The primary challenge of density-functional-theory exploration of alloy systems concerns the size of computational model. Small alloy models can hardly exhibit the chemical disorder properly, while large models induce difficulty in sampling the alignments within the massive material space. We study this problem with the γ phase of the mixed halide inorganic perovskite alloy CsPbBr₂Cl. The distribution of alloy formation energy becomes narrower when the size of the model system increases along $\sqrt{2} \times \sqrt{2} \times 2$, $2 \times 2 \times 2$, and $2\sqrt{2} \times 2\sqrt{2} \times 2$ models. This is primarily because the distribution of Br distribution parameters, which plays a leading role in determining the formation energy range, is more narrow for larger models. As a result, larger entropy stability effect can be observed with larger models especially at high temperatures, for which the approximation using mixing entropy based on the ideal solution model becomes better.

I. INTRODUCTION

Halide perovskites are promising candidates for next-generation optoelectronics owing to their outstanding electronic and optical properties, as well as the common starting materials and low synthesis cost [1]. For example, the record power conversion efficiency of single-junction perovskite solar cells has broken the 26% mark [2,3], catching up with the conventional, expensive, and still market-dominating single-crystalline silicon devices [4,5]; the conversion efficiency against indoor white light has reached ~ 45% [6,7]; high-brightness, high external quantum efficiency, and excellent monochromaticity have been achieved with perovskite light-emitting diodes (PeLEDs) [8–10]; and perovskite-based X-ray detectors recently exhibit high detection sensitivity, low detection limit,

^{*} These two authors contribute equally.

[†] jingrui.li@xjtu.edu.cn

and low attenuation capability [11–13]. These emergent techniques are on their way to industrialization and commercialization, especially providing that the major barriers being overcome or circumvented, primary the instability of perovskite materials and devices against heat, moisture, and oxygen.

Alloying strategy is important and common in designing halide perovskite materials, as the many isostructural ABX₃ (A, B, and X denote the monovalent cation, bivalent cation, and halide anion, respectively) members offer a large flexibility in engineering the perovskite alloy composition toward desired materials properties [8, 14, 15]. Specifically, $FA_{1-x-y}MA_xCs_yPb(I_{1-z}Br_z)_3$ (FA = $(H_2N)_2CH^+$, formamidinium; and MA = $CH_3NH_3^+$, methylammonium) with mixing at both A and X sites is one of today's most preferred core material for perovskite solar cells [16, 17]; B-site substitution (usually Sn for Pb) is a common mean to reduce the environmental hazard of these emergent techniques because of lead; X-site alloying is the primary measure to tune the materials band gap, which is important for the desired emission wavelengths of PeLEDs [18, 19], and against different artificial light sources for indoor photovoltaics [20–22]. Instability issues especially phase segregation are thus induced into the perovskite materials by alloying [8, 9, 15, 23].

First-principles calculations primarily using density functional theory (DFT) play an important role in studying the properties of perovskites including alloys. There are different approaches in previous studies for this purpose, mostly due to different sizes of model systems. Traverse DFT studies over all possible configurations (i.e., alignments of mixed anions) can be conducted for small model systems, such as the 8-perovskite-unit model (i.e., $(ABX_3)_8$) for $FA_{1-x}Cs_xSnI_3$ (8 A sites) [24] and the 4-unit models for $CsPb(I_{1-x}Br_x)_3$ and $CsPb(Br_{1-x}Cl_x)_3$ (12 X sites) [25]. Energyminimizing algorithms such as Monte Carlo simulated annealing were employed to search for the minimal energy configurations of large model systems such as the 12-unit model for $FA_{1-x}Cs_xPbI_3$ (12 A sites) [26] and the 8-unit model for $\text{CsPb}(\text{I}_{1-x}\text{Br}_x)_3$ and $\text{CsPb}(\text{Br}_{1-x}\text{Cl}_x)_3$ (24 A sites) [27]. Alternatively, DFT calculations data of sampled configurations were used to train clusterexpansion models (4-unit models for binary mixed-halide perovskites [28,29]) or machine-learning (ML) models (8-unit models for binary mixed-halide perovskites [27]). Notably, our group studied all four phases of both binary alloys $\text{CsPb}(I_{1-x}\text{Br}_x)_3$ and $\text{CsPb}(\text{Br}_{1-x}\text{Cl}_x)_3$ with traverse DFT calculations on the 4-unit model systems (which are the smallest for both γ and δ phases) [25]. For the first time, we have evaluated the thermodynamic state functions including Helmholtz free energy, internal energy, and configurational entropy for each phases and composition at different temperatures based on DFT data, with (i) correcting the conventional approach using on the mixing entropy based on the ideal solution model, and (ii) construct the temperature vs. composition phase diagrams for these alloys.

