An Initial Study of Human-Scale Blockage in sub-THz Radio Propagation with Application to Indoor Passive Localization

F. Paonessa, G. Virone, S. Kianoush, A. Nordio, S. Savazzi Consiglio Nazionale delle Ricerche, CNR-IEIIT, Italy.

Abstract—This paper empirically investigates the body induced electromagnetic (EM) effects, namely the human body blockage, by conducting indoor measurement campaigns in the unexplored sub-THz W-band (75-110 GHz) and G-band (170-260 GHz). The proposed analysis focuses on both the alterations of channel frequency response induced by body presence, fully or partially obstructing the line-of-sight (LoS) between transmitter and recevier, as well as on the channel impulse response (CIR) for selected movements of the target, i.e. crossing the LoS of the radio link. The proposed study has applications in device-free radio localization and radio frequency (RF) sensing scenarios where the EM radiation or environmental radio signals are collected and processed to detect and locate people without requiring them to wear any electronic devices. Although preliminary, the study reveals that discrimination of the blockage micro-movements is possible, achieving higher precision compared to classical RF sensing and localization using cm-scale wavelengths (2.4-6 GHz bands).

Index Terms—sub-THz radiation, channel impulse response integrated sensing and communication, EM body models.

I. INTRODUCTION

Radio frequency (RF) sensing consists of an opportunistic set of techniques capable to detect, locate, and track people in a monitored area covered by ambient RF signals [1]. Targeting the *Integrated Sensing and Communication* paradigm [2], device free localization (DFL) systems can transform each RF node of the wireless network covering the monitored area into a *virtual sensor* capable of performing sensing operations. RF sensing methods typically employ frequencies in the unlicensed 2.4–5 GHz ISM bands [3], and up to 30–60 GHz [4]. In both cases RF signals are characterized by wavelengths of only a few centimeters (cm-scale). However, multipath effects strongly limit their accuracy, thus reducing their widespread acceptance. On the contrary, sub-terahertz (sub-THz) radiation, generally characterized by mm-scale wavelengths (mmWave), can be viewed as much better suited for high-resolution body

Fig. 1. (right) Measurement setup with Vector Network Analyzer (VNA), mmWave extenders (black boxes), and truncated waveguide antennas (goldplated waveguide sections) in the laboratory environment. The white arrow identifies the line-of-sight. (left) 2D projection of the measurement setup: the shaded shape represents the human body.

occupancy detection and vision applications due to its very short wavelength and reduced multipath effects. The diffusion of THz radios for 6G and beyond communication systems [5] is thus expected to pave the way towards novel joint communication, sensing and computing paradigms.

Most of the sensing and vision techniques proposed for localization, and behavior recognition [6] such as Bayesian filtering, tomography and holography [7]–[9], require a detailed understanding of the effects of human/object blockage and its physical/EM properties. While body effects are well understood for classical ISM bands [10]–[12] and up to 30–60 GHz [13], [14], the human body blockage at frequencies beyond 100 GHz has been insufficiently analyzed so far [15]. Although there are several studies proposing physical and statistical models for assessing the impact of human blockage on communication performance [16], [17], a limited body of knowledge exists regarding the EM and physical characterization in terms of both time and frequency domains, which is critical for human-scale sensing applications.

In this paper, we provide a first study targeting the characterization of human blockage in the unexplored W-band (75–110 GHz) and G-band (170–260 GHz). To this aim, we carried out an indoor measurement campaign collecting the target-induced RF footprints for different offsets to the blocker crossing the LoS path. Small movements of the target as traversing the link are represented here by using a full-body phantom, which accurately simulates a human subject in the blockage study. The main contributions of the proposed study are:

- empirical measurements of human body blockage process in the indoor environment considering the dual (full) bands of 75–110 GHz and 170–260 GHz;
- frequency and time domain analysis of the blockage effects, considering the channel frequency response and the impulse response (CIR) for different offsets to the target crossing the LoS path;
- characterization of the area around the link that is most sensitive to the blocker when approaching the LoS, for both the considered bands.

