{u}^{(q)\dagger}$. It has a similar mathematical structure as expressions of the ionisation rates derived from the spectral decomposition of the resolvent operator for atoms interacting with a weak probe beam in the presence of a strong static electric field [46, 47] or a strong laser field [48, 49].

Table 1. Detunings and Rabi frequencies used in the examples, in units of 2π GHz.

Examples	$\Delta_p^{(1)}$	$\Delta_p^{(2)}$	$\Delta_p^{(3)}$	$\Delta_p^{(4)}$	$\Omega_{c;13}$	$\Omega_{c;14}$	$\Omega_{c;23}$	$\Omega_{c;24}$

Figure 2b		variable			0.9	1.1	0.6	0.9

more complicated case is reported elsewhere [31]. Here the system comprises only five states, namely a single lower energy state (state 0, here the only element of group A) and four higher energy states (states 1, 2, 3 and 4, forming group B). As shown in figure 1a, state 0 is coupled to states 1 and 2 by the probe field while states 1 and 2 are coupled to states 3 and 4 by the coupling field. States 1 and 2 decay to state 0 only, whereas states 3 and 4 are assumed to have zero decay rates. The parameters of the model are largely arbitrary and do not correspond to any actual system. We assume a frequency of 1 GHz for the coupling field and, in most of the calculations, a frequency of 100 THz for the probe field (this frequency is varied around 100 THz in figure 2b). State 0 being the only member of group A , we choose ω^{ref} to coincide with $\omega^{(0)}$ so that $\delta\omega^{(0)} = 0$. We set the detunings $\Delta_p^{(i)}$ and the Rabi frequencies $\Omega_{c;ij}$ to the values specified in table 1. We also assume that $\langle 0|\hat{D}_z|1\rangle = 2\langle 0|\hat{D}_z|2\rangle$. For consistency, we thus set $\Omega_{p;10} = 2\Omega_{p;20}$ and $\Gamma^{(1)} = 4\Gamma^{(2)}$. Specifically, we take $\Gamma_1 = 2\pi \times 3.6$ GHz, $\Gamma_2 = 2\pi \times 0.9$ GHz and, when obtaining the results shown in figure 1, $\Omega_{p;10} = 2\pi \times 10$ GHz and $\Omega_{p;20} = 2\pi \times 5$ GHz (other values of $\Omega_{p;10}$ and $\Omega_{p;20}$ are used in figure 2).

How some of the populations and coherences vary in time for this set of parameters is shown in figure 1b–f: The time-dependent harmonic components $\rho_{ij;N}^{\text{rw}}(t)$ are calculated by numerically integrating equation (24) and the density matrix is obtained by summing these harmonic components as per equation (30). The range of values of N used in the computation is sufficiently wide to ensure that the results do not depend on the truncation of the system (24) to a finite number of equations (we take $N_{\text{min}} = -30$, $N_{\text{max}} = 30$). Results calculated by numerically integrating equation (18) are also presented for the case of a zero coupling field (the dotted curves in figures 1a and 1b).

How the ground state population $\rho_{00}^{\text{rw}}(t)$ and the imaginary parts of the coherences $\rho_{10}^{\text{rw}}(t)$ and $\rho_{20}^{\text{rw}}(t)$ vary immediately after the probe laser is turned on is shown in figure 1b and, over a longer time period, in figure 1c. In the absence of the coupling field (i.e., for $\Omega_{c;ij} \equiv 0$), the populations and coherences rapidly settle to constant values. However, they continue to oscillate markedly past the initial transients when the coupling field is strong. As shown by the solid curves, they settle into a state of periodic oscillation of period $4\pi/\omega$ when $t \rightarrow \infty$. By contrast, the harmonic components converge to constant values, reached asymptotically after a short phase of damped oscillations (figures 1d–f, no results are shown for $N = 1$ and 3 because $\rho_{00;N}^{\text{rw}}(t)$, $\rho_{10;N}^{\text{rw}}(t)$ and $\rho_{20;N}^{\text{rw}}(t)$ are identically zero for odd values of N). One can also note the importance of the $N \neq 0$