The biggest challenges for (DFT-based) computational study of alloys concerns the size and number of the model systems. In principle, we need large enough computational models that can properly exhibit the long-range order of alloys, whose short-range order is missing due to the ion or atom mixing (i.e., chemical disorder). And we need many configurations of alloyed ions to present the disorder character. This is, in principle, infeasible at least with pure DFT approach because of the massive computational resource demanded (note that the size of materials space grows with the combinatorial number related to the size of model system). Possible solutions should include: (i) to find the proper size of computational model system that can balance the computational cost and the reliability of results, and (ii) to develop advanced property-evaluating methods (such as ML based on DFT training data) whose accuracy is at the DFT level. To this end, size effects study of computational model systems for alloys is important. Note: The special quasirandom structures method [30,31] is widely used for modeling alloy materials. It uses Monte Carlo simulated annealing to minimize the difference between the cluster correlation functions of the constructed supercell configuration and those of the random structure. This method pays particular attention to the random alignment of alloyed ions or atoms. It also encounters the size-effects problem: the figure of merit of the best matching configuration decreases with the size of model system.

In this work, we study the inorganic mixed-halide perovskite alloy CsPbBr₂Cl in its roomtemperature γ (space group *Pnma*) phase. This is a typical blue-light emitting material for PeLEDs [32,33] and closely related to candidate materials for harvesting ultraviolet light in indoor scenarios [20, 34]. Previous computational studies indicate that it is located at the formation free energy convex hull within a large temperature range [25], and the fully regular configuration has the lowest alloy formation energy through the whole CsPb(Br_{1-x}Cl_x)₃ space [25,27–29]. To study the effects of model size, we collect DFT calculation data from randomly sampled configurations of $2 \times 2 \times 2$ (8-unit) and $2\sqrt{2} \times 2\sqrt{2} \times 2$ (16-unit) model systems and compare them with the traverse DFT data of the smallest $\sqrt{2} \times \sqrt{2} \times 2$ (4-unit) model. To estimate the impact of model size, we pay particular attention to the distribution of alloy formation energies, and eventually use this information to evaluate the thermodynamic state functions of each model.

The remainder of this article is organized as follows. In Sec. II, we briefly describe the investigated model systems and introduce some distribution parameters that distinguish the configurations. Section III presents the computational results, based on which a detailed discussion on the model size effects are conducted in Sec. IV. Finally, Sec. V concludes with a summary.

II. COMPUTATIONAL MODELS OF THE CsPbBr₂Cl ALLOY

A. Structure models of the CsPbBr₂Cl alloy

In this paper we focus on the alloy formation energy which is defined as

$$E_i = E_{\text{total}}(i) - \frac{2}{3}E_{\text{total}}(\text{CsPbBr}_3) - \frac{1}{3}E_{\text{total}}(\text{CsPbCl}_3)$$
(1)

with *i* indexing the CsPbBr₂Cl alloy configuration and E_{total} the DFT calculated total energy (per one perovskite unit, i.e., 5 atoms). We considered three different models for the γ phase of CsPbBr₂Cl, including the minimal one $\sqrt{2} \times \sqrt{2} \times 2$ and two larger ones, $2 \times 2 \times 2$ and $2\sqrt{2} \times 2\sqrt{2} \times 2$ (Fig. 1). We must notice that in this context, the " γ phase" means that the configurations were constructed according to the following protocol: (i) a regular γ phase CsPbX₃ structure was generated, which can be characterized by the $a^-b^-c^+$ Glazer tilting of the halide octahedra (X₆); (ii) Br⁻ and Cl⁻ ions were randomly occupying the X sites with the ratio 2 : 1. In most cases, these structures do not exhibit the *Pnma* symmetry, because (a) for the equivalent sites in CsPbX₃, their local chemical environments are different in CsPbBr₂Cl because of the random Br/Cl alignment, and as a result, (b) the octahedral tilting in the DFT relaxed structure is not as regular as in the pure CsPbBr₃ or CsPbCl₃. Nevertheless, they can still be categorized in the γ phase as the DFT relaxed structures exhibit $a^-b^-c^+$ -like octahedral tilting.

FIG 1. Three structure models (from left to right: $\sqrt{2} \times \sqrt{2} \times 2$, $2 \times 2 \times 2$, and $2\sqrt{2} \times 2\sqrt{2} \times 2$) for the γ phase of CsPbBr₂Cl. Cs, Pb, in-plane halides, and out-of-plane halides are colored in green, dark gray, brown, and red, respectively.

The relaxed structure of each configuration and thus its properties are uniquely determined by the halide alignment. The first parameter is the Br proportion in the in-plane (IP) halides. Here, in-plane means that the halides (brown in Fig. 1, labeled by ab hereafter) are approximately located in the plane spanned by the lattice vectors, around which the halide octahedral tilt out-of-phase. Out-of-plane (OP) halides (red in Fig. 1) are located between two neighboring **ab** planes. The possible numbers of IP Br atoms and the corresponding numbers of possible alloy configurations of different models are listed in Table I. For example, the total number of Br/Cl alignments with 6 IP Br in the $\sqrt{2} \times \sqrt{2} \times 2$ is $C_8^6 C_4^2 = 168$.

