ABSTRACT

We present spatially resolved VLT/SINFONI spectroscopy with adaptive optics of type-2 active galactic nuclei (AGN) from the SINFONI Survey for Unveiling the Physics and Effect of Radiative feedback (SUPER), which targeted X-ray bright ($L_{2-10 \text{ keV}} \geq 10^{42} \text{ erg s}^{-1}$) AGN at the Cosmic Noon ($z \sim 2$). Our analysis of the rest-frame optical spectra unveils ionised outflows in all seven examined targets, as traced via [O III] $\lambda 5007$ line emission, moving at $v \geq 600 \text{ km s}^{-1}$. In six objects these outflows are clearly spatially resolved and extend on 2–4 kpc scales, whereas marginally resolved in the remaining one. Interestingly, these SUPER type-2 AGN are all heavily obscured sources ($N_{\text{H}} \geq 10^{23} \text{ cm}^{-2}$) and host faster ionised outflows than their type-1 counterparts within the same range of bolometric luminosity ($L_{\text{bol}} \sim 10^{44.8-46.5} \text{ erg s}^{-1}$). SUPER has hence provided observational evidence that the type-1/type-2 dichotomy at $z \sim 2$ might not be driven simply by projection effects, but might reflect two distinct obscuring life stages of active galaxies, as predicted by evolutionary models. Within this picture, SUPER type-2 AGN might be undergoing the ‘blow-out’ phase, where the large amount of obscuring material efficiently accelerates large-scale outflows via radiation pressure on dust, eventually unveiling the central active nucleus and signal the start of the bright, unobscured type-1 AGN phase. Moreover, the overall population of ionised outflows detected in SUPER has velocities comparable with the escape speed of their dark matter halos, and in general high enough to reach 30–50 kpc distances from the centre. These outflows are hence likely to sweep away the gas (at least) out of the baryonic disk and/or to heat the host gas reservoir, thus reducing and possibly quenching star formation.

Key words. galaxies: active - galaxies: evolution - galaxies: high-redshift - quasars: emission lines - techniques: imaging spectroscopy

1. Introduction

A key question in galaxy evolution is how active galactic nuclei (AGN) interact with their host galaxy and shape its physical properties, from gas content to star formation (SF) and chemical enrichment. This so-called AGN feedback typically acts via massive outflows (e.g. King 2005; Fabian 2012; Costa et al. 2014), powered on sub-pc scales by the radiative output of accreting supermassive black holes (BH), and then accelerated up to galaxy scales of $\sim 1-10$ kpc (e.g. King & Pounds 2015). These winds are considered the main responsible for quenching SF within their host, by heating or expelling the gas reservoir from which new stars form (i.e. ‘preventive’ versus ‘ejective’ feedback), and settling the observed scaling relations between BH mass and host galaxy properties (e.g. Ferrarese & Merritt 2000; Marconi & Hunt 2003; Kormendy & Ho 2013; Marasco et al. 2021).

To date we have plenty of observational evidence of AGN-driven outflows from low (e.g. Feruglio et al. 2010; Harrison et al. 2014; Woo et al. 2016) to high redshift ($z > 1$; e.g. Maiolino et al. 2012; Förster Schreiber et al. 2014; Carniani et al. 2023), in different gas phases (e.g. Cicone et al. 2018). While mm/sub-mm interferometric observations are optimally suited to investigate the cold molecular ($T < 100 \text{ K}$) component of AGN-driven outflows (typically via CO line emission; Cicone et al. 2014;

Morganti et al. 2015; Chartas et al. 2020), optical/near-IR Integral Field Spectroscopy (IFS) enables detailed spatially resolved studies of the warmer ionised component of outflows. To trace ionised outflows, the most commonly adopted tracer is the optical [O III] $\lambda 5007$ line emission (e.g. Cano-Díaz et al. 2012; Venturi et al. 2018; Marshall et al. 2023), a forbidden line transition which can originate only from low-density regions ($n_{\text{e}} < 10^6 \text{ cm}^{-3}$), thus excluding any potential contamination from high-density AGN Broad Line Region (BLR). Therefore, [O III] $\lambda 5007$ is an excellent tracer of ionised gas extended on 1–10 kpc scales.

Thanks to high-quality IFS observations, obtained with ground-based adaptive optics (AO) assisted facilities or from space with the *James Webb Space Telescope*, AGN-driven ionised outflows and feedback mechanisms have been deeply investigated at $z > 1$ (e.g. Förster Schreiber et al. 2014; Perna et al. 2015b, 2023; Wylezalek et al. 2022; Cresci et al. 2023; Marshall et al. 2023; Vayner et al. 2023), with the primary focus on the so-called Cosmic Noon ($z \sim 2$), where both SF and BH accretion histories reach the peak of their activity (Madau & Dickinson 2014). This makes the redshift range $z \sim 1-3$ the golden epoch of AGN feedback, where its effects are expected to be maximised.

Nonetheless, the high-redshift search has primarily focused so far on brighter distant sources ($L_{\text{bol}} > 10^{46} \text{ erg s}^{-1}$; e.g. Bischetti et al. 2017; Perrotta et al. 2019), easier to detect and to examine, which has led to a biased census of high-redshift AGN-driven outflows. In addition to this, the lack of direct observa-

* e-mail: gtozzi@mpe.mpg.de

tional evidence confirming (or disproving) key theoretical predictions prevents us from a clear and complete picture of AGN feedback and outflows, with several questions still open. For instance, how do AGN-driven outflows really affect their host galaxy? Do they quench SF activity efficiently? Are they representative of a particular life stage of galaxies' evolution?

One of these theoretical scenarios still waiting for observational proof predicts that AGN galaxies experience a first dust-enshrouded life stage (e.g. Hopkins et al. 2006; Menci et al. 2008), where the central nucleus is obscured by dust and gas, which fuel both supermassive BH growth and SF efficiently. This sets the stage to the short-lived (a few tens of Myr) 'blow-out' phase (e.g. Hopkins et al. 2008), during which powerful AGN-driven winds sweep away obscuring material and make the central AGN visible and unobscured. Such an evolutionary scenario was proposed to explain the observed dichotomy between red and blue quasars (e.g. Brusa et al. 2010; Klindt et al. 2019; Perrotta et al. 2019; Fawcett et al. 2023), with the former representing the brief obscured, transitional phase featured by powerful winds accelerated via radiation pressure on dust (e.g. King & Pounds 2015; Costa et al. 2018). For this reason, X-ray bright (easier to detect) but optically obscured AGN at $z = 1 - 3$ have been deeply investigated for years, as optimal candidates undergoing the blow-out phase (e.g. Brusa et al. 2015, 2016; Cresci et al. 2015, 2023; Perna et al. 2015a,b; Veilleux et al. 2023), hence as the most promising targets to catch AGN feedback and outflows in action.

To draw a coherent picture of AGN feedback at the Cosmic Noon, it is fundamental to conduct systematic and unbiased searches for outflows in statistically large samples. The KMOS AGN Survey at High redshift (KASHz; Harrison et al. 2016) has provided spatially-resolved information for hundreds of X-ray selected AGN, revealing ionised gas velocities likely indicative of outflows in about 50% of the examined sample (Harrison et al. 2016). However, KASHz employed seeing-limited observations with a typical spatial resolution of 4–9 kpc at $z > 1$ (i.e. $>0.5''$), which is not sufficient to trace outflows and their properties in detail. To reach higher spatial resolution, we can exploit more time-consuming AO-assisted observations of smaller samples, yet still representative of the AGN population at $z \sim 2$.

Our completed Large Programme SUPER (Survey for Unveiling the Physics and Effect of Radiative feedback; PI: V. Mainieri, ID: 196.A-0377), carried out with the near-IR spectrograph SINFONI (Eisenhauer et al. 2003) at the Very Large Telescope (VLT) of the European Southern Observatory (ESO), has collected AO-assisted IFS data of a representative sample of X-ray AGN ($L_{2-10 \text{ keV}} \geq 10^{42} \text{ erg s}^{-1}$) at $z \sim 2$, spanning a wide range of bolometric luminosity ($L_{\text{bol}} = 10^{44-48} \text{ erg s}^{-1}$). Presented by Circosta et al. (2018), the SUPER survey offers us the extraordinary possibility of investigating AGN-driven ionised outflows in a few tens of AGN at the Cosmic Noon, selected in an unbiased way with respect to the chance of hosting outflows. Thanks to SINFONI AO system, we reached exquisite angular resolutions of $0.2''-0.5''$, capable of probing spatial scales down to 2–4 kpc at $z \sim 2$.

In such a perspective, this paper continues the series of publications dedicated to SUPER¹, by presenting SINFONI observations of the type-2 AGN subsample. In particular, this work complements the analysis carried out by Kakkad et al. (2020) of the ionised outflows in the SUPER type-1 AGN (see also Vietri et al. 2020), by extending the study of ionised outflows to the SUPER type-2 systems (see also Lamperti et al. 2021). We still employ

[O III] λ 5007 line emission to trace large-scale ionised outflows, and then compare the inferred properties of the type-2 ionised outflows with those of the type-1 counterparts, aiming at uncovering possible differences between these two AGN populations.

This paper is organised as follows. In Sect. 2, we introduce the SUPER type-2 AGN subsample examined in this work, and present our SINFONI observations as well as data reduction strategy. In Sect. 3, we describe the fitting procedure adopted to derive ionised gas properties from SINFONI data. The inferred results on ionised outflows are then presented in Sect. 4, whereas in Sect. 5 they are studied as a function of host galaxy properties and compared with those previously obtained for the SUPER type-1 AGN (Kakkad et al. 2020). Further discussion on our main findings as well as comparison with results from the literature is found in Sect. 6. We finally draw our conclusions in Sect. 7. A Λ CDM flat cosmology with $\Omega_{\text{m},0} = 0.3$, $\Omega_{\Lambda,0} = 0.7$ and $H_0 = 70 \text{ km s}^{-1} \text{ Mpc}^{-1}$ is adopted throughout this work.

2. Sample and data description

The sample presented in this work is part of the SUPER survey (ID: 196.A-0377; PI: V. Mainieri), which acquired near-IR IFS observations of 33² blindly selected X-ray AGN at $z \sim 2$ (see Circosta et al. 2018 for details on sample selection and properties). The total 33-AGN observed sample consists of: 21 type-1 AGN, deeply investigated in Kakkad et al. (2020) and Kakkad et al. (2023); and 12 type-2 AGN, whose SINFONI observations are presented and analysed in this work. All together these three papers investigate ionised outflows with an unprecedented spatial resolution of $\sim \text{kpc}$ in an unbiased sample of AGN at cosmic noon, using [O III] line emission as outflow tracer, and search for links between outflow properties (e.g. velocity, mass rate) and fundamental AGN/host galaxy parameters (e.g. bolometric luminosity, stellar mass, star formation rate). In the following subsections, we first introduce the observed type-2 AGN subsample (Sect. 2.1), then we briefly describe the observations, the data reduction, and the final type-2 AGN sample (i.e. seven objects) analysed in this paper (Sect. 2.2).

2.1. Observed SUPER type-2 AGN subsample

SUPER targeted 12 type-2 AGN in total: six sources are from the *Chandra* Deep Field-South (CDF-S; Luo et al. 2017); whereas the other six are from the COSMOS-Legacy survey (Civano et al. 2016). Before being observed with SINFONI, they were identified as type-2 systems based on the absence of BLR emission in the archival rest-frame UV spectra (Circosta et al. 2018). Their type-2 spectral classification was then confirmed by SINFONI observations, showing no BLR components in rest-frame optical Balmer hydrogen lines ($H\alpha$ and $H\beta$), typically less extinguished than UV emission lines. In Table 1, we list some main properties of the 12 observed type-2 AGN, including spectroscopic redshift z ; bolometric luminosity L_{bol} , stellar mass M_* , and SFR, all derived from Spectral Energy Distribution (SED) fitting (Circosta et al. 2018); 2–10 keV X-ray luminosity $L_{2-10 \text{ keV}}$ and hydrogen column density N_{H} inferred from archival X-ray spectra (Circosta et al. 2018). Redshift values have been obtained from rest-frame optical SINFONI spectra (see Sect. 3.1), except for sources being undetected or marginally detected (five in total) in

² Compared to the original 39-AGN SUPER sample, six objects were not observed eventually. This was a consequence of time lost because of bad weather conditions, since part of the survey was executed in visitor mode rather than in service.