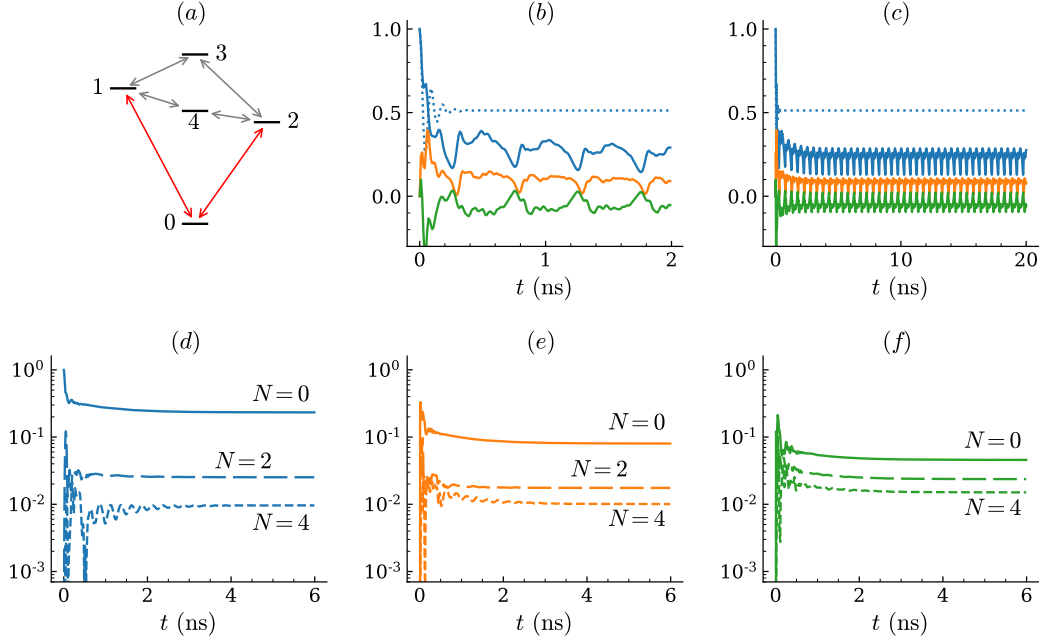

Figure 1. (a) The five-state system considered in Section 4: states 1 and 2 are addressed from state 0 by the probe field, while states 1 and 2 are coupled to states 3 and 4 by the coupling field. (b) and (c) Dotted blue curves: time evolution of $\rho_{00}^{\text{rw}}(t)$ in the absence of the coupling field. Solid curves, from top to bottom: time evolution of $\rho_{00}^{\text{rw}}(t)$ (solid blue curves), $\text{Im} \rho_{10}^{\text{rw}}(t)$ (solid orange curves) and $\text{Im} \rho_{20}^{\text{rw}}(t)$ (solid green curves) in the presence of the coupling field. (d) Time evolution of $|\text{Re} \rho_{00;N}^{\text{rw}}(t)|$ for $N = 0$ (solid curve), $N = 2$ (long-dashed curve) and $N = 4$ (short-dashed curve). (e) The same as (d) for $|\text{Im} \rho_{10;N}^{\text{rw}}(t)|$. (f) The same as (d) for $|\text{Im} \rho_{20;N}^{\text{rw}}(t)|$.

harmonic components of the ground state population although state 0 does not directly interact with the coupling field in the present model. These harmonic components are responsible for the oscillation of $\rho_{00}^{\text{rw}}(t)$ and arise from the indirect interaction of the ground state with the coupling field originating from its coupling to states 1 and 2 by the probe field.

The results shown in figures 1b–f refer to a relatively strong probe field. Convergence to the predictions of the weak probe approximation for decreasing values of \mathcal{E}_p is illustrated by figure 2a, which shows results obtained by integrating equation (24) for values of $\Omega_{p;10}$ and $\Omega_{p;20}$ scaled by a factor $1/\alpha$: the probe field has the same strength as in figures 1b–f when $\alpha = 1$, but is weaker by a factor $1/\alpha$ when $\alpha > 1$. The calculation is done for a sufficiently large value of t (200 ns) that the harmonic components $\rho_{ij;N}^{\text{rw}}(t)$ have become constant in time. As expected, and as can be seen from the figure, $\rho_{00;N=0}^{\text{rw}}(t)$ tends to 1 and $\rho_{00;N \neq 0}^{\text{rw}}(t)$ tends to 0 when α increases. Moreover, $\rho_{10;0}^{\text{rw}}(t)$ and $\rho_{20;0}^{\text{rw}}(t)$ tend to the values predicted by equation (40), namely $\rho_{10;0}^{\text{wp}}$ and $\rho_{20;0}^{\text{wp}}$. These values are proportional to \mathcal{E}_p , thus proportional to $1/\alpha$ here. (As can be deduced from a perturbative analysis and is apparent from the figure, $\rho_{00;2}^{\text{rw}}(t) \propto 1/\alpha^2$.)