The total number of configurations are $C_{12}^8 = 495$, $C_{24}^{16} = 735471$, and $C_{48}^{32} = 2.25 \times 10^{12}$ for $\sqrt{2} \times \sqrt{2} \times 2$, $2 \times 2 \times 2$, and $2\sqrt{2} \times 2\sqrt{2} \times 2$, respectively. For $\sqrt{2} \times \sqrt{2} \times 2$, the number is reduced to 44 because of symmetry thus allowing for a traverse DFT exploration [25]. While for the other two models, it is infeasible to perform DFT calculation on each configuration even symmetry can reduce the total number of configurations by some orders of magnitude. We sampled configurations of these two models according to the IP-OP distribution of halides as listed in Table I.

B. Halide distribution parameters and machine learning

The large number of mixed halide configurations in the large $2 \times 2 \times 2$ and $2\sqrt{2} \times 2\sqrt{2} \times 2$ structure models motivate to call of ML techniques. The aim is to rapidly predict the alloy formation energies of any given mixed halide alignments, to describe which we need a proper coding.

We can use a set of parameters that describe the halide alignment. The IP/OP Br proportion, denoted by $p_{\rm Br}^{\rm IP}$ hereafter, already introduced in Fig. 1 and Table I provides the information of individual Br⁻ ions' locations. In this regard it can be considered a one-body parameter. Twobody parameters give the information of the probability of two specific halides being found with a certain distance. These include

- *p*_{SS}: IP nearest-neighbor (NN) Br-Br proportion with both Br⁻ ions on the same side (SS, i.e., above or below the plane in terms of *c*) of the *ab* plane (Fig. 2 red). The total number of SS-NN halide pairs of an *n*-unit model is 2*n*.
- *p*_{DS}: IP NN Br-Br proportion with two Br⁻ ions on the different sides (DS) of the *ab* plane (Fig. 2 blue). The total number of DS-NN halide pairs of an *n*-unit model is 2*n*.
- p_{OP}: OP NN Br-Br proportion with one IP and one OP Br⁻ ions (Fig. 2 green). The total number of OP-NN halide pairs of an n-unit model is 8n.
- *p*_{CP}: The portion of Br-Br pairs with both IP Br⁻ ions at the neighboring *ab* planes (cross-plane or CP), with similar coordinates along both *a* and *b* (Fig. 2 orange). The total number of OP-NN halide pairs of an *n*-unit model is 8*n*.
- $p_{\rm SC}$: The portion of Br-Br pairs with both OP Br⁻ ions at the same column (SC, i.e., with

similar coordinates along both a and b), connected with one Pb²⁺ ion (Fig. 2 yellow). The total number of SC halide pairs of an *n*-unit model is *n*.

p_{CC}: The portion of Br-Br pairs with both OP Br⁻ ions at the nearest two columns (cross-column or CC), with similar coordinates along c (Fig. 2 purple). The total number of SC halide pairs of an n-unit model is 2n.

The whole set of parameters, $\{p_{Br}^{IP}, p_{SS}, p_{DS}, p_{OP}, p_{CP}, p_{SC}, p_{CC}\}$, are used as the first feature for our ML study.

FIG 2. Br-Br distribution parameters: SS, DS, OP, CP, SC, and CC (colored by red, blue, green, orange, yellow, and purple, respectively). Also shown is the coordinates (a, b, c) system.

Another feature for describing the atomic structure of CsPbBr₂Cl alloy is the many-body tensor representation (MBTR) [35]. MBTR is a structural descriptor that considers structural motifs such as elemental contents (k = 1), interatomic distances (k = 2), bond angles (k = 3), etc. to form a vector representation of an atomic geometry [35,36]. A previous study shows that the k = 1 term does not improve the model accuracy when higher-order terms were included [37], and it is the same for all configurations considered in this paper. It is generally concluded that the inclusion of the k = 3 term produces a minimal improvement in accuracy with significantly increasing the computational cost [27,37]. Therefore we only consider the k = 2 term in this paper, similar as in previous studies [27,37]. The second-order MBTR encodes the distances of all pairs of atoms of the investigated structure by

$$\boldsymbol{M}_{\mathrm{E}_{1}\mathrm{E}_{2}}(x) = \sum_{l_{1}, l_{2}} w_{l_{1}l_{2}} \frac{1}{\varsigma\sqrt{2\pi}} \exp\left(-\frac{\left(x - R_{l_{1}l_{2}}^{-1}\right)^{2}}{2\varsigma^{2}}\right),$$
(2)

where $R_{l_1l_2}$ is the interatomic (cartesian) distance between the l_1 th atom of element E_1 and the l_2 atom of E_2 , ς is the Gaussian width parameter. The sum runs over all atoms of element E_1