¹ Link to the SUPER webpage <http://www.super-survey.org/>.

Table 1. Main properties of the 12 observed type-2 AGN from SUPER. From left, columns report: sky field and target ID; coordinates of the optical counterpart of the target (J2000); spectroscopic redshift z ; galaxy stellar mass M_* , star formation rate (SFR), AGN bolometric luminosity L_{bol} , all with 1σ uncertainties, derived from SED fitting (Circosta et al. 2018); 2–10 keV X-ray luminosity $L_{2-10 \text{ keV}}$ and hydrogen column density N_{H} with 90% confidence level errors, measured from archival X-ray data (Circosta et al. 2018); whether the object is detected in SINFONI observations, hence included in the final analysed sample (see Sect. 2.2). The redshift of the detected objects is inferred from rest-frame optical SINFONI spectra (Sect. 3.1), whereas for the others from archival rest-frame UV spectra (marked with †).

our SINFONI data (see Sect. 2.2). For these sources, the redshift has been measured from archival rest-frame UV spectra (marked with †). Depending on the quality of [O III] detection in SINFONI H -band spectra, the last column shows what objects are included in the final type-2 AGN sample (i.e. seven objects) analysed in this work (details in Sect. 2.2).

2.2. Observations and data reduction

SUPER targets were observed with SINFONI between November 2015 and December 2018. All observations were planned to be carried out in AO mode using a laser guide star (LGS), covering both H band, targeting $H\beta$ and [O III] $\lambda\lambda 4959, 5007$ emission lines, and K band, targeting $H\alpha$, [N II] $\lambda\lambda 6549, 83$, and [S II] $\lambda\lambda 6716, 31$.

Due to the absence of suitable stars close to the targets, observations of ten out of 12 type-2 AGN were performed in AO-assisted mode with no tip-tilt star (i.e. in Seeing Enhancer mode; Davies et al. 2008), using both H and K gratings ($R \sim 3000$ and $R \sim 4000$, respectively); the remaining two objects were observed with no-AO (cid_1253 with H and K gratings; cid_971 with the HK grating, $R \sim 1500$) in order to optimize the time available during the visitor-mode observing run, reduced because of bad weather conditions. For AO-assisted observations, we adopted a plate scale of $3'' \times 3''$ with a spatial sampling of $0.05'' \times 0.1''$, then re-sampled to $0.05'' \times 0.05''$ in the final datacube. For the two targets observed in seeing-limited mode, we instead selected the largest field of view (FoV; $8'' \times 8''$), corresponding to a pixel scale of $0.25'' \times 0.25''$. Before or after each observing block, a dedicated bright star was observed to estimate the Point Spread Function (PSF) of our AO-assisted SINFONI observations, as full width at half maximum (FWHM) of a 2D-Gaussian fitting to the total flux distribution of the PSF star (θ_{PSF} values in Table 2).

Below we summarise the main steps of the reduction procedure applied to SINFONI type-2 AGN datacubes, whereas we refer the reader to Kakkad et al. (2020) for a detailed description of the SUPER observational strategy. We reduced all observations using the ESOREX pipeline (3.1.1), which returns a distortion-corrected and wavelength-calibrated datacube of the science target, as well as of the PSF and telluric stars. We then removed background sky emission via the IDL routine ‘sky-

sub.pro’ (Davies 2007), and used our own custom-made python routines to perform flux calibration (based on Piqueras López et al. 2012) and to reconstruct the final datacube for each observed target. As a final check, we compared the synthetic photometry measured from SINFONI integrated spectra with both archival photometric measurements (Circosta et al. 2018), and the synthetic photometry from KMOS integrated spectra, when available (Scholtz et al., in prep.). From this comparison, we estimated a typical relative uncertainty on the flux calibration of our SINFONI data of about 20% for all employed bands.

In Table 2, we show the main parameters of SINFONI observations of the 12 SUPER type-2 AGN. For each target, we specify the observing mode (AO/noAO), and list the following parameters for the corresponding adopted grating (H , K , HK): absolute (AB) magnitude measured from SINFONI integrated spectra, total exposure time t_{exp} , spatial resolution θ_{PSF} (i.e. PSF FWHM), and detected emission lines for the seven objects with [O III] detected with a total, spatially integrated $S/N > 2$, that is the crucial tracer of ionised outflows employed in our study. Five of these systems have also $H\alpha + [\text{N II}]$ detected with a $S/N > 2$, whereas $H\alpha$ is totally undetected or marginally detected ($S/N < 2$) in cid_1057 and cid_1143, respectively. Although not suitable for our analysis, we report for completeness that we also marginally detect [O III] and/or $H\alpha$ in XID427 and cid_1253. Finally, the remaining three targets (i.e. XID522, XID57 and cid_971) are totally undetected in SINFONI observations. We point out that these non-detections or poor detections are a consequence of the lower integration time, due to the observing time lost because of bad weather conditions, which particularly penalised SUPER type-2 objects, being these also the faintest sources of the SUPER sample ($L_{\text{bol}} < 10^{46} \text{ erg s}^{-1}$).

In the following, this paper will focus on the seven type-2 AGN with [O III] detected at $S/N > 2$, which allows us to perform a spatially-resolved analysis of [O III] line emission and thus search for ionised outflows signatures. These sources have all a ‘yes’ associated in the last column of Table 1. In particular, three of them are CDF-S sources (XID36, XID419, XID614), whereas four are from COSMOS (cid_1057, cid_1143, cid_2682, cid_451).

Table 2. SINFONI observations of the 12 SUPER type-2 AGN. For each target, we list the observing mode (AO/noAO) and the following parameters for each adopted grating (H , K , HK): absolute (AB) magnitude measured from SINFONI integrated spectra accounting for the corresponding filter transmission curve, total on-source exposure time t_{exp} , spatial resolution θ_{PSF} (computed as PSF FWHM), and detected emission lines for the objects with [O III] detected at $S/N > 2$. For these sources, we indicate marginal detections ($S/N < 2$) of $H\alpha$ with a † symbol. The AB magnitudes marked with ** have required a correction factor (~ 2) to match the previous synthetic measurements (Circosta et al. 2018).

3. Data analysis

In this section, we analyse SINFONI H -band observations of the seven type-2 AGN well detected ($S/N > 2$) in [O III], to spatially map [O III] line emission and its kinematics, looking for evidence of high-velocity outflowing gas (Sect. 3.1). Unfortunately, the quality of K -band data is worse (i.e. lower S/N) for most objects, thus preventing us from an accurate mapping of K -band line emission across the SINFONI FoV. In Sect. 3.2 we use combined integrated measurements of $H\alpha$ and $H\beta$ fluxes from K - and H -band data, respectively, to estimate dust extinction. Being these targets obscured (type-2) AGN, correcting for dust extinction is a crucial step to get reliable estimates of outflow energetics (see Sect. 4.2).

3.1. Spectral fitting

For the spectral fitting of SINFONI H -band datacubes, we adopt the fitting code presented in Marasco et al. (2020) (see also Tozzi et al. 2021 for more details), and fit all cubes in the rest-frame optical wavelength range of 4800–5200Å. Being distant type-2 AGN, their SINFONI spectra show neither BLR emission nor strong (AGN and/or stellar) continuum, but consist of only ‘narrow’ ($\text{FWHM} \lesssim 2000 \text{ km s}^{-1}$) emission lines, either originating from AGN Narrow Line Region (NLR) or due to a different kinematics (i.e. outflow, disk rotation). In addition to [O III] $\lambda\lambda 5007, 4959$ emission line doublet (detected in all seven examined sources), we also detect faint $H\beta$ line emission in four

H -band datacubes (i.e. XID36, XID914, cid_1143, cid_1057; see Figs. 1-3).

As a first step, we apply a spatial Gaussian smoothing of the data channel by channel to enhance the visibility of real gas structures. To do this without deteriorating the instrumental PSF, we smooth each datacube with a Gaussian kernel of width $\sigma_{\text{smooth}} \sim 0.1 - 0.2''$, that is as large as possible, yet still smaller than the instrumental PSF FWHM (i.e. $\sigma_{\text{smooth}} < \theta_{\text{PSF}}/2.35$). After this, we model spaxel-by-spaxel the observed line emission via multiple Gaussian components, following the prescriptions summarised below:

- We fit the [O III] $\lambda\lambda 5007, 4959$ line doublet with two Gaussian components sharing the same kinematics (mean velocity v and velocity dispersion σ), imposing a fixed flux ratio of 3. Hereafter, we refer to the brighter doublet component (i.e. [O III] $\lambda 5007$) simply as [O III].
- When detected, faint $H\beta$ line emission is modelled with v and σ fixed to the best-fit values obtained for [O III], hence with flux as the only free parameter.
- In each spaxel, we reiterate the line modelling using an increasing number of Gaussian components for each emission line, from one to the maximum number which best reproduces complex line profiles in high S/N spaxels. We then select the optimal (minimum) number of Gaussian components required in each spaxel via a Kolmogorov-Smirnov test on the residuals. Five H -band datasets require up to two Gaussian components; cid_1057 up to three components, given the presence of both blue and red [O III] wings detected; in-