The paper is organized as follows. Section III focuses on frequency domain analysis considering the W and G bands separately. The study reveals that simple statistical analysis of the received power is not sufficient to reconstruct the blocker location. Next, in Section IV we consider the more challenging G band and characterize the CIR as an optimized set of power/amplitude and delay features. Perturbations of CIR features induced by the blockage are analyzed. Planned future experiments and the general approach to CIR characterization are summarized in the Section V.

II. MEASUREMENT SETUP AND ENVIRONMENT

The measurement sessions were conducted in an indoor laboratory environment with an approximate size of 4×4 m and a floor-to-ceiling height of 3 m. To describe the system geometry we considered the 2D Cartesian coordinate system depicted in Fig. 1 whose origin coincides with the transmitter (TX). This coordinate system identifies an horizontal plane placed at about h = 1 m from the floor. As shown in the figure, TX and RX nodes are spaced by d = 0.92 m apart, along the ζ_1 axis. The target obstructing the LoS link is represented by a simplified phantom (metal cylinder with height 50 cm and diameter 6 cm) which is used to replace the human body. The projection of the target baricenter on the coordinate system has coordinates (x, y). The complex frequency domain channel coefficient [19] were measured using a vector network analyzer (VNA) connected to a pair of mmWave extenders for both W and G bands. For both bands we conducted 6 experiments, by varying the target offset w.r.t. the LoS path connecting the TX and RX, namely we considered $y \in \{0, 3, 6, 12, 25, 50\}$ cm. Note that, in the case y = 0 the target is completely obstructing the LoS path. For each band and target offset, the VNA collected the transmission coefficients, measured at equally spaced frequencies, as detailed in Tab. I. Furthermore, we also measured the channel frequency response in the target's absence with the purpose of calibrating the system.

Fig. 2. W band: amplitude of transmission coefficient (top) and body-induced excess attenuation probability functions (bottom) plotted versus frequency for target positions $y \in \{0, 3, 6, 12, 25, 50\}$ cm.

III. FREQUENCY-DOMAIN ANALYSIS

In this Section we focus on frequency domain analysis and we aim to verify the possibility of discriminating the target position by monitoring the channel frequency response. In particular we discuss the problem of passive detection of the target considering the set of hypotheses $\{F_i\}_{i=1}^6$, where the index *i* is the identifier of the experiments previously described, and refers to the target offset $y = y_i$. The frequency responses in the W and G bands are evaluated separately. Specifically, each band was sampled at equally spaced frequencies f_1, \ldots, f_{N_f} , where $N_f = 1001$ is the number of sampling points.

During calibration, carried out with no target, we measured and stored the free-space transmission coefficient $T_0(f_k)$, for

TABLE I VNA SETTINGS AND ANTENNA SPECS.

Network Analyzer settings			Antenna specs	
w	Start/Stop Freq.	75/110 GHz	Туре	Truncated Waveguide
	Freq. spacing	35 MHz	FHPBW	about 90°
	Resolution BW	1 kHz	Polarization	Vertical
G	Start/Stop Freq.	170/260 GHz	Antenna gain	6-8 dBi
	Freq. spacing	90 MHz	TX power	4-18 dBm
	Resolution BW	1 kHz		

TABLE II FREQUENCY DOMAIN ANALYSIS: BODY INDUCED RF ATTENUATION AVERAGE AND STANDARD DEVIATION

	W band $(\overline{A}_i, \triangle A_i)$	G band $(\overline{A}_i, \triangle A_i)$
$y_1 = 0 \mathrm{cm}$	(14.3 dB, 5.3 dB)	(16.6 dB, 6.8 dB)
$y_2 = 3 \mathrm{cm}$	n.a.	(2.67 dB, 4.45 dB)
$y_3 = 6 \mathrm{cm}$	(0.36 dB, 1.52 dB)	(-0.1 dB, 3.4 dB)
$y_4 = 12 \text{ cm}$	(-0.05 dB, 1.03 dB)	(-0.08 dB, 3.18 dB)
$y_5 = 25 \mathrm{cm}$	(-0.08 dB, 0.69 dB)	(-0.06 dB, 2.9 dB)
$y_6 = 50 \mathrm{cm}$	(.002 dB, 0.42 dB)	(-0.05 dB, 2.85 dB)

Fig. 3. G band: amplitude of transmission coefficient (top) and body-induced excess attenuation probability functions (bottom) plotted versus frequency, for target positions $y \in \{0, 3, 6, 12, 25, 50\}$ cm.