(indexed by l_1) and E_2 (indexed by l_2) within a cutoff distance, except that $l_1 \neq l_2$ when $E_1 = E_2$. The weighting function is defined by

$$w_{l_1 l_2} = \begin{cases} e^{-sR_{l_1 l_2}}, & \text{when } R_{l_1 l_2} \leqslant r_{\text{cutoff}}, \\ 0, & \text{when } R_{l_1 l_2} > r_{\text{cutoff}}, \end{cases}$$
(3)

with s controling its decay rate with $R_{l_1l_2}$. In practice, one can limit all atoms of element E_1 within the unit cell without loss of generality, and search for all atoms of E_2 within the sphere of radius r_{cutoff} centered at this E_1 atom, thus avoiding double counting.

The thus generated second-order MBTRs are continuous functions of x whose dimension is the inverse of interatomic distance. They are then discretized at a set of equidistance grid points over a certain range of x values. In this way, the MBTRs of all or particular atom pairs construct a vector presentation M of a given atomic structure.

MBTR has many advantages as a descriptor that maps the atomic structures to Hilbert space elements [35]. A particular merit is that MBTR, as a continuous function of the atomic coordinates (note: $R_{l_1l_2} = ||\mathbf{R}_{l_2} - \mathbf{R}_{l_1}||$ with \mathbf{R}_l denoting the cartesian coordinate of the *l*th atom), allows a direct evaluation of its gradient. Therefore one can compute the atomic forces and stress tensor components directly from the ML model [27]. Nevertheless, we mainly focus on the relationship of how the formation energy of an alloy structure depends on the alignment of the alloyed element atoms in this paper. Thus we evaluate the MBTR of each configuration at its starting structure, which is initiate by linear interpolation between the relaxed CsPbBr₃ and CsPbCl₃ structures according to Vegard's law (i.e., the starting structures of different configurations only differ in the order of halide ions).

We correlate the ML features with the energy labels E_{label} using kernel-ridge regression (KRR) with the Gaussian kernel k based on previous studies [27,37] and tests:

$$E_{\text{label}} = \sum_{i}^{N} \beta_{i} k(\boldsymbol{s}, \boldsymbol{s}_{i}), \qquad (4)$$

$$k(\boldsymbol{s}, \boldsymbol{s}_i) = \exp(-\gamma ||\boldsymbol{s} - \boldsymbol{s}'||_2^2), \qquad (5)$$

with s denoting the feature of a particular structure, β_i fitting coefficients, and γ the width parameter controlling the kernel. The determination of $\{\beta_i\}$ is done according to the following matrix form

$$\boldsymbol{\beta} = (\boldsymbol{K} + \alpha \boldsymbol{I})^{-1} \boldsymbol{E}_{\text{label}}^{\text{ref}}$$
(6)

with K the kernel matrix $K_{ij} = k(s_i, s_j)$, E_{label}^{ref} the energy labels of the reference data set, and α the regularization parameter. The hyperparameters, including α and γ and for the MBTR-ML case

also σ , are optimized during the training of ML models using the Bayesian optimization structure search (BOSS) code [38].

III. RESULTS

A. Benchmarking the DS-PAW calculations

Figure 3 compares the alloy formation energies of all 44 small-size models of CsPbBr₂Cl, obtained from structure optimization calculations using DS-PAW vs. FHI-aims (data from our previous study [25]). The results by these two softwares are generally similar, with the DS-PAW results slightly higher than the FHI-aims results. The root-mean-square error is 2.6 meV (per formula unit, similarly hereinafter), and the largest deviation is 6.9 meV Specifically, the portions of configurations with which the deviation is within [0, 1] meV, (1, 2] meV, and (2, 3] meV are $\frac{17}{44} = 0.39$, $\frac{10}{44} = 0.23$, and $\frac{8}{44} = 0.18$, meaning that the result difference between these two softwares are within 3 meV for 82% of samples. Overall, linear refinement indicates that DS-PAW result = 0.94 FHI-aims result + 3.0 meV, with the coefficient of determination $R^2 = 0.95$.

FIG 3. Comparison between the alloy formation energies of all 44 small-size models calculated by DS-PAW and FHI-aims.

The average expended resources for the DS-PAW and FHI-aims calculations are 56.6 and 133.1 CPU h, respectively. Based on the comparison of computational accuracy and cost between these two softwares, we can conclude that DS-PAW performs well as it reaches the accuracy of FHI-aims which is widely used for halide perovskites [25,27,39–42] but requiring about only 40% CPU hours.