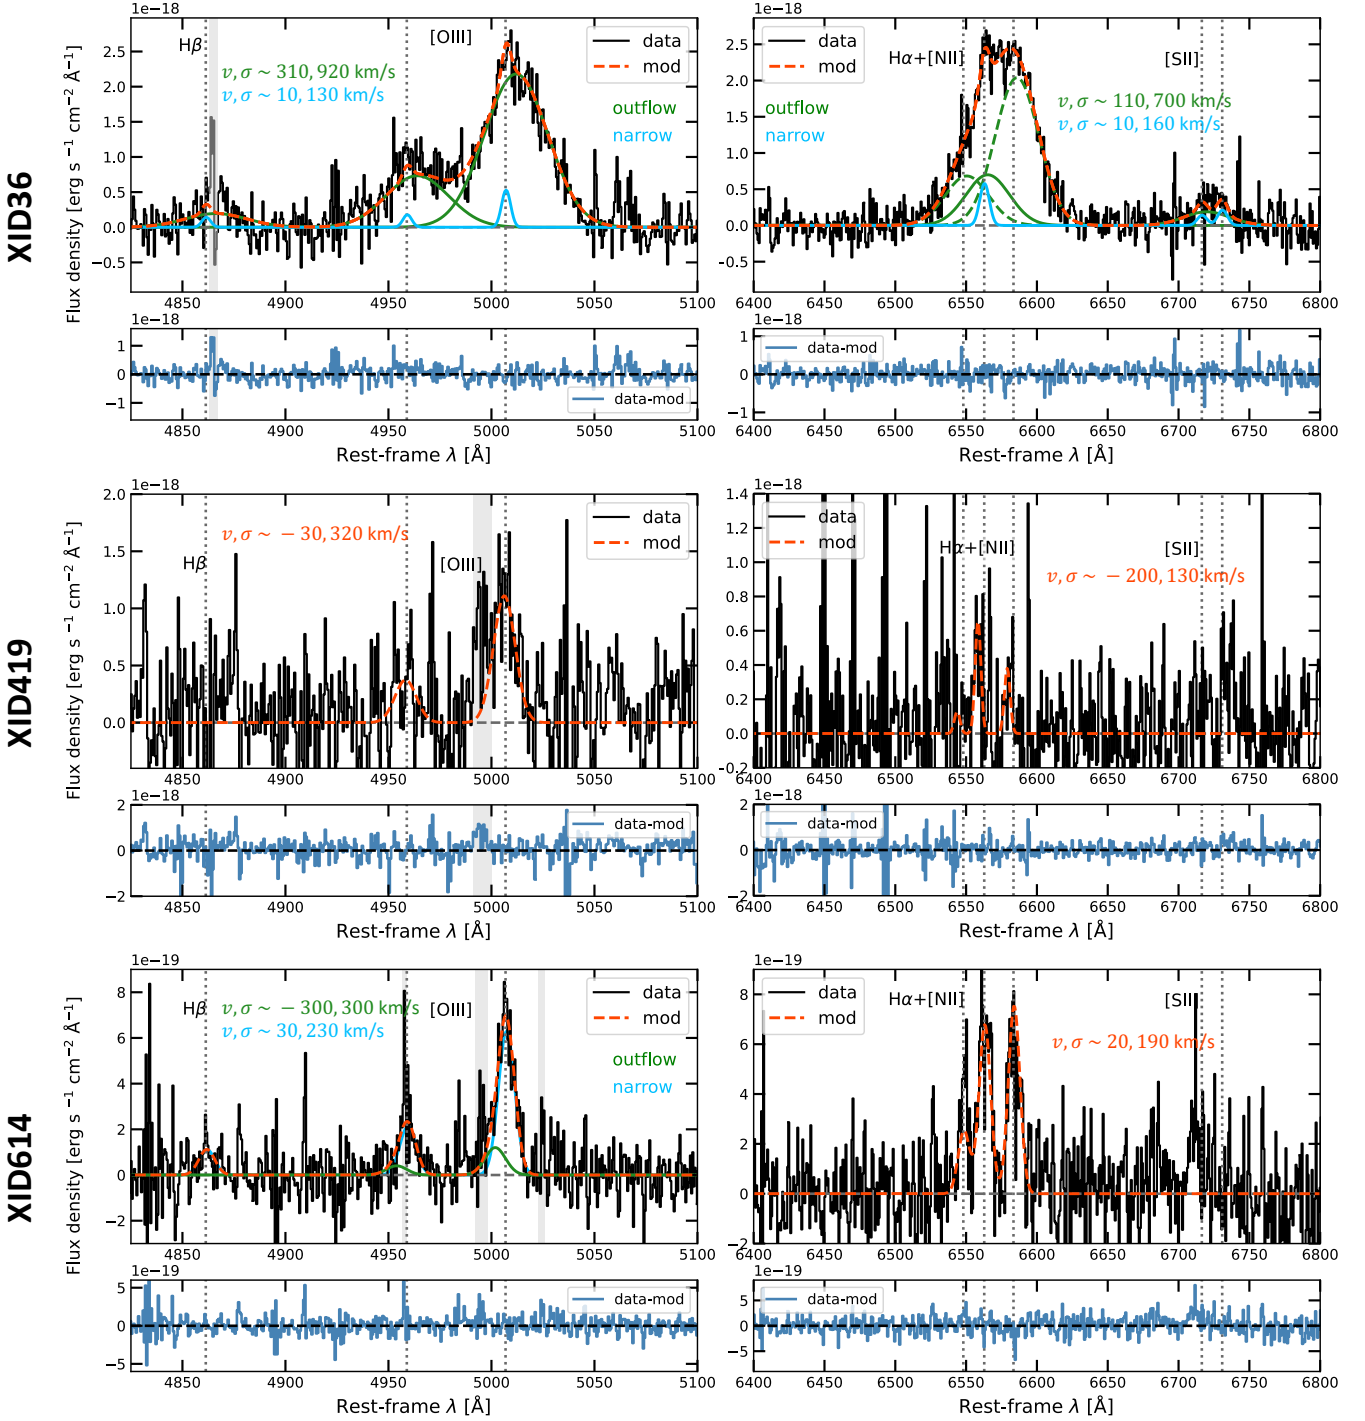

Fig. 1. Integrated H - and K -band spectra extracted from SINFONI datacubes of XID36 (top), XID419 (middle) and XID614 (bottom), with a $0.25''$ -radius aperture, after subtracting continuum emission modelled with a 1st-degree polynomial. Data are shown in black, with total emission-line model drawn on the top in red. For multi-Gaussian modellings, we plot separately narrow, systemic components (light blue) and broad high-velocity ones (green), associated with outflows. In the top right panel, green solid and dashed lines represent the outflow component of H α and [N II] doublet, respectively. Mean velocity v and velocity dispersion σ values of each Gaussian component are displayed. Shaded grey regions indicate masked channels contaminated by sky line residuals, while vertical dotted lines mark rest-frame emission line wavelengths at the redshift of each source, as computed in Sect. 3.1. Below each main panel, a second one shows corresponding residuals (i.e. data–model).

stead, one component is sufficient to model single-spxel line emission in XID419.

- We also add a 1st-degree polynomial to reproduce any faint continuum emission over the entire fitted wavelength range.

Several spectra require multiple Gaussian components to reproduce simultaneously both narrow, low-velocity line emission and broad, high-velocity wings in [O III] line profile. Whereas the latter are considered the typical signature of fast outflowing gas (discussed in Sect. 4.1), narrow, low-velocity line emission

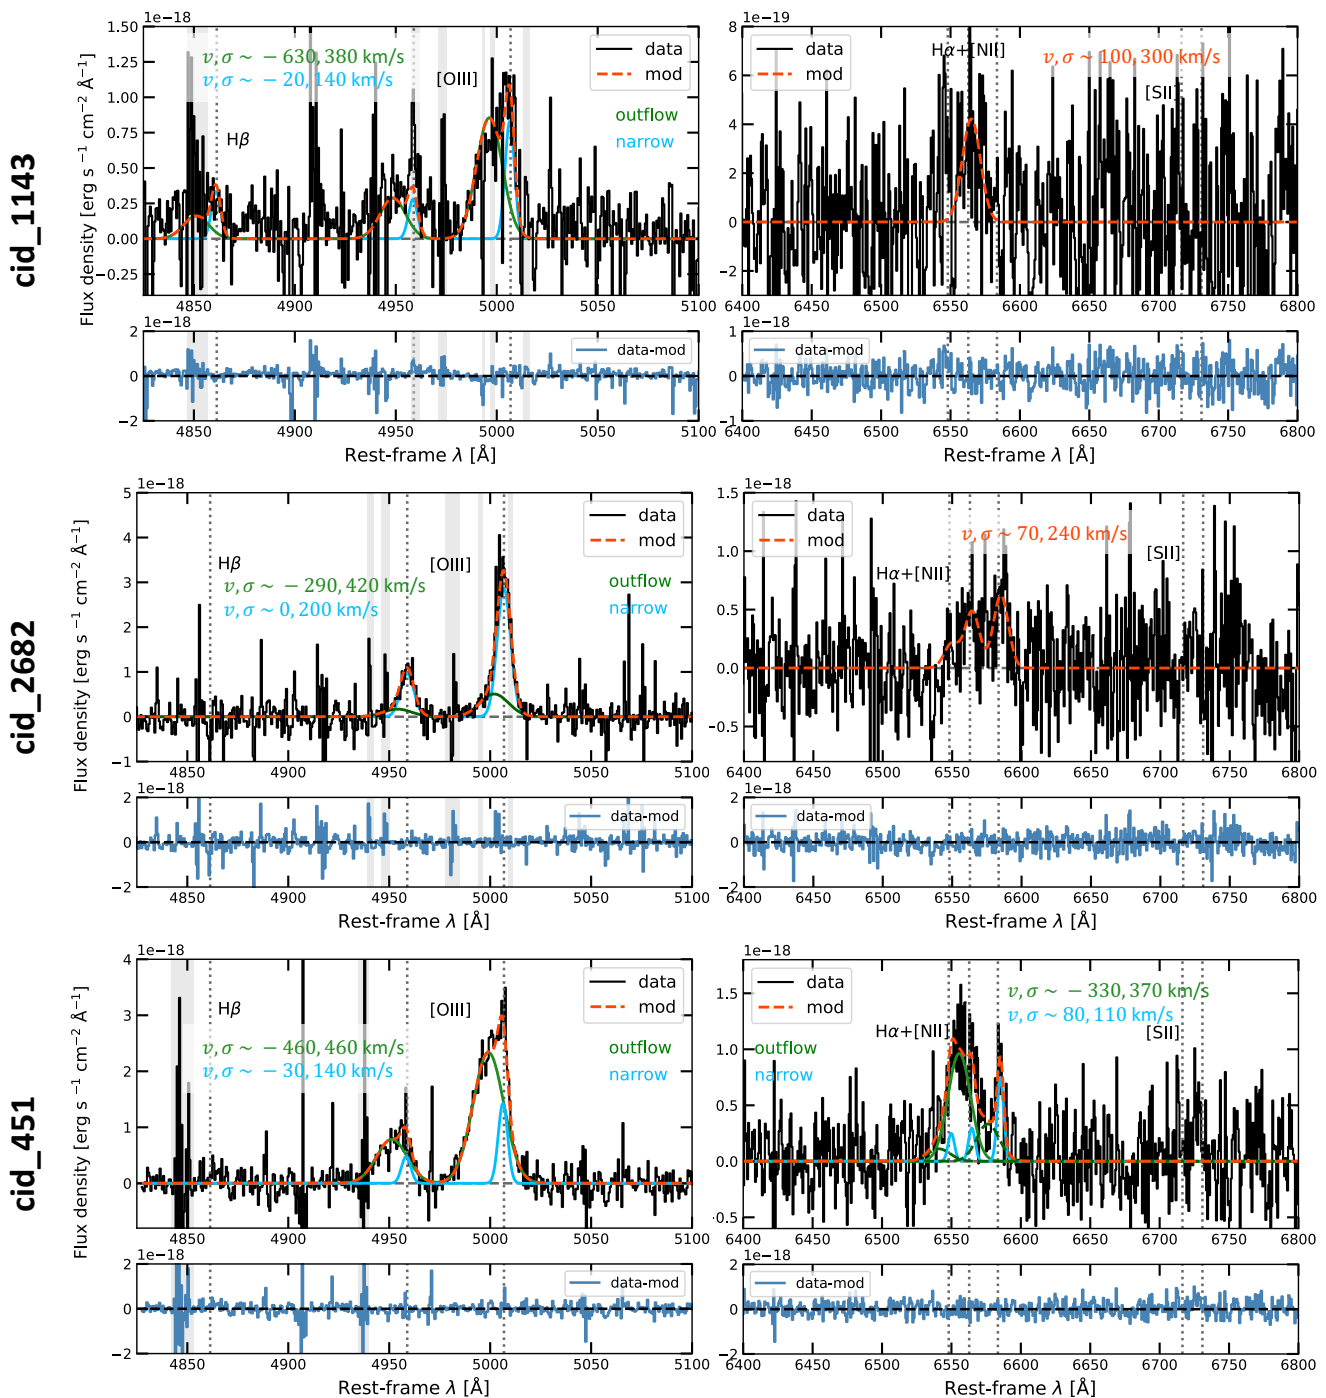

Fig. 2. Integrated H - and K -band spectra extracted from SINFONI datacubes of cid_1143 (top), cid_2682 (middle) and cid_451 (bottom), with a $0.25''$ -radius aperture, after subtracting continuum emission modelled with a 1st-degree polynomial. Same as in Fig. 2. In K -band spectrum of cid_1143, we fit only $H\alpha$ line emission due to the low S/N ($S/N < 2$) of this dataset.

is typically due to nearly systemic gas motions (e.g. NLR, disk rotation). In fact, we use the narrowest [O III] line component to measure the redshift of each source: we extract a H -band integrated spectrum from a small aperture ($0.1''$ -radius) centred on the overall H -band emission peak (corresponding to [O III] emission peak), and set to 0 km s^{-1} the peak of the narrowest [O III] line component. We estimate an uncertainty of $\Delta z = 0.001$ on our [O III]-based measurements of z , due to SINFONI H -band spectral resolution ($R \sim 3000$) and the typical S/N of the line.

3.2. Dust extinction from integrated spectra

Since the targets examined in this work are all type-2 AGN highly obscured in the X-rays ($N_{\text{H}} \gtrsim 10^{23} \text{ cm}^{-2}$; Circosta et al. 2018), rest-frame optical emission is expected to be significantly affected by extinction effects. In particular, in Sect. 4.2 we correct our measurements of [O III] outflow luminosity for dust extinction to estimate intrinsic energetics of ionised outflows. Below, we derive rest-frame optical dust extinction from spatially integrated $H\alpha/H\beta$ ratios for the seven examined type-2 AGN.

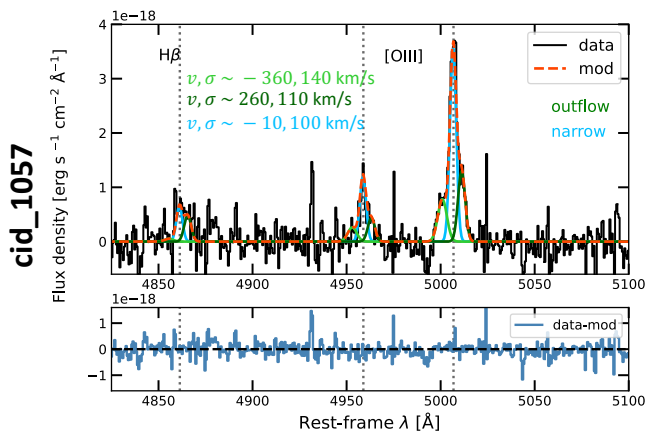

Fig. 3. Integrated H -band spectrum of cid_1057, extracted from SINFONI datacube with a $0.25''$ -radius aperture, after subtracting continuum emission modelled with a 1st-degree polynomial. Same as in Fig. 2. Three Gaussian components are used to properly model [O III] line profile: one for systemic, narrow line emission (light blue), two for the blue and red wings detected in [O III] (different green colours).