 $k = 1, ..., N_f$. We then denoted by $T(f_k, i)$ the transmission coefficient measured during experiment *i* at frequency f_k , with target offset y_i . The RF attenuation due to the target at offset y_i and measured at frequency f_k is given by $A_{k,i} = -10 \log_{10} [T(f_k, i) / T_0(f_k)]$. The term $A_{k,i}$ can be considered a random variable with average $\overline{A}_i = 1/N_f \sum_{k=1}^{N_f} A_{k,i}$ and standard deviation $\triangle A_i = \sqrt{1/N_f \sum_{k=1}^{N_f} [A_{k,i} - \overline{A}_i]^2}$. We also denote by $\Pr(A_{k,i} | F_i)$ the sample distribution of $A_{k,i}$, conditioned to the hypothesis F_i . The detection of the target offset can be obtained by one-vs-all classification using the log-likelihood-ratios (LLRs) for each hypotheses pair:

$$\Gamma_{i,j} = \log\left[\frac{\Pr\left(A_{k,i} | \mathbf{F}_i\right)}{\Pr\left(A_{k,j} | \mathbf{F}_j\right)}\right], \forall (i,j), i \neq j,$$
(1)

and applying a majority voting policy.

In Figure 2 and in Table II we show the results obtained in the W band. Specifically, the table reports the mean, \overline{A}_i , and the standard deviation $\triangle A_i$, for all the monitored target positions whereas in the figure we plotted the amplitude of the transmission coefficient and the sample distribution $\Pr(A_{k,i} | \mathbf{F}_i)$.

We observe that, excluding the case i = 1, where the target is completely blocking the LoS link, the sample distributions do not significantly differ, except for negligible variations of the standard deviation. This causes the decision regions of the LLR tests (1) for the cases i > 1 to be almost overlapped, with average separation less than 1 dB, thus penalizing the detection performance. Instead, the body induced average RF attenuation for the target blocking the LoS, i.e., i = 1 and y = $y_1 = 0$, is $\overline{A}_0 = 14.3 \,\mathrm{dB}$, which is consistent with conventional scalar diffraction theory models [10]. A similar situation is observed when analyzing the G band (see Figure 3 and Table II). Compared to the W band, much stronger variations of the RF attenuation, $\triangle A_i$ (up to 10 dB) are observed, for target offset $y \leq 3$ cm. The body induced average RF attenuation for y = 0 cm is $\overline{A}_0 = 16.6$ dB. From the figure, the only clearly recognizable target positions offsets are y = 0 cm and $y = 3 \,\mathrm{cm}.$

IV. CHANNEL IMPULSE RESPONSE CHARACTERIZATION AND ANALYSIS

In the following, we model the CIR as a discrete set of power/amplitude and delay features. The presence of the blockage introduces new multi-path components and may enhance or attenuate existing ones. The target effects on propagation are here modelled as alterations of selected multipath features. These alterations can be further processed to reveal

Fig. 4. Channel Impulse Response (dB) plotted versus the path length (cm) for target offsets $y \in \{0, 3, 6\}$ (top) and $y \in \{12, 25, 50\}$ cm (bottom). The CIR response in the absence of target is represented by the solid black lines. The main perturbations due to the target presence are highlighted.

the unknown position of the target with respect to the LoS link.

The CIR features are obtained from the power delay profile (PDP) that is estimated from the complex measurements of the frequency response. PDPs are used in several motion sensing and localization-based applications [18], combined with Direction of Arrival estimation [20]. In what follows, and according to previous analysis, we focus on the measurements in the G band.