B. Energy distribution diagrams of model systems of different sizes

Different to that we sampled all possible configurations of the smallest model system, the configurations of the medium and the large model systems were randomly sampled. Nevertheless, we expect that these random samples to contain most of the characters of the energy level distribution. To this end, we use density of states (DOS) to describe the distribution of alloy formation energies of the whole ensemble of CsPbBr₂Cl configurations for each model system size. It is defined by

$$\rho(E) = A \sum_{i} g_{i} e^{-(E - E_{i})^{2}/\sigma^{2}}, \quad \int \rho(E) dE = N$$
(7)

where A is the normalization factor, g_i the degree of degeneracy and E_i the alloy formation energy of the *i*th configuration, σ the width parameter (we chose $\sigma = 0.5$ meV), N is the total number of possible configurations. The smallest system is explored by a traverse DFT study, with g_i obtained from symmetry analysis (see Ref. [25]). While for either the medium or the large system, the DOS is constructed based on 100 randomly sampled configurations. As the sampling was performed according to a certain distribution of alloy configurations, we have all $g_i = 1$.

The DOS scheme (Fig. 4) converts the discrete representation of (alloy formation) energy levels to a (quasi-)continuum of possibility distribution over a certain range of energies. It is obvious that as the model system size increases, the DOS distribution becomes narrower. Specific analysis is as follows. Firstly, the signals in the range E < 6 meV for the smallest model system vanish in the DOS for both larger model systems. The minimal-energy peak of the smallest model is at -5.2 meV, contributed from the fully ordered structure ($p_{\rm Br}^{\rm IP} = 1$). The peak centered at 5.1 meV for the smallest model system is noticeable because of the high degree of degeneracy (32) of the corresponding configuration where 7 Br⁻ anions occupy the IP sites (i.e., $p_{\rm Br}^{\rm IP} = 0.875$). However, configurations with both parameters were not sampled for both larger model systems due to the low possibilities (e.g., for $p_{\rm Br}^{\rm IP} = 0.875$, the proportions are 4.6×10^{-3} and 2.9×10^{-5} for the medium and large models, respectively). Secondly, for the medium model system, configurations with alloy formation energy ranging between 28 and 33 meV noticeably contribute to the DOS, while these configurations are not allowed by the smallest model system meaning that they are relatively largely disordered. Finally, both low- and high-energy "tails" of the medium model system DOS vanish for the large system, indicating that the corresponding configurations were not sampled for the latter. As a result, the arithmetic mean energy increases from the smallest (18.0 meV) to the medium (20.1 meV) model system, then slightly decreases when the model system size further increases (19.2 meV).

FIG 4. Density of states (DOS) diagrams calculated with the smallest ($\sqrt{2} \times \sqrt{2} \times 2$, in black), medium (2 × 2 × 2, in red), and large ($2\sqrt{2} \times 2\sqrt{2} \times 2$, in blue) models.

C. Thermodynamics properties

From the DOS schemes we can calculate the partition function Z and therewith the thermodynamic state functions, namely the Helmholtz free energy F, the internal energy U, and the configurational entropy S, for each model by

$$Z = \int \rho(E) \mathrm{e}^{-nE/k_{\mathrm{B}}T} \,\mathrm{d}\,E\,,\tag{8}$$

$$F = -\frac{1}{n}k_{\rm B}T\ln(Z)\,,\tag{9}$$

$$U = \frac{1}{nZ} \int E\rho(E) \mathrm{e}^{-nE/k_{\mathrm{B}}T} \,\mathrm{d}E\,,\tag{10}$$

$$S = \frac{U - F}{T} \tag{11}$$

with n denoting the number of perovskite units in the model system. The results are presented in Fig. 5.

The calculated Helmholtz free energy (F) lines (Fig. 5a) show a cross at T = 200 K: F(small) < F(medium) < F(large) when T < 200 K, while the opposite trend is observed when T > 200 K.

FIG 5. Thermodynamic state functions of the smallest (black), medium (red), and large (blue) model systems calculated from their DOSs. **a** Helmholtz free energy. **b** configurational entropy in terms of its proportion to the value based on the ideal solution model. **c** internal energy. Also shown are: in **a**, Helmholtz free energies calculated by adding the mixing entropy term based on the ideal solution model to either the arithmetic mean energy (dashed lines) or the minimal formation energy (dotted lines); and in **c**, the arithmetic mean energy (dashed lines).

This can be rationalized by the alloy formation energy ranges of the sampled configurations: the contribution of the low-energy configurations of the smallest model system dominates the DOS at relatively low temperatures, while for the larger model systems, they were not sampled due to the low probabilities. As temperature increases, high-energy configurations play increasingly important role. The large $(2\sqrt{2} \times 2\sqrt{2} \times 2)$ model exhibits the narrowest $\rho(E)$ distribution, thus showing the largest entropy stabilization effect as reflected by the smallest F values.