To accurately correct for dust extinction, in principle we should: (i) account for spatial variations of $H\alpha/H\beta$ ratios across the FoV using spaxel-by-spaxel measurements; (ii) consider extinction effects exclusively on the outflow component, which may differ from those affecting the bulk of the ionised gas or any other kinematic component (e.g. disk rotation, AGN NLR). Yet, the S/N on $H\alpha$ and $H\beta$ in our SINFONI data is not high enough for such an accurate, spatial mapping of dust extinction. Indeed, their detection is mostly limited to central brighter spaxels, with $H\beta$ undetected in three sources (even in integrated spectra), whereas $H\alpha$ is totally undetected in cid_1057 and marginally ($S/N < 2$) detected in cid_1143. Therefore, we extract integrated K - and H -band spectra of each object to increase the S/N on $H\alpha$ and $H\beta$, so as to estimate (or put constraints on) dust extinction. The only target of the 7-AGN sample for which this is not possible is cid_1057, being totally undetected in $H\alpha$. Therefore, in the following we describe first how we estimate (or constrain) dust extinction from SINFONI integrated spectra in the six objects with $H\alpha$ detected, and then assumptions adopted for cid_1057.

We extract integrated K - and H -band spectra of each target using an aperture of $\sim 0.25''$ -radius centred on the source (Figs. 1, 2, 3), and fit them following the same prescriptions described in Sect. 3.1. In particular, Gaussian profiles fitted to $H\alpha$ and [N II] $\lambda\lambda 6549, 83$ are constrained to have the same velocity and velocity dispersion, with the additional constraint of a fixed flux ratio of 3 on the two [N II] doublet components. In XID36, we model also faint [S II] $\lambda\lambda 6716, 31$ line emission, following the same prescriptions adopted for $H\beta$ in H -band datasets. In most cases, one Gaussian component is enough to reproduce K -band emission lines; XID36 and cid_451 instead require an additional broader component ($\sigma \sim 700$ km s $^{-1}$ in XID36, $\sigma \sim 400$ km s $^{-1}$ in cid_451).

In Figs. 1 and 2, we show H - and K -band spectra extracted with a $0.25''$ -radius aperture from SINFONI datacubes, after subtracting the 1st-degree polynomial used to reproduce any residual faint continuum emission. Data are shown in black, with total emission-line model drawn on the top in red. For multi-Gaussian fittings, we separately plot components used to reproduce narrow, systemic line emission (light blue), and broad high-velocity line emission (green), likely associated with ionised out-

flows. For all spectra, we also display velocity v and velocity dispersion σ values of each Gaussian component, using same colours as for the corresponding Gaussian component. In Fig. 3, we also show an integrated H -band spectrum of cid_1057, extracted with the same $0.25''$ -radius aperture. In this source, the [O III] emission line exhibits an asymmetric profile which is well reproduced by three Gaussian components: one for systemic, narrow line emission (light blue), two for the blue and red [O III] wings (in different green colours). Excluding XID419, the only target requiring a single-Gaussian modelling, we find mean values of $\langle |v| \rangle \sim 380$ km s $^{-1}$ and $\langle \sigma \rangle \sim 440$ km s $^{-1}$ for the broad outflow (green) component, whereas $\langle |v| \rangle \sim 20$ km s $^{-1}$ and $\langle \sigma \rangle \sim 160$ km s $^{-1}$ for the narrow, nearly systemic one.

Since we do not detect broad, high-velocity wings in $H\beta$ line profile, possibly associated with outflows, in any object (in $H\alpha$ only in XID36 and cid_451), we take integrated total $H\alpha/H\beta$ ratios to get an estimate of total dust extinction (Calzetti et al. 2000), and assume it to also affect outflow emission. For XID36, XID614 and cid_1143, with both hydrogen lines detected, we estimate A_V and relative uncertainty via error propagation. For cid_1143, due to the low S/N on $H\alpha$ and $H\beta$, we obtain a value of A_V consistent with 0 (i.e. no extinction) within the uncertainty ($A_V = 1.2 \pm 1.8$). Since A_V must be non-negative, we adopt $A_V = 1.2^{+1.8}_{-1.2}$. In XID419, cid_2682 and cid_451 instead, where we do not detect $H\beta$, we estimate a lower limit to A_V , considering a $2\sigma_{\text{noise}}$ upper limit to $H\beta$ flux. Finally, for cid_1057, the only source totally undetected in $H\alpha$, we consider an A_V value computed as the average of the three A_V measurements obtained for XID36, XID614 and cid_1143, taking the maximum distance of these estimates from the mean as uncertainty (i.e. $A_V = 1.8 \pm 1.0$). We will use these A_V values later in Sect. 4.2 to get the dust-corrected [O III] outflow flux in each source, hence the corresponding outflow mass.

4. Results

4.1. Evidence of spatially resolved outflows

Our spectral modelling of [O III] line emission has clearly revealed prominent wings in the [O III] line profile of four galaxies (i.e. XID36, cid_1143, cid_451, cid_1057; see Figs. 1-3), pointing to the presence of gas moving at high speed with respect to the galaxy systemic velocity. Also in XID614 and cid_2682, the [O III] line profile shows a faint blue wing (see Figs. 1, 2), whereas it is hard to assess at first sight the presence of any possible blue [O III] wing in XID419 (see Fig. 1), due to bright residual sky emission. In this section we inspect kinematic maps of [O III] line emission (Figs. 4-7) to confirm the presence of ionised outflows in higher-S/N detections, and to search for evidence in more ambiguous cases.

In Figs. 4-7, we show maps of [O III] line emission with a $S/N > 3$ cut, displaying the spatial distribution and kinematics of ionised gas in all seven examined type-2 AGN. First-column maps show the [O III] intensity field computed as moment-0 of the total line profile (upper panel); and ratio values (f_{300} ; lower panel) of the flux in high-velocity channels ($|v| > 300$ km s $^{-1}$) to moment-0 flux, a simplified but reasonable approximation of [O III] flux carried by outflows (Kakkad et al. 2020). For the seven examined type-2 AGN, we find that the total (i.e. spatially integrated) flux at $|v| > 300$ km s $^{-1}$ represents a significant fraction of the total moment-0 flux, ranging from 21% (in cid_1057) to 66% (in XID36).

In addition, maps in the second and third columns of Figs. 4-7 display ionised gas kinematics described in terms of non-

Fig. 4. Morphology and kinematics of ionised gas in XID36 and XID419, as traced by total [O III] line emission. For each target, maps show: the intensity (moment-0) field; v_{50} , v_{10} , v_{90} percentile velocities and w_{80} line width; and the ratio f_{300} of the flux contained in [O III] wings (i.e. $|v| > 300$ km s⁻¹) to the moment-0 flux. Dashed and dotted circles correspond, respectively, to the 0.25''-radius aperture used to extract integrated spectra (Sect. 3.2), and to the mean H -band PSF of radius $\langle \theta_{\text{PSF}} \rangle / 2$ (see Table 2). In XID419 the two circles have the same 0.25'' radius. In all maps, we apply a $S/N > 3$ cut and mark the position of [O III] peak emission with a cross.

parametric percentile velocities³. Compared to parametric values, percentile velocities have the advantage of being independent on the adopted fitting function (e.g. the number of Gaussian components), which in turn may strongly depend on the S/N of the examined data (e.g. Harrison et al. 2014; Zakamska & Greene 2014). In particular, we compute v_{50} , v_{10} , v_{90} velocities, and the w_{80} line width (i.e. $w_{80} = v_{90} - v_{10}$), approximately equal to the FWHM of a Gaussian profile. Extreme v_{10} and v_{90} values are widely adopted as a reliable approximation of outflow veloc-

ity, for its approaching and receding components (e.g. Harrison et al. 2014; Carniani et al. 2015; Cresci et al. 2015), respectively. Compared to moment-1 and moment-2 values (i.e. mean velocity and velocity dispersion, respectively), which may be affected by significant geometrical projection effects, v_{10} and v_{90} help avoid possible underestimates of the real outflow velocity, due to our ignorance about intrinsic outflow geometry and inclination to the line of sight. Maps of v_{10} and v_{90} overall feature high velocities, with absolute values up to 800–1100 km s⁻¹ in four targets (XID36, XID419, cid_1143, cid_451), and to 600–700 km s⁻¹ in the remaining three (XID614, cid_1057, cid_2682). These large velocities are accompanied by w_{80} line widths larger than 800

³ Percentile velocities v_{xx} used in the following are defined as the velocity containing xx% of the total [O III] line flux.