A. CIR response

The CIR response, $h_0(\tau)$, in absence of the target is represented by a discrete dataset of K_0 amplitude $\alpha_0 = [\alpha_{k,0}]_{k=1}^{K_0}$ and delay $\tau_0 = [\tau_{k,0}]_{k=1}^{K_0}$ features as

$$h_0(\tau | \boldsymbol{\alpha}_0, \boldsymbol{\tau}_0) = \sum_{k=1}^{K_0} \alpha_{k,0} \delta(\tau - \tau_{k,0}), \qquad (2)$$

where K_0 is the number of main observable multipath components, while $\alpha_{k,0}$ and $\tau_{k,0}$ are the amplitude and delay of path k, respectively. According to the previously described blockage scenario, we assume that the target presence causes "perturbations" of the multipath components, in both amplitude and delay. Such perturbations can be isolated from noisy observations of the PDPs so as to estimate the target offset y_i .

When the target is located at position y_i , i = 1, ..., 6, the CIR can be modelled as

$$h_i(\tau | \boldsymbol{\alpha}_i, \boldsymbol{\tau}_i) = h_0(\tau | \widetilde{\boldsymbol{\alpha}}_0, \boldsymbol{\tau}_0) + \sum_{k=1}^{\Delta K_i} \alpha_{k,i} \delta(\tau - \tau_{k,i}), \quad (3)$$

and be represented by an augmented dataset comprising $K_i = K_0 + \triangle K_i$ multipath components, whose amplitude and delays are

$$\boldsymbol{\alpha}_{i} = \left[\widetilde{\alpha}_{1,0}, ..., \widetilde{\alpha}_{K_{0},0}, \alpha_{1,i}, ..., \alpha_{\bigtriangleup K_{i},i} \right],$$

$$\boldsymbol{\tau}_{i} = \left[\tau_{1,0}, ..., \tau_{K_{0},0}, \tau_{1,i}, ..., \tau_{\bigtriangleup K_{i},i} \right].$$
(4)

where $\tilde{\alpha}_{k,0} = \rho_{k,i} \alpha_{k,0}$ and the parameter $\rho_{k,i}$ models the amplitude perturbation with respect to that observed in the target's absence (2). The terms, $\alpha_{k,i}$ and $\tau_{k,i}$ model the *additional* multipath components the target might give rise to.

B. Analysis in the G band

Figure 4 shows the estimated PDP response, plotted versus the path length $z = c\tau$ (in cm), where c is the speed of light for target offset $y \in \{0, 3, 6\}$ cm (top) and $y = \{12, 25, 50\}$ cm (bottom). The corresponding PDP measured without the target is represented by solid black lines. By analyzing the results, we identify $K_0 = 6$ main multipath components in absence of the target.

However, the target presence can introduce up to 3 new components, i.e., $\Delta K_i \leq 3$. The new CIR components also loosely depend on the target offset w.r.t. the LoS path, thus enabling the localization of the obstruction.

We observe that for $y \leq 6$ cm (i.e., i = 1, 2, 3), no additional multipath components are introduced, w.r.t. $h_0(\tau)$. Therefore, for i = 1, 2, 3, $\Delta K_i = 0$. On the other hand, a significant attenuation of the existing paths is observed, namely $\tilde{\alpha}_{k,0} < \alpha_{k,0}$. Excluding the first component, the CIR power features $(\tilde{\alpha}_{k,0})$ are subject to an attenuation ρ_k , i = 1, 2, 3 ranging between 6 and 21 dB.

For larger offsets (y > 6 cm) we observe that the target presence gives rise to new paths. In such case the value of y can be inferred from the average path length of the new components.

V. CONCLUSIONS

This paper provides an initial study of the characterization of human blockage in the sub-THz band. We conducted a measurement campaign focused on the collection of complex transmission coefficients for different offsets of the blocker crossing the line-of-sight (LoS) path. Frequency and time domain analysis of the blockage effects are considered. In particular, we analyzed the channel frequency response and the impulse response (CIR) for different blockage offsets. Our experiments highlighted that the RF attenuation due to the target presence are much stronger in the G band (170-260 GHz) than in the W band (75-110 GHz). From the CIR response we also observed that the presence of the blockage gives rise to new multi-path components, while enhancing or attenuating the existing ones. The target effects on the signal propagation are modelled as alterations of selected CIR multipath features. Importantly, the additional path components introduced by the target are characterized by a path length which depends on the target location. This allows to estimate the target offset w.r.t. the LoS link. These results are promising and are expected to open new opportunities towards precise passive radio localization as well as targeting integrated sensing and communication applications.