When neglecting the volume change (which is adequate for solid states), we have dF = -S dT. At room temperature or higher ($T \ge 300$ K), all three models exhibit an approximate linear dependence of F on T (Fig. 5a), indicating that the configurational entropy S is nearly constant within this temperature range. Figure 5b clearly shows this character. Define the mixing entropy based on the ideal solution model by [25]

$$S' = 3k_{\rm B} \left[\frac{2}{3} \ln \left(\frac{2}{3} \right) + \frac{1}{3} \ln \left(\frac{1}{3} \right) \right],\tag{12}$$

Fig. 5b shows the evolution of S/S' with temperature. From 300 to 700 K, the proportions of configurational entropy in the ideal-solution-model-based mixing entropy of the smallest, medium, and large models increase from 74.1% to 80.0%, from 81.3% to 86.9%, and from 88.8% to 92.2%, respectively. The configurational entropy trend stays at S(large) > S(medium) > S(small) within the whole temperature range, which is in accordance with the slope trend of F of these three models shown in Fig. 5. As a final note, the configurational entropy of the smallest model is significantly

smaller than the other two models at 100 K, indicating that only a few configurations contribute to the thermodynamic properties of the whole ensemble of the smallest model at low temperatures.

Figure 5a provide an approximate method to evaluate the Helmholtz free energy of an alloy ensemble: subtracting the entropy term TS' obtained from the ideal solution model (Eq. 12) from the arithmetic mean energy E_{avg} (dashed lines). From the definition of internal energy U (Eq. 10), we know that U it is always below E_{avg} unless all configurations have exactly the same energy value. U approaches E_{avg} as temperature increases, as shown in Fig. 5c. As $E_{avg} > U$ and S' > S, $(E_{avg} - TS')$ might be a good approximation to F = U - TS as both errors cancel each other to a certain extend.

Finally, we shortly discuss another way to evaluate the entropy stabilization effect which was widely used in computational studies [24,26,43]: subtracting the entropy term TS' obtained from the ideal solution model (Eq. 12) from the (quasi)minimal alloy formation energy E_{\min} , which can be obtained from DFT calculations on a series of test configurations and usually in combination with some minimization algorithm such as Monte Carlo simulated annealing [27–29,44]. According to Fig. 5a, this is a worse approach to F compared to ($E_{avg} - TS'$). This is because $E_{\min} < U$ and SI > S therefore the errors of both terms lead to a smaller F but can never cancel each other.

IV. DISCUSSION

The results presented in Sec. III show noticeable size effects of the model systems of $CsPbBr_2Cl$ alloy. They can be summarized as: the larger the model system, the narrower the distribution of alloy formation energy, the larger the configurational entropy (i.e., the closer to the mixing entropy based on the ideal solution model), and the smaller the Helmholtz free energy at room temperature or higher (i.e., the larger the entropy stabilization effect). In addition, large models are inappropriate to describe the low-temperature behavior of this alloy because the low-energy configurations were missed during the sampling.

A. Energy distribution

The proportion data listed in Table I can be converted into a quasi-continous distribution function $\rho(x)$, with $x = \frac{m}{2n} = p_{\text{Br}}^{\text{IP}}$ denoting the Br portion in all IP halides. Accordingly we have $\int \rho(x) \, dx = 1$ with the integration running through the whole domain $x \in \left[\frac{1}{2}, 1\right]$. Figure 6 shows the evolution of $\rho(x)$ function with the model system size z increases. From $\lim_{n \to +\infty} n! =$ $\sqrt{2\pi n}(n/e)^n$, we have for the infinite model limit

$$\lim_{n \to +\infty} \varrho(x) = \lim_{n \to +\infty} 2n \frac{C_{2n}^m C_n^{2n-m}}{C_{3n}^{2n}}$$
$$\sim \exp\left(-2n \left[2(1-x)\ln(1-x) + x\ln(x) + (x-\frac{1}{2})\ln\left(x-\frac{1}{2}\right)\right]\right) \tag{13}$$

(more precisely, this is available within the major part of the domain $x \in \lfloor \frac{1}{2}, 1 \rfloor$ except when x is very close to the edge $\frac{1}{2}$ or 1). Because of the coefficient 2n in the exponent, the exponential part dominates the character of $\varrho(x)$ with the following character: (i) $\varrho(x)$ exhibits a single, Gaussianlike peak at $x = \frac{2}{3}$, and (ii) the width of this peak decreases as n increases. As a result, in the infinite model limit, almost all configurations will be characterized by $x = \frac{2}{3}$ which is natural because of the Br₂Cl stoichiometry.

FIG 6. Configuration distribution with respective to the IP Br proportion parameter p_{Br}^{IP} (labeled by x). Data of model systems of different sizes z = 4, 8, 16, 32, 64 (only the first three considered in this paper) are colored in black, red, green, blue, and yellow, respectively.