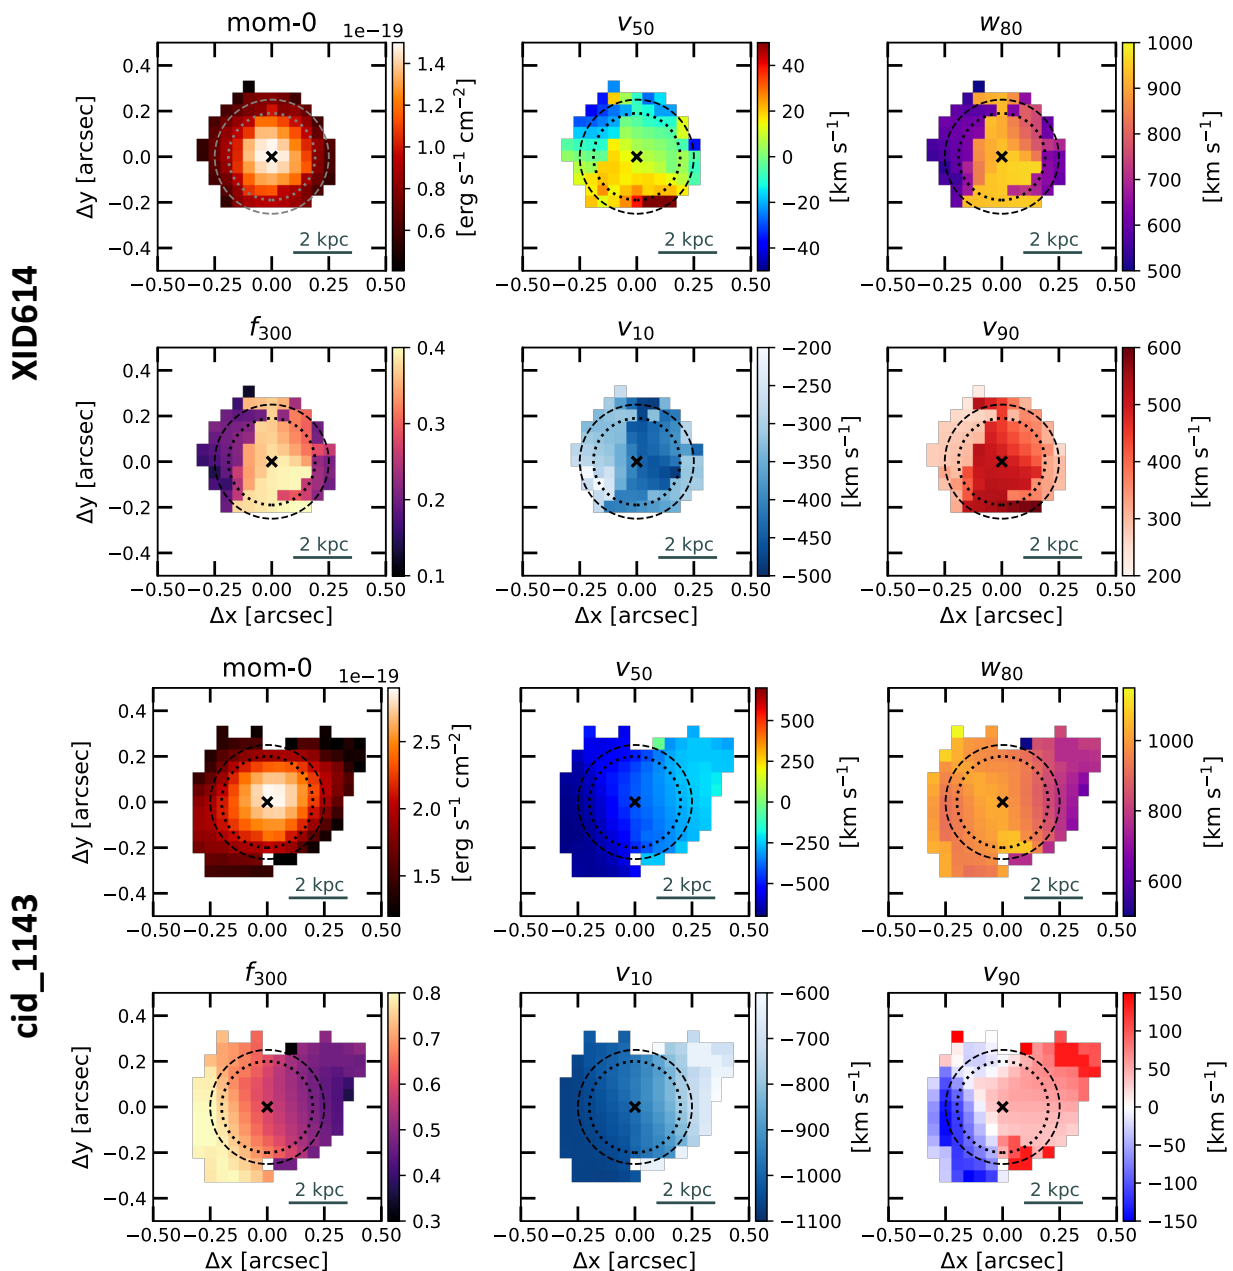

Fig. 5. Morphology and kinematics of ionised gas in XID614 and cid_1143, as traced by total [O III] line emission. Same as in Fig. 4.

km s^{-1} in most of the FoV of all targets, with maximum values of at least 1000 km s^{-1} (about 1700 km s^{-1} in XID36 and 1200 km s^{-1} in cid_451).

Ionised outflows are the most likely explanation to the high-velocity kinematics observed in all targets, since alternative phenomena can hardly lead to such high values of velocity and line width. In fact, SF-driven outflows are typically characterised by lower velocities (e.g. Arribas et al. 2014; Förster Schreiber et al. 2019); whereas galactic inflows are mostly observed in absorption with low bulk velocities and σ values (e.g. Bouché et al. 2013). Large line widths might also be due to turbulence in the interstellar medium induced by the interaction of nuclear activity with the host environment, as observed in low-redshift type-2 active galaxies (e.g. Woo et al. 2016; Fischer et al. 2018; Venturi et al. 2021; Girdhar et al. 2022). Yet, such turbulence-induced effects are often associated with relatively low centroid veloci-

ties (i.e. $|v| < 200 - 300 \text{ km s}^{-1}$), typical of gas at systemic or following rotation (Woo et al. 2016; Fischer et al. 2018). This does not seem to be the case of the broad components reproducing [O III] line wings in SUPER type-2 systems, which exhibit centroid velocities $|v| \gtrsim 300 \text{ km s}^{-1}$ (see green v values shown in Figs. 1–3), unlikely associated with galaxy rotation. Moreover, we point out that turbulence-induced effects have been traced so far in observations of local Seyfert galaxies at high spatial resolution and sensitivity (see e.g. Fischer et al. 2018; Venturi et al. 2021; Girdhar et al. 2022). As a consequence, it might be hard to detect them in lower-quality observations at $z \sim 2$ like SUPER, with a spatial resolution of 2–4 kpc.

Similarly, the observed large [O III] line widths and prominent asymmetries (mostly blueshifted wings) can be hardly accounted for by merging scenarios. This is also supported by the lack of clear [O III] double peaks and by the relatively unper-

Fig. 6. Morphology and kinematics of ionised gas in cid_2682 and cid_451, as traced by total [O III] line emission. Same as in Fig. 4.

turbed morphology of stellar continuum emission, as traced by rest-frame $260 \mu\text{m}$ FIR continuum emission (when available for SUPER targets, see Lamperti et al. 2021). Although harder to detect than line emission due to gas, stellar continuum can better unveil the presence of a second merging galaxy. The only SUPER galaxy showing some degree of perturbed morphology is cid_1143, which exhibits an offset of about 2 kpc between the centroids of rest-frame optical line emission (i.e. $H\alpha$ and [O III]) and rest-frame $260 \mu\text{m}$ FIR continuum, respectively (Lamperti et al. 2021). This may indicate the presence of a companion for this galaxy but, even if it did, given the offset of the possible companion from FIR continuum, this is not expected to contribute to the flux in the galaxy center, where we observe v_{10} velocities of about 1000 km s^{-1} . For the other sources we can instead likely rule out early mergers based on the observational evidence available so far, although the S/N of our SINFONI ob-

servations might not be sufficient to detect faint merger signatures and to identify especially final-state mergers.

On the other side, v_{50} velocities are useful to describe the velocity field of the component dominating the overall kinematics of ionised gas. In all galaxies, we find moderate v_{50} values ($|v_{50}| < 400 \text{ km s}^{-1}$; even $|v_{50}| < 100 \text{ km s}^{-1}$ in XID614 and cid_2682), with a predominance of blueshifted v_{50} values. This means that a significant fraction of [O III] line emission is found in the blue line wing, further supporting the presence of fast ionised outflows in these galaxies. In XID36 instead, v_{50} velocities appear redshifted almost everywhere (reaching 400 km s^{-1}), as a consequence of the extended [O III] red wing, which dominates the overall [O III] kinematics in this object (see Fig. 1). In a few galaxies, we also detect a smooth velocity gradient of v_{50} : in cid_1143 it is outflow-dominated, with all blueshifted v_{50} velocities of increasing absolute value from NW to SE (N is up,

Fig. 7. Morphology and kinematics of ionised gas in cid_1057, as traced by total [O III] line emission. Same as in Fig. 4.

E to left); in contrast, in XID419 and XID614 outflow emission does not seem to be the dominant component, being the v_{50} field consistent with disk rotation, with velocities ranging from negative to positive values passing through the galaxy centre. The presence of outflows in these two galaxies is better highlighted by the high values of v_{10} and v_{90} , as previously discussed.

In all maps of Figs. 4-7, we draw two circles corresponding: to the aperture used in Sect. 3.2 to extract integrated SINFONI spectra (dashed); and to the mean H -band PSF (dotted), namely, with a radius equal to $\langle \theta_{\text{PSF}} \rangle / 2$ (see Table 2). In XID419 (Fig. 4) the two circles have the same radius. Compared to the corresponding H -band PSF, we see that the extent of $S/N > 3$ [O III] line emission at $|v| > 300 \text{ km s}^{-1}$ is clearly larger than the instrumental PSF radius in all galaxies except for XID614. This ensures that the high-velocity [O III] emission associated with the outflows is spatially resolved in at least six objects of our sample. In XID614, $S/N > 3$ [O III] maps and H -band PSF have approximately the same extent in all directions (see Fig. 5). However, the fact that we see structures and variations in gas kinematics across the FoV of XID614 suggests that high-velocity [O III] line emission at large distance is at least marginally spatially resolved in our data.

4.2. Ionised outflow properties and energetics

Since $H\beta$ is detected at low S/N in our H -band observations, due to extinction effects, we derive ionised outflow properties from higher- S/N [O III] line emission⁴. Properties such as outflow velocity v_{out} , radial extent R_{out} , and [O III] luminosity $L_{\text{out}}^{[\text{OIII}]}$ can be directly measured from SINFONI data, while other physical quantities (i.e. electron density n_e , oxygen abundance [O/H]) must be assumed in the calculation of outflow mass rate \dot{M}_{out} .

⁴ Using [O III] line emission requires more assumptions than $H\alpha$ or $H\beta$, but the latter are overall detected at a lower S/N compared to [O III], thus motivating our choice.

4.2.1. Directly measured outflow properties

The outflow properties we can measure directly are v_{out} , R_{out} and $L_{\text{out}}^{[\text{OIII}]}$. As outflow velocity v_{out} , we consider for each target the maximum absolute value of all observed v_{10} or v_{90} velocities (i.e. $v_{\text{out}} = \max[|v_{10}|, |v_{90}|]$). This definition is widely adopted in the literature (e.g. Cresci et al. 2015; Carniani et al. 2015; Tozzi et al. 2021; Vayner et al. 2021a,b) and relies on the assumption that all observed lower velocities are consequence of projection effects. Other works instead use w_{80} as outflow velocity (e.g. Harrison et al. 2012; Kakkad et al. 2016, 2020), being w_{80} less affected by projection effects compared to v_{10} and v_{90} . Yet, we point out that w_{80} values depend more strongly on line shapes, systematically leading to higher velocities for symmetric line profiles than asymmetric ones, where only one wing is detected as a possible consequence of dust extinction. Dust effects indeed seem to be the most likely explanation for the (blueshifted) asymmetric [O III] profiles found in most of our type-2 AGN, which could be hardly accounted for by standard unified models (e.g. Antonucci 1993; Urry & Padovani 1995; further discussions are presented in Sect. 6).

For this reason, we here adopt $v_{\text{out}} = \max[|v_{10}|, |v_{90}|]$ to define the outflow velocity, unlike the previous w_{80} -based approach adopted in Kakkad et al. (2020) for the SUPER type-1 sample. However, as pointed out in Sect. 4.1, all type-2 AGN show $w_{80} > 800 \text{ km s}^{-1}$ in most of the FoV, thus meeting the $w_{80} > 600 \text{ km s}^{-1}$ criterion used in Kakkad et al. (2020) to identify [O III] outflow emission (e.g. see also Harrison et al. 2016).

Overall, we find wind velocities within the range $v_{\text{out}} \sim 600 - 1100 \text{ km s}^{-1}$, with a mean outflow velocity $\langle v_{\text{out}} \rangle \sim 830 \text{ km s}^{-1}$. For comparison, we also compute for each object the outflow velocity defined as $v_{\text{max}} = v_{\text{bro}} + 2\sigma_{\text{bro}}$ (Rupke & Veilleux 2013), where v_{bro} and σ_{bro} are the velocity and velocity dispersion, respectively, of the broad Gaussian components associated with outflows. This parametric definition of outflow velocity typically delivers values slightly larger compared to the v_{out} definition based on $v_{10,90}$ but, being adopted in several works (e.g. Brusa et al. 2015; Fiore et al. 2017; Leung et al. 2019; Perrotta

et al. 2019; Kakkad et al. 2020), it is a useful quantity to compute for comparing our results with other from the literature (see Sect. 6). For XID419, we estimate v_{\max} as twice the σ value of the single Gaussian employed, as done in Kakkad et al. (2020). The v_{out} values inferred for each galaxy are listed in Table 3, along with maximum observed values of v_{\max} and w_{80} (as well as other outflow properties inferred in the following).

To estimate R_{out} instead, we first infer the observed (maximum) outflow radius R_{obs} , measured as the maximum extent from the centre of [O III] line emission at $|\nu| > 300 \text{ km s}^{-1}$. We then correct R_{obs} for the H -band PSF (i.e. $R_{\text{out}} = \sqrt{R_{\text{obs}}^2 - (\langle\theta_{\text{PSF}}\rangle/2)^2}$, with $\langle\theta_{\text{PSF}}\rangle$ being the average PSF FWHM, see Table 2), thus obtaining intrinsic radii of a few kpc for spatially resolved outflows ($R_{\text{out}} \sim 2\text{--}4 \text{ kpc}$). For XID614, where the ionised outflow is marginally resolved, we consider the resulting value as an upper limit to R_{out} (i.e. $R_{\text{out}} < 1.9 \text{ kpc}$). All R_{out} estimates and upper limits are listed in Table 3.