Figure 2. (a) From top to bottom, variation with the scaling parameter α of $\rho_{00;0}^{\text{FW}}(t)$ (solid blue curve), of $|\text{Im} \rho_{10;0}^{\text{FW}}(t)|$ (solid orange curve), of $|\text{Im} \rho_{20;0}^{\text{FW}}(t)|$ (solid green curve), and of $|\text{Re} \rho_{00;2}^{\text{WP}}(t)|$ (dashed blue curve), at $t = 200$ ns. The dash-dotted black lines show how $|\text{Im} \rho_{10;0}^{\text{FW}}(t)|$ and $|\text{Im} \rho_{20;0}^{\text{FW}}(t)|$ vary for the same parameters. (b) The variation of the absorption coefficient with probe frequency in the presence of the coupling field (solid red curve and black markers) and in the absence of the coupling field (dotted red curve and grey markers). The markers refer to the energy and width of the dressed states contributing most to the absorption spectrum in the range of frequencies spanned by the figure: the real part of the quasienergy of each of these dressed states is identified by a + sign located at the corresponding value of $\Delta\omega_p^{(q)}$, and its decay width is indicated by a horizontal bar (see text).

Finally, part (b) of figure 2 illustrates the use of this formalism in the calculation and analysis of an absorption spectrum. The weak probe approximation is assumed to hold. As in part (a) of the figure, the system is also taken to be in the stationary state it relaxes into following the turn on of the probe field, after the initial transients. Here, however, ω_p is varied: we set

$$\omega_p = \omega_{p0} + \Delta\omega_p, \quad (58)$$

with $\omega_{p0}/(2\pi) = 100$ THz. The detunings $\Delta_p^{(i)}$ thus vary with $\Delta\omega_p$ and have the same values as in Figures 1 and 2a when $\Delta\omega_p = 0$. The susceptibility and the absorption coefficient are calculated as functions of $\Delta\omega_p$, by way of equations (41) and (7) respectively, with the products $N_d \langle 0 | \hat{D}_z | 1 \rangle / (\epsilon_0 \mathcal{E}_p)$ and $N_d \langle 0 | \hat{D}_z | 2 \rangle / (\epsilon_0 \mathcal{E}_p)$ set to values sufficiently low that $|\chi(\omega_p, \omega_c, \mathcal{E}_c)| \ll 1$.

The resulting absorption spectrum is plotted in figure 2b, both for the values of $\Omega_{c;ij}$ stated in table 1 (the solid curve) and for the case of a zero coupling field ($\Omega_{c;ij} \equiv 0$, the dotted curve). The relevant quasienergies are also indicated in the figure: As shown by equation (56), a dressed state of quasienergy $\epsilon^{(q)}$ contributes to the coherences ρ_{i0}^{WP} mostly over a range of values of $\Delta\omega_p$ extending from $\Delta\omega_p^{(q)} - |\text{Im} \epsilon^{(q)}/\hbar|$ to $\Delta\omega_p^{(q)} + |\text{Im} \epsilon^{(q)}/\hbar|$, where $\Delta\omega_p^{(q)}$ is the value of $\Delta\omega_p$ such that $\text{Re} \epsilon^{(q)}/\hbar + \omega^{(0)} + \omega_p = 0$. Accordingly, we identify the dressed states contributing most to the spectrum by + signs positioned at the corresponding values of $\Delta\omega_p^{(q)}$ and we represent their widths by bars of length $2 |\text{Im} \epsilon^{(q)}/\hbar|$. (The vertical position of these markers is arbitrary and has no physical meaning.)

The ground state interacts only with the bare states 1 and 2 when $\mathcal{E}_c = 0$. Diagonalising the matrix \mathbf{F} , in that case, yields quasienergies either of the form $N\hbar\omega_c - \hbar(\omega^{(1)} - i\Gamma^{(1)}/2)$ or of the form $N\hbar\omega_c - \hbar(\omega^{(2)} - i\Gamma^{(2)}/2)$, $N = 0, \pm 1, \pm 2, \dots$. Only the two solutions for which $\epsilon^{(a)}$ is either exactly $-\hbar(\omega^{(1)} - i\Gamma^{(1)}/2)$ or $-\hbar(\omega^{(2)} - i\Gamma^{(2)}/2)$ are relevant here, because, in the notation of equation (56), $\mathbf{u}^{(a)}\mathbf{b}^{(0)} = 0$ for the other solutions in the absence of the coupling field. The corresponding states overlap in energy within their respective decay width, as shown by the grey horizontal bars in the figure. The overlap results in a single non-Lorentzian peak in the absorption spectrum. This peak splits into multiple structures when the coupling field is on, for the relatively large values of $\Omega_{c;ij}$ assumed in the calculation. The structures originate from the interfering contributions of many dressed states. For clarity, only the 15 states contributing most to the spectrum in the range of frequencies considered are identified in the figure (the black markers).

Acknowledgements

This work has much benefited from discussions with Robin Shakeshaft, a number of years ago, in regard to the non-Hermitian Floquet theory of multiphoton processes in strong laser fields. It has also benefited from discussions with the late Howard Taylor in regard to the related calculations reported in reference [48], and with Alistair Brewin and Matt Jones in regard to the use of Floquet calculations in the spectroscopy of Rydberg excitons.