Figure 7 shows the alloy formation energies of sampled configurations at each IP Br proportions. A general trend that the energy decreases with $p_{\rm Br}^{\rm IP}$ increases can be observed. The limit case of this trend was reported in previous studies: the minimal energy configuration exhibits a fully ordered Br⁻/Cl⁻ alignment so that all Br⁻ anions occupy the IP halide sites [25,27,29]; while in the maximal energy configuration, all OP halide sites are occupied by the larger halide Br⁻, and accordingly the Br⁻ proportion in IP halide sites is 0.5 [25].

FIG 7. Alloy formation energy distribution at each IP Br proportion. **a** Smallest ($\sqrt{2} \times \sqrt{2} \times 2$) model. **b** Medium (2 × 2 × 2) model. **c** Large (2 $\sqrt{2} \times 2\sqrt{2} \times 2$) model. The vertical dashed lines mark $p_{\rm Br}^{\rm IP} = \frac{2}{3}$.

Such a trend eases our analysis of the model-size dependence of the energy distribution by combining Figs. 6 and 7. The probability that the configurations with $p_{\rm Br}^{\rm IP}$ parameters close to $\frac{2}{3}$ are sampled increases with the size of model system. Fig. 7 shows that the energies of these configurations are approximately distributed within the range [10, 30] meV, in good accordance with the arithmetic mean energies of all three models as alluded to. In addition, the energy distribution is narrower for larger model system, partly because larger model system allows configurations with $p_{\rm Br}^{\rm IP}$ closer to $\frac{2}{3}$ (the $p_{\rm Br}^{\rm IP}$ parameters closest to $\frac{2}{3}$ for the smallest, medium, and large model systems are $\frac{5}{8}$, $\frac{11}{16}$, and $\frac{21}{32}$, 0.042, 0.021, and 0.010 away from $\frac{2}{3}$, respectively).

In principle, additional DFT calculation data are required to improve and eventually the DOS. However, this correspond to tremendous demand of computational resource and is infeasible for large model systems (such as the "medium" and "large" in this paper). Recently, the MBTR-KRR ML model has been successfully applied to inorganic mixed halide perovskites [27]. It can predict not only the formation energy but also the atomic forces of a $2 \times 2 \times 2$ supercell at the DFT accuracy ($\sim 10^6$ and $\sim 10^4$ faster, respectively), therefore it can perform structure optimization whose results are very similar to DFT. This would therefore be a proper choice if we want to construct the DOS of alloy formation energies in a (quasi)traverse manner. Nevertheless, it is natural to regard that the total energy of the relaxed structure of a particular CsPbBr₂Cl configuration uniquely depends on the "topological" Br/Cl alignment, i.e., not including detailed atomic coordinate variation. We consider either the Br distribution parameters defined in Sec. II B or only-halide (i.e., Br–Br, Cl–Cl, and Br–Cl) second-order MBTR satisfy this requirement.

Based on the DOS character of all three models, we only perform ML study on the configurations whose $p_{\text{Br}}^{\text{IP}}$ parameters are close to $\frac{2}{3}$. These include: $p_{\text{Br}}^{\text{IP}} = \frac{5}{8}$ and $\frac{6}{8}$ for the smallest ($\sqrt{2} \times \sqrt{2} \times 2$)

FIG 8. KRR ML model of alloy formation energies of all configurations with $p_{\rm Br}^{\rm IP} \approx \frac{2}{3}$. **a** Using all Br distribution parameters defined in Sec. II B as feature. b Using only-halide MBTR as feature.

model, $p_{\text{Br}}^{\text{IP}} = \frac{10}{16}$ and $\frac{11}{16}$ for the medium $(2 \times 2 \times 2)$ model, and $p_{\text{Br}}^{\text{IP}} = \frac{21}{32}$ and $\frac{22}{32}$ for the largest $(2\sqrt{2} \times 2\sqrt{2} \times 2)$ model. The total number of data entries, 128, is rather small because of the limited number of overall samples. We divided them as 100 for training and 28 for testing. Figure 8 shows the ML results using the Br-distribution parameters (Fig. 8a) and halide-only MBTR (Fig. 8b). Both ML models show good accuracy as reflected by the relatively small mean absolute error (MAE) values. Br-distribution-parameters-based ML model has a much lower R^2 coefficient than the MBTR-based model, in accordance with its larger MAE. Overall, the MBTR-KRR ML model performs better, and can fulfill the aim of approximately predicting the formation energy of the optimized structure of an alloy configuration.