For a measurement of the [O III] flux associated with ionised winds, we follow the same prescriptions adopted by Kakkad et al. (2020) for the SUPER type-1 AGN. We hence consider the total [O III] flux contained in the high-velocity line channels (i.e. $|\nu| > 300 \text{ km s}^{-1}$), by summing up the flux contributions of all spaxels with $S/N > 3$ on [O III]. Considering the quality of our data, a non-parametric approach is more suitable than a parametric one based on the results from the multi-Gaussian modelling, where the detection of a broad ‘outflow’ component depends on the S/N of the data. In XID419 indeed, due to the low S/N, the [O III] line profile is sufficiently well reproduced by a single Gaussian component across the FoV, with no need for an additional component. Yet, the f_{300} ratio map shown in Fig. 4 unveils a non-negligible fraction (varying within 0.3–0.5) of [O III] flux in $|\nu| > 300 \text{ km s}^{-1}$ line channels, overall suggesting that high-velocity gas is outflowing in this galaxy as well (as discussed in Sect. 4.1). However, we point out that by summing spaxel-by-spaxel the flux of broad Gaussian components (for the six objects requiring a multi-Gaussian modelling of [O III]) we obtain [O III] outflow fluxes close to our non-parametric estimates, differing on average by a factor of about 2 (same found in Kakkad et al. 2020 for type-1 AGN).

Finally, we correct all inferred (non-parametric) [O III] outflow fluxes for dust extinction using the A_V values inferred in Sect. 3.2 (see Table 3), and convert them to intrinsic [O III] outflow luminosities $L_{\text{out}}^{\text{[OIII]}}$. All resulting dust-corrected $L_{\text{out}}^{\text{[OIII]}}$ values are also reported in Table 3.

4.2.2. Ionised outflow mass rate

The three quantities directly measured in the previous subsection - namely, v_{out} , R_{out} and $L_{\text{out}}^{\text{[OIII]}}$ - are fundamental ingredients to compute the mass rate of ionised outflows. Following the prescriptions adopted by Kakkad et al. (2020) for the SUPER type-1 AGN sample, we calculate ionised outflow masses M_{out} as follows (for an electron temperature of $T \sim 10^4 \text{ K}$; e.g. Carniani et al. 2015; Kakkad et al. 2016):

$$M_{\text{out}} = 0.8 \times 10^8 \left(\frac{L_{\text{out}}^{\text{[OIII]}}}{10^{44} \text{ erg s}^{-1}} \right) \left(\frac{n_e}{500 \text{ cm}^{-3}} \right)^{-1} \frac{M_{\odot}}{10^{[\text{O}/\text{H}]}} \quad (1)$$

where all oxygen is assumed to be ionised to O^{2+} , n_e and [O/H] are electron density and oxygen abundance in solar units, respectively. For a uniformly filled (i.e. constant n_e) outflow of

bi-conical geometry, the mass rate \dot{M}_{out} at a certain radius R_{out} can be then calculated as (Fiore et al. 2017):

$$\dot{M}_{\text{out}} = 3 \frac{M_{\text{out}} v_{\text{out}}}{R_{\text{out}}}, \quad (2)$$

which gives the instantaneous mass rate of ionised gas crossing a spherical sector at a distance R_{out} from the central AGN.

Equation 1 requires values of [O/H] and n_e , but none of them can be measured from our data. In principle, n_e can be inferred from $[\text{S II}]_{\lambda 6716}/[\text{S II}]_{\lambda 6731}$ flux ratio (e.g. Osterbrock & Ferland 2006), but [S II] is undetected in our SINFONI K -band data, except for some faint [S II] emission in XID36 (see Fig. 1). Therefore, we assume a solar [O/H] abundance and $n_e = 500 \pm 250 \text{ cm}^{-3}$ (i.e. 50% uncertainty) in agreement with previous studies (e.g. Storchi-Bergmann et al. 2010; Carniani et al. 2015; Riffel et al. 2015; Davies et al. 2020; Cresci et al. 2023) and consistently with prescriptions adopted in Kakkad et al. (2020) for SUPER type-1 AGN.

In Table 3, we summarise the properties of the ionised outflows in the seven SUPER type-2 AGN, with corresponding uncertainties. We also list the escape velocity v_{esc} from the total galaxy gravitational potential, computed at R_{out} (see Sect. 5.2) and the A_V estimates (or lower limits, derived in Sect. 3.2) used to obtain the corresponding dust-corrected $L_{\text{out}}^{\text{[OIII]}}$ measurements (or lower limits). Errors v_{out} , w_{80} and v_{\max} are the uncertainties resulting from the kinematic analysis, while those on A_V , $L_{\text{out}}^{\text{[OIII]}}$ and \dot{M}_{out} are computed via error propagation. Due to the asymmetric uncertainty on A_V for cid_1143, errors on the $L_{\text{out}}^{\text{[OIII]}}$ and \dot{M}_{out} for this object correspond to the minimum-maximum range of possible values, determined by the minimum/maximum values of the physical quantities they depend on. Despite being not obvious how to estimate an uncertainty on R_{out} , we do not expect errors smaller than the SINFONI spatial pixel (i.e. $0.05''$), which corresponds to about 0.4 kpc at $z \sim 2$. Nevertheless, the uncertainty on \dot{M}_{out} is dominated by the large errors on A_V (larger than 50%) and n_e (assumed equal to 50%). Finally, we notice that the inferred upper limit to R_{out} in XID614 leads to a corresponding lower limit to \dot{M}_{out} (i.e. $\dot{M}_{\text{out}} > 1.7 M_{\odot} \text{ yr}^{-1}$).

Before SUPER, the galaxy cid_415 was observed with SINFONI in AO-mode, but with the largest $0.250''$ pixel-scale and the lower spectral-resolution HK filter ($R \sim 1500$). We notice that our inferred values of R_{out} and v_{out} ($R_{\text{out}} \sim 2.6 \text{ kpc}$ and $v_{\text{out}} \sim 950 \text{ km s}^{-1}$) are both smaller than those previously found ($R_{\text{out}} \sim 5 \text{ kpc}$ and $v_{\text{out}} \sim 1600 \text{ km s}^{-1}$; Perna et al. 2015b), based on these first SINFONI dataset. The smaller value of R_{out} is likely consequence of a surface brightness loss in our SINFONI data, due to the smaller pixel ($0.100''$) adopted in SUPER. Instead, the discrepancy in v_{out} is due to a more extreme definition of outflow velocity adopted in Perna et al. (2015b) (i.e. v_{05}), combined also with slightly different inferred redshifts ($z = 2.444$ in this work against $z = 2.45$ in Perna et al. (2015b)), which leads to a systematic difference of about $\sim 520 \text{ km s}^{-1}$ in the adopted systemic galaxy velocity (with respect to which all velocities are computed). After accounting for these discrepancies, the two v_{out} values are consistent.

5. Comparison with SUPER type-1 AGN

In addition to presenting results on ionised outflows in SUPER type-2 AGN, this paper investigates ionised wind properties as

Table 3. Main properties of ionised outflows in the seven SUPER type-2 AGN examined in this work. From left, columns list for each galaxy: (1) V -band extinction A_V (inferred in Sect. 3.2); (2) outflow radius R_{out} ; (3) outflow velocity $v_{\text{out}} = \max[|v_{10}|, |v_{90}|]$; (4) dust-corrected [O III] outflow luminosity $L_{\text{out}}^{\text{[OIII]}}$, inferred from $|v| > 300 \text{ km s}^{-1}$ line channels; (5) outflow mass rate \dot{M}_{out} ; (6) escape velocity v_{esc} of the total galaxy system, computed at R_{out} (see Sect. 5.2); maximum observed values of (7) w_{80} and (8) $v_{\text{max}} = v_{\text{bro}} + 2\sigma_{\text{bro}}$ (Rupke & Veilleux 2013).

Target ID	A_V	R_{out} kpc	v_{out} km s $^{-1}$	$L_{\text{out}}^{\text{[OIII]}}$ 10 42 erg s $^{-1}$	\dot{M}_{out} M $_{\odot}$ yr $^{-1}$	v_{esc} km s $^{-1}$	w_{80} km s $^{-1}$	v_{max} km s $^{-1}$

a function of AGN properties (i.e. AGN bolometric luminosity L_{bol} , hydrogen column density N_{H}) and host galaxy parameters (i.e. stellar mass M_* , star formation rate, escape velocity v_{esc}) for the full SUPER sample, aiming at unveiling any difference between type-1 and type-2 systems which possibly sheds light on the intrinsic nature of these two AGN classes. Except for v_{esc} (see Sect. 5.2) and N_{H} (measured from archival X-ray spectra, Circosta et al. 2018), all other AGN/host galaxy properties were derived by Circosta et al. (2018) using the SED fitting code CIGALE (Code Investigating GALaxy Emission; Noll et al. 2009), and are overall confirmed by the latest updates presented in Bertola et al. (2024). Values of M_* , star formation rate (SFR), L_{bol} and N_{H} for the SUPER type-2 AGN are found listed in Table 1 (see Kakkad et al. 2020 for the type-1 AGN).

5.1. Faster outflows in type-2 AGN at the low-luminosity end

The key result of this work is shown by the three panels of Fig. 8, which overall display outflow velocity as a function of AGN bolometric luminosity L_{bol} for the full SUPER sample, divided into type-2 (coloured thick crosses) and type-1 (grey squares) AGN. In particular, in the left and middle panels $v_{\text{out}} = \max[|v_{10}|, |v_{90}|]$ and $v_{\text{max}} = v_{\text{bro}} + 2\sigma_{\text{bro}}$ are displayed along the y-axis, respectively, with the type-1 AGN measurements taken consistently from Kakkad et al. (2020). In addition to showing the well-known trend of larger outflow velocity at increasing AGN luminosity (e.g. Bae & Woo 2014; Woo et al. 2016; Perna et al. 2017; Rakshit & Woo 2018; discussed in Sect. 6), both panels unveil consistently the same following result in the lower L_{bol} regime (i.e. $L_{\text{bol}} \sim 10^{44.8-46.5}$ erg s $^{-1}$; orange shading), where all SUPER type-2 AGN are found. Interestingly, the SUPER type-2 AGN host overall faster ionised outflows than their type-1 counterparts within the same L_{bol} range, and appear to depart from the global $v_{\text{out,max}} - L_{\text{bol}}$ increasing trend followed by the SUPER type-1 AGN. Not surprisingly, the v_{max} value of XID419 is the lowest of the type-2 sample, since v_{max} for this target is computed as 2σ (see Sect. 4.2.1), with σ referring to the single Gaussian component employed.

To better appreciate the deviation of the type-2 velocity measurements from the type-1 ones, we fit a linear relation to the type-1 distribution in both $v_{\text{out}} - L_{\text{bol}}$ and $v_{\text{max}} - L_{\text{bol}}$ planes (blue dashed-dotted line), from which type-2 velocities deviate increasingly at lower luminosities by up to about 0.8dex in both panels, and with a mean deviation of 0.4 dex. In the middle panel, we also draw for comparison the empirical $v_{\text{max}} - L_{\text{bol}}$ relation inferred in Fiore et al. (2017) (black dotted line), and an updated version by Musiimenta et al. (2023) (black dashed line),

including recent results and considering $z > 0.5$ AGN only. The type-1 population appears to overall follow the empirical relation by Musiimenta et al. (2023), as opposed to the type-2 measurements. We point out that the small number (i.e. seven) of type-2 measurements prevents us from an accurate linear fit to the type-2 distribution of measurements.

In Appendix A we show additional plots where we compare other outflow properties and AGN/host galaxy parameters, none of which pointing to either a clear trend or interesting discrepancy between the type-1 and type-2 populations in SUPER. In particular, the left and right panels of Fig. A.1 display v_{out} plotted against M_* and SFR, respectively; whereas in Fig. A.2 we searched for trends of outflow mass rate with L_{bol} . Although the $v_{\text{out}} - L_{\text{bol}}$ plane reveals a clear type-1/type-2 dichotomy, it is hard to establish whether a separation between the two AGN populations is also present in terms of outflows mass rate, due to the large uncertainty on this quantity. In fact, mass rate estimates strongly depend on the accuracy of other measured parameters (e.g. A_V , R_{out}), and also require several quantities to be assumed (e.g. n_e , [O/H], ionisation). All this uncertainty inevitably increases the scatter in the resulting mass rate values, thus possibly hiding the type-1/type-2 dichotomy instead visible in terms of the more directly inferred outflow velocities.

We investigate the potential effect of different nuclear obscuring conditions on driving outflows in the right panel of Fig. 8, aiming at shedding light on the nature of our unveiled type-1/type-2 dichotomy. To remove any dependence of v_{out} on AGN luminosity (discussed in Sect. 6), we normalise v_{out} to L_{bol} (in units of 10^{45} erg s $^{-1}$), and plot the resulting $v_{\text{out}}/L_{\text{bol}}$ ratios against the hydrogen column density N_{H} , measured from X-ray data in Circosta et al. 2018 for the full SUPER sample. Light-orange markers identify type-1 AGN lying in the low- L_{bol} regime (i.e. $L_{\text{bol}} \sim 10^{44.8-46.5}$ erg s $^{-1}$, orange shading in the left and middle panels), whereas high- L_{bol} type-1 objects are plotted as grey markers. Upper/lower limits to N_{H} are finally shown as triangles. In the right panel, we can clearly see that SUPER type-1 and type-2 AGN occupy two distinct regions of the $(v_{\text{out}}/L_{\text{bol}}) - N_{\text{H}}$ plane. The distribution of SUPER measurements along the x-axis shows their X-ray obscured/unobscured classification (see Circosta et al. 2018). All SUPER type-2 AGN lie in the X-ray highly-obscured regime ($N_{\text{H}} \gtrsim 10^{23}$ cm $^{-2}$), whereas most of the type-1 population exhibits unobscured conditions ($N_{\text{H}} \lesssim 10^{22}$ cm $^{-2}$), with some system lying in the intermediate-obscuration region ($N_{\text{H}} \sim 10^{22} - 10^{23}$ cm $^{-2}$). The combined resulting separation along the y-axis is more interesting and unexpected: the SUPER type-2 sample indeed features $v_{\text{out}}/L_{\text{bol}}$ values varying within $\sim 30-1500$ (with only cid_451 smaller than 80), with a

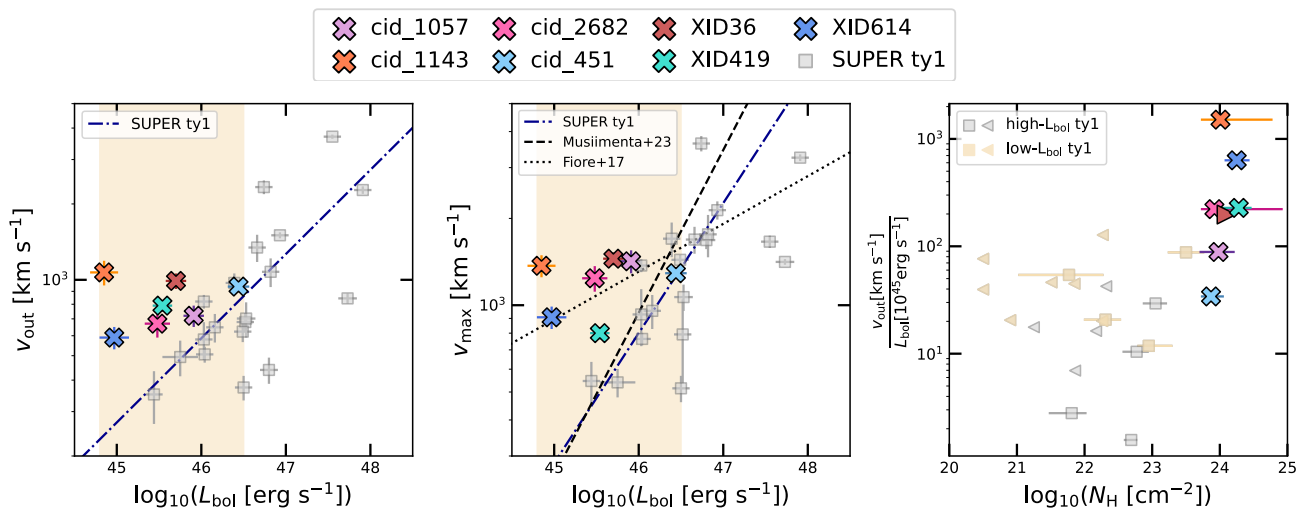

Fig. 8. Outflow velocities v_{out} and v_{max} (left and middle panels) as a function of L_{bol} , and $v_{\text{out}}/L_{\text{bol}}$ ratios versus X-ray N_{H} measurements (right panel). Coloured crosses and grey squares represent SUPER type-2 and type-1 AGN; triangles in the right panel indicate upper/lower limits to N_{H} . Blue dashed-dotted lines represent our best-fit linear relation to the type-1 measurements, from which type-2 points depart increasingly at decreasing L_{bol} (mean deviation of 0.4dex). In the middle panel, we draw for comparison the empirical relation by Fiore et al. (2017) (dotted line), along with a more recent version from Musiimenta et al. (2023) (dashed). The orange shading in the left and middle panels marks the low- L_{bol} range (i.e. $L_{\text{bol}} = 10^{44.8-46.5}$ erg s⁻¹), where we compare type-1 and type-2 AGN measurements. In the right-hand panel we consistently use light-orange markers to identify type-1 AGN lying in the low- L_{bol} regime. All panels overall point to faster winds in type-2 obscured AGN than in type-1 systems at lower L_{bol} , as a consequence of a more efficient acceleration of outflows in dusty, obscured environments.

mean value of ~ 400 , while almost all type-1 AGN have ratios smaller than 50, with an overall mean value of ~ 40 . This points to the picture where AGN-driven outflows are accelerated more efficiently in more obscured environments (further discussion in Sect. 6).

To further check and quantify the observed discrepancy in outflow velocity between SUPER type-1 and type-2 AGN, we directly compare the ‘mean’ [O III] line profiles of SUPER type-1 and type-2 AGN, by separately stacking [O III] integrated spectra of the type-1/type-2 objects with $L_{\text{bol}} \sim 10^{44.8-46.5}$ erg s⁻¹ (Fig. 9): these are all seven type-2 AGN and eleven type-1 systems (i.e. those lying within the orange shading of Fig. 8). Selecting objects over this broad (about two orders of magnitude) range of luminosity ensures us to account for possible over/underestimates of L_{bol} from SED fitting in type-2 AGN (Circosta et al. 2018), due to fainter AGN emission hard to constrain. However, we check the reliability of the SED-based measurements for the type-2 AGN by estimating L_{bol} also from dust-corrected [O III] luminosity (Lamastra et al. 2009) and from X-ray 2-10 keV luminosity (Duras et al. 2020). We thus find L_{bol} values derived from SED fitting to agree with the [O III]-based estimates within a factor of 2 on average (computed for the four objects with A_{V} estimates, see Table 3), and from X-ray-based values by a mean factor of 4, without obvious biases towards higher or lower L_{bol} with respect to the SED fitting derivation.

For each selected AGN, we extract an integrated [O III] $\lambda 5007$ spectrum using an aperture of 0.25''-radius, after removing continuum emission in SUPER type-2 datacubes (see Sect. 3.1), and continuum+BLR emission in type-1 datacubes (Kakkad et al. 2020). We exclude from the stack spectra with a S/N < 5 on [O III], to allow for a more accurate comparison of line profiles. We thus finally remain with six S/N > 5 type-2 spectra (all but XID419) and six S/N > 5 type-1 spectra (X_N_66_23, X_N_115_23, cid_467, S82X1905, S82X1940, S82X2058). Each type-1/type-2 spectrum is weighed by the inverse of its squared noise before being added to the stack, and then the final stacked type-2 and

type-1 spectra (red and blue spectra in Fig. 9, respectively) are normalised to the resulting respective [O III] peak. We point out that results similar to those described below are obtained even by stacking unweighted spectra. In Fig. 9, we show the resulting stacked [O III] line profiles of the selected type-2 (red) and type-1 (blue) SUPER AGN, using a binning twice larger than SINFONI spectral channel to remove noisier channels. The type-2 [O III] line profile exhibits more prominent blue and red wings than type-1 spectrum. Via multiple stacks of type-2 integrated spectra, each time excluding one object, we check that all type-2 objects contribute to the [O III] blue wing, whereas the red wing is dominated by XID36. Because of the brighter and more prominent blue wing, the type-2 [O III] line profile also appears more asymmetric than the type-1 one.

We measure the v_{10} velocity of each resulting stacked type-1/type-2 spectrum (vertical dashed lines in Fig. 9) and quantify the corresponding uncertainty as the standard deviation of the v_{10} distribution resulting from a bootstrap of 400 stacks of six type-1/type-2 spectra, randomly selected with equal probability and allowing for repetitions. We thus obtain $v_{10}^{\text{ty2}} = -1200 \pm 80$ km s⁻¹ for the type-2 line profile, and $v_{10}^{\text{ty1}} = -730 \pm 90$ km s⁻¹ for the type-1 spectrum (see Fig. 9), corresponding to a 2.7σ difference in the [O III] blue wing of the AGN samples. We notice that the identification of extended [O III] wings at high velocity is generally more challenging in type-1 AGN than in type-2 systems, due to the presence of bright BLR emission (i.e. H β and Fe II) in the [O III] wavelength range. Therefore, as a check of the goodness of the BLR and continuum modelling of the SUPER type-1 AGN, we also stack type-1 spectra without removing BLR emission (i.e. only continuum emission removed), employing best-fit results from Kakkad et al. (2020). We find that no evident Fe II emission bumps are present in correspondence of the [O III] line wings, and that the bulk of BLR emission in this spectral region is due to extremely large red wings of the H β BLR line component (see Figs. A.1-A.4 in Kakkad et al. 2020). This supports the reliability of our comparison between type-1 and

Fig. 9. Stacked [O III] λ 5007 spectra of type-2 (red) and type-1 (blue) AGN from SUPER with $L_{\text{bol}} \sim 10^{44.8-46.5}$ (orange shading in Fig. 8), resulting from integrated (aperture of $0.25''$ -radius), subtracted [O III] spectra with $S/N > 5$. Integrated spectra are averaged by the inverse of squared noise, and then the resulting stacked spectrum is normalised to the final [O III] peak. Comparing the two stacked spectra, we find a statistically significant (2.7σ) difference in [O III] blue wing, which is more prominent in type-2 spectrum of about 500 km s^{-1} compared to the type-1 stack.

type-2 stacked spectra (see Fig. 9) and furthermore strengthens our result of a type-1/type-2 dichotomy in ionised outflow velocity, as firstly pointed out by our spatially-resolved measurements (shown in Fig. 8). The origin of such an observed difference, revealing faster ionised outflows in type-2 AGN, is discussed in Sect. 6.

5.2. Can ionised outflows escape galaxy gravitational potential?

One of the main channels via which outflows can quench (or at least reduce) galactic SF is through the ejection of a substantial amount of gas out of the host galaxy, otherwise available to form new stars. This requires outflows energetic enough to efficiently sweep away the gas on large scales, eventually escaping the gravitational potential of their galaxy. Kakkad et al. (2020) presented a first investigation of the ‘ejective’ ability of the ionised outflows detected in the SUPER type-1 sample and found that, for most galaxies, only a modest fraction ($< 10\%$) of the outflowing gas can effectively escape the host’s gravitational potential well. In this section, we compare the outflow velocities with the escape velocity of each galaxy for the full SUPER sample, homogeneously for all objects using a more accurate mass modelling.

Following prescriptions from the literature (Marasco et al. 2023), we use the python package galpy (Bovy 2015) to build a dynamical mass model consisting of a dark matter (DM) halo, a stellar disk, and a gaseous disk, to derive the total escape velocity profile for SUPER targets with known M_* , derived from SED fitting (Circosta et al. 2018). All examined type-2 AGN galaxies have M_* estimates ranging within $M_* \sim 10^{10.7-11.2} M_\odot$ (see Table 1), while for only few type-1 systems M_* estimates are available ($M_* \sim 10^{10.1-11.2} M_\odot$). In fact, stellar emission is typically buried in the bright AGN component of type-1 systems, thus preventing us from constraining M_* in most cases (only six SUPER type-1; see Table A.2 in Circosta et al. 2018).