B. Thermodynamic properties

From Eqs. 8-11, we can easily understand the observed trend of size effects on the thermodynamic properties at high temperatures. This is directly based on the interand when calculating Z using Eq. 8, $\rho(E)e^{-nE/k_{\rm B}T}$. For larger T and narrower $\rho(E)$ peak, the difference of $e^{-nE/k_{\rm B}T}$ values for energies within the peak is smaller. In the limit of $\frac{\langle \Delta E \rangle}{T} \rightarrow 0$ ($\langle \Delta E \rangle$ denotes the energy deviation of the ensemble), we have

$$Z = e^{-n\langle E \rangle/k_{\rm B}T} \int \rho(E) \,\mathrm{d}\, E = e^{-n\langle E \rangle/k_{\rm B}T} \Omega \,, \tag{14}$$

$$F = \langle E \rangle - \frac{1}{n} k_{\rm B} T \ln(\Omega) \,, \tag{15}$$

$$U = \langle E \rangle, \tag{16}$$

$$S = \frac{1}{n}\ln(\Omega) = S' \tag{17}$$

with Ω denoting the number of configurations. The underlying physics is straightforward: since most of the configurations have nearly the same energy, their contribution to the thermodynamic properties of the whole ensemble are approximately equal. In this case, the ideal solution model is a good approximation.

The timeperature-evolution of the thermodynamic properties of the smallest model system can also be analyzed based on $\rho(E)e^{-nE/k_{\rm B}T}$ (Fig. 9). As the structural parameter distribution (Fig. 6) of this model system is rather flat, the $\rho(E)$ (DOS, Fig. 4) is wide and structured. As a result, the $\rho(E)e^{-nE/k_{\rm B}T}$ function which exhibit the major contribution to the partition function Z shows a transition from low- to high-energy regions as T increases. When the temperature is as low as 100 K, most of the contribution to the ensemble is provided by the minimal-energy configuration (E = -5.2 meV or 4E = -20.8 meV) despite the low degree of degeneracy (1). Accordingly, the configurational entropy is very small. At 200 K, the contribution from this minimal-energy configuration rapidly decays, while the major contribution is from the configuration (32-fold degenerate, E = 5.1 eV). As temperature further increases, configurations with higher energies becomes increasingly important, and accordingly the configurational entropy increases.

In sum, the high-temperature thermodynamic behavior of the inorganic halide perovskite alloy CsPbBr₂Cl can be properly evaluated, because the energy distribution of most of the configurations is relatively narrow and can already be adequately reflected by our large model that contains 16 perovskite units. In contrast, the low-temperature behavior is more complicated. Minimal-energy configurations are naturally important at low temperatures. If their proportion is low (especially in large model systems), the evaluation of low-temperature thermodynamic properties of alloys remains open and will be subject to future work.

V. CONCLUSION

In summary, we explore the effects of model size on the computational study of thermodynamic properties of representative all-inorganic mixed-halide alloy CsPbBr₂Cl. While the distribution of

FIG 9. Interand of partition function calculation (Eq. 8) of the smallest model system at different temperatures.

alloy formation energies for the smallest model is wide and structured, it becomes narrow when the size of model system increases, with configurations within both low- and high-energy regions being less sampled. As a result, the Helmholtz free energy of the alloy ensemble is more negative for larger model at room temperature or higher, indicating a stronger entropy stability effect. Overall, we observe obvious size effects of computational model systems for the CsPbBr₂Cl, which rapidly decay when the model system becomes larger.

VI. METHOD

For DFT structure optimization calculations, we chose the Perdew-Burke-Ernzerhof exchangecorrelation functional for solids (PBEsol) [45] implemented in the DFT software DS-PAW, which is based on plane wave basis functions and projected augmented wave pseudo-potentials [46] and distributed over the Device Studio platform [47]. PBEsol has already proved its suitability in modeling halide perovskites [27, 42, 48–50] and was used for the calculations of CsPbBr₂Cl alloys [25], whose data were used as reference in this paper. The plane-wave cutoff was set to 600 eV based on test calculations. Structural relaxation was performed using the conjugate gradient method with the convergence criteria for total energy and atomic forces set to 10^{-4} eV and 0.05 eV · Å⁻¹, respectively. Γ -centered $8 \times 8 \times 6$, $6 \times 6 \times 6$, and $4 \times 4 \times 6$ k-point meshes were used for the Brillouin zone integration for the $\sqrt{2} \times \sqrt{2} \times 2$, $2 \times 2 \times 2$, and $2\sqrt{2} \times 2\sqrt{2} \times 2$ model systems, respectively.

VII. ACKNOWLEDGEMENT

The authors thank Hua Dong, Jie Xu, Fang Yuan, and Jarno Laakso for fruitful discussions. We gratefully acknowledge HZWTECH for providing computational facilities. We also thank the computational resources provided by Xi'an Jiaotong University's HPC platform and the Computing Center in Xi'an. F.P. thanks Shenbo Yang and Duo Zhang from HZETECH for technical assistance. This work was supported by the Natural Science Foundation of Shaanxi Province of China (grant No. 2023-YBGY-447) and the National Natural Science Foundation of China (grant No. 62281330043).