For the DM halo, we assume a Navarro-Frenk-White (NFW, Navarro et al. 1997) profile, with a virial mass M_{200} derived from M_* via the stellar-to-halo mass relation of Girelli et al. (2020), and a concentration c determined from the $M_{200} - c$ relation of Dutton & Macciò (2014); both relations are computed at the redshift of each target. We model the stellar disk with a double-exponential profile with scale-length R_d and scale-height $R_d/5$, assuming R_d equal to the half-light radius R_{50} divided by 1.68 (correct for a pure exponential disk, Sérsic index $n = 1$). We determine R_{50} from the size- M_* relation for a disk galaxy ($n = 1$) at $z \sim 2.2$ (Mowla et al. 2019). Since we have CO-based measurements of molecular gas mass M_{gas} for a few SUPER AGN (Circosta et al. 2021), we model a gaseous disk of M_{gas} equal to the mean value measured for SUPER targets (i.e. $M_{\text{gas}} \sim 6 \times 10^9 M_\odot$), and same size as the stellar disk, since we expect the molecular gas to extend on scales comparable to those of stars. In doing so, we derive the escape velocity profile of the total modelled mass distribution (i.e. DM halo + stellar disk + gas disk).

Figure 10 displays v_{out} as a function of the escape velocity at the maximum inferred outflow radius R_{out} for SUPER type-2 (coloured symbols) and all those type-1 (grey) AGN with known M_* (Circosta et al. 2018), hence not L_{bol} -matched to the type-2 AGN sample. The two panels display data points corresponding to two distinct definitions of escape speed: one derived according to the classical definition⁵ (v_{esc} in the left panel; also listed in Table 3), which translates in more practical terms to the velocity needed to reach the virial radius R_{vir} of the DM halo, as derived from our mass modelling ($R_{\text{vir}} \sim 80 - 160 \text{ kpc}$); the other one corresponding to a less rigid definition of escape speed ($v_{\text{esc}}^{10R_e}$ in the right panel), namely the velocity required to reach $10 R_e$ (i.e. $\sim 30\text{-}50 \text{ kpc}$, depending on the galaxy). This second set of values shows whether the outflows can travel up to distances of tens of kpc from the centre of the galaxy, and escape (at least) the gravitational potential of the galaxy baryonic component (i.e. stellar disk + gas disk). Triangles indicate lower limits to the escape speed, corresponding to upper limits to R_{out} , since escape speed curves increase at decreasing R_{out} . A dashed line indicates the locus of points where v_{out} are equal to escape speed values. Under the simplifying assumption that our dynamical modelling introduces no further uncertainty, we consider the error on our escape speed values to be due to the total uncertainty on M_* , including both statistical (from SED fitting Circosta et al. 2018) and systematic ($\sim 0.1 \text{ dex}$; Pacifici et al. 2023) uncertainties.

In the left panel of Fig. 10, the overall majority of galaxies have v_{out} values consistent or nearly consistent with v_{esc} to infinity. Unfortunately, the uncertainties and simplified assumptions of our dynamical modelling prevent us from firmly testing whether these outflows can effectively sweep up a significant amount of gas out of the DM halo, as predicted by the ejective feedback scenario. Indeed, we derived the outflow velocity (assumed to be constant in our model) from our observed velocity measurements, which are subject to inclination effects and limited to few kpc from the centre of each galaxy, beyond which line emission gets fainter and the S/N drops. Moreover, our dynamical model includes only gravity and no hydrodynamic effects, which may instead play a major role. Outflows could hence get trapped in gaseous halos, eventually cool and be re-accreted, even if they have high initial velocities. This would contribute to hampering the wind ejective ability to expel the gas reservoir of their host, unlike model predictions (e.g. King & Pounds 2015; Zinger et al. 2020). Yet, the distribution of measurements

⁵ The minimum velocity required by an object to reach to infinity, with a final null velocity.

Fig. 10. Outflow velocity v_{out} as a function of escape velocity computed at R_{out} , as inferred from our mass modelling of SUPER type-2 (coloured symbols) and all those type-1 (grey) AGN galaxies with known M_* , hence not L_{bol} -matched to the type-2 AGN sample. We display two sets of escape speed values: one inferred according to the classical definition of escape velocity to infinity (v_{out} , left panel), hence that one needed to escape the DM halo ($R_{\text{vir}} \sim 80 - 160$ kpc); the other one corresponding to the escape velocity required to reach $10 R_e$ ($v_{\text{esc}}^{10R_e}$, right panel), that is ~ 30 – 50 kpc for the galaxies here considered. Triangles represent lower limits to the escape speed (due to an inferred upper limit to R_{out}), whereas dashed line indicates $v_{\text{out}} = v_{\text{esc}}$ and $v_{\text{out}} = v_{\text{esc}}^{10R_e}$ values, respectively. The overall distribution of measurements suggests that, although possibly unable to escape the DM halo, the outflows however can impact the host galaxy reservoir up to galaxy scales (i.e. tens of kpc).

in the right panel of Fig. 10 strongly suggests that, even if these outflows do not successfully escape the total gravitational potential well (i.e. the DM halo), they are likely to impact the host gas reservoir up to galaxy scales (i.e. 30–50 kpc). They can hence sweep gas out of the galaxy disk and/or provide feedback through a ‘preventive’ mode (e.g. van de Voort et al. 2011), by injecting energy and driving turbulence in the surrounding medium. All this will eventually prevent gas from cooling and collapsing to form new stars. Even inferring escape speeds at a fixed radius of 50 kpc for all galaxies, we obtain escape speeds similar to $v_{\text{esc}}^{10R_e}$. Finally, as opposed to Fig. 8, we notice that Fig. 10 shows no clear separation between type-1 and type-2 AGN measurements.

6. Discussion

Our analysis has unveiled that SUPER type-2 AGN host faster ionised outflows than their type-1 counterparts in the lower L_{bol} regime ($L_{\text{bol}} \sim 10^{44.8-46.5}$), as traced by higher [O III] velocities. At low redshift ($z < 0.8$), several studies have searched for differences in ionised outflow properties between type-2 and type-1 systems in large AGN samples (e.g. Mullaney et al. 2013; Bae & Woo 2014; Rakshit & Woo 2018; Wang et al. 2018; Rojas et al. 2020). In general, they found narrower and more symmetric [O III] line profiles in type-2 AGN, indicating the detection of both blueshifted and redshifted outflow components; whereas, almost exclusively blueshifted outflows in type-1 AGN, with typically larger line widths and more negative velocities. This can be explained in terms of biconical outflow geometry in the context of standard unification models (e.g. Antonucci 1993; Urry & Padovani 1995), as a consequence of orientation effects along the line of sight, combined with dust obscuration. Indeed, assuming a nearly face-on orientation of type-1 AGN, with well visible BLR emission along the line of sight, the receding cone of the outflow remains hidden on the the opposite side of the galaxy disk plane.

However, most of these low-redshift studies do not consider the well known dependence of outflow kinematics on AGN lu-

minosity and accretion rate (e.g. Bae & Woo 2014; Woo et al. 2016; Rakshit & Woo 2018), and overall compare more luminous type-1 AGN with fainter type-2 samples, possibly leading to an only apparent discrepancy. Moreover, nowadays observational evidence increasingly challenges the standard unified picture of AGN, such as the discovery of changing-look AGN (see Ricci & Trakhtenbrot 2023 for a recent review), which favours the interpretation of the type-1/type-2 AGN dichotomy in terms of distinct phases within a common evolutionary sequence.

At high redshift ($z > 1$), where more complex processes are expected to take place - especially at crucial cosmic epochs of galaxy evolution such as $z \sim 2$ - orientation effects might play a minor role compared to low redshift. Previous works have indeed provided evidence that at high redshift the bulk of the dust obscuration comes from the host galaxy rather than being due to the classical dusty torus (e.g. Gilli et al. 2014, 2022; Perna et al. 2018; Circosta et al. 2019). This is consistent with results from numerical simulations according to which different AGN classes correspond to distinct evolutionary phases of galaxies’ life cycle (Hopkins et al. 2006; Menci et al. 2008). In particular, X-ray bright but obscured ($L_{2-10 \text{ keV}} > 10^{44} \text{ erg s}^{-1}$, $N_{\text{H}} \gtrsim 10^{22} \text{ cm}^{-2}$) AGN at $z \sim 2$ have been proposed to be in the active ‘blow-out’ phase of AGN galaxies’ evolution (e.g. Brusa et al. 2010; Urrutia et al. 2012) and, in fact, powerful outflows have been detected in such systems (e.g. Brusa et al. 2015, 2016; Zakamska et al. 2016; Perna et al. 2015a,b; Vayner et al. 2023; Glikman et al. 2024). In these obscured sources, dusty material favours the acceleration of outflows (e.g. Ishibashi & Fabian 2015; Costa et al. 2018), which efficiently clear out obscuring dust and finally unveil the AGN. Radiation-pressure on dust has been indeed identified as the main mechanism responsible for the larger [O III] velocities and line widths observed in extremely red and luminous quasars (ERQs; $L_{\text{bol}} > 10^{47} \text{ erg s}^{-1}$), compared to blue quasars at $z = 2 - 3$ (Perrotta et al. 2019).

However, Villar Martín et al. (2020) provided a revised comparison of the [O III] kinematics in 20 ERQs from Perrotta et al. (2019) with other AGN samples matched in luminosity, and found the [O III] velocities of ERQs to be overall consistent with

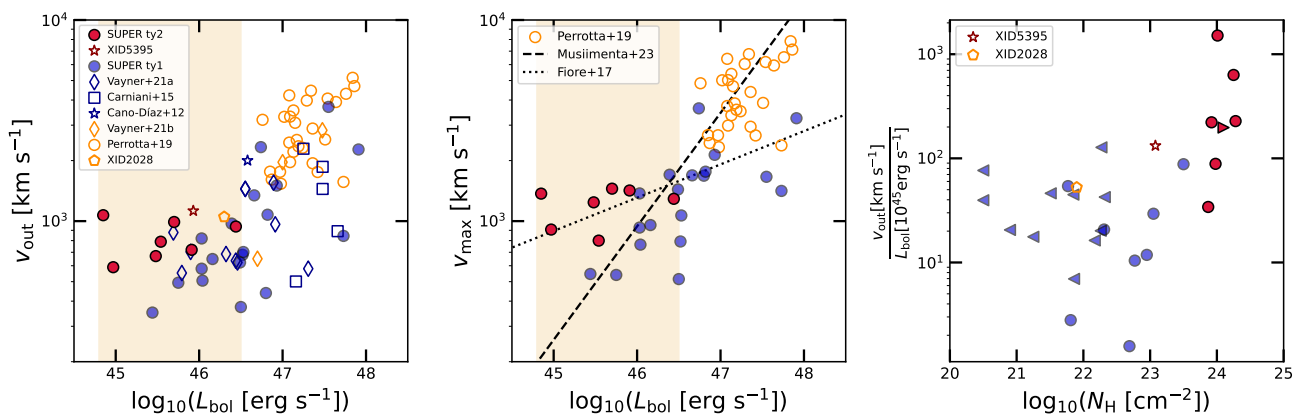

Fig. 11. Same panels as in Fig. 8, showing SUPER type-2 (red filled circles) and type-1 (blue filled circles) measurements along with IFS-based results from the literature of other type-2 (red empty star; XID5395, Brusa et al. 2016) and type-1 AGN (blue empty symbols; Cano-Díaz et al. 2012; Carniani et al. 2015; Vayner et al. 2021a) at $z \sim 1 - 3$. Orange symbols represent red obscured systems which are nevertheless optically classified as type-1 AGN (Perrotta et al. 2019; Vayner et al. 2021b; Cresci et al. 2023; Veilleux et al. 2023). Outflow velocities from Brusa et al. (2016) and Perrotta et al. (2019) have been corrected to account for discrepancies with v_{out} and v_{max} definitions here adopted (see Sect. 6). While ‘standard’ blue type-1 and red type-2 from the literature agree with values found in SUPER, the orange points, almost all at $L_{\text{bol}} \gtrsim 10^{47}$ erg s $^{-1}$, clearly show that higher outflow velocities are recovered if we select optical type-1 but dusty obscured objects.

those of luminous blue quasars. A similar result was also found by Temple et al. (2019), who compared the [O III] kinematics in a sample of luminous ($L_{\text{bol}} \approx 10^{47}$ erg s $^{-1}$), heavily reddened quasars at $z > 2$ to unobscured quasars in the same luminosity and redshift range. On the contrary, larger [O III] velocities have been observed by DiPompeo et al. (2018) in obscured AGN at $z < 0.4$, resembling the obscured high-redshift population based on their optical/IR colours, and matched in luminosity with unobscured objects. All these controversial results show how complex carrying out such a comparison is, and leaves the debate open.

Figure 11 displays the same panels as in Fig. 8 and compares the results obtained for SUPER targets with measurements from the literature. In particular, we collect from the literature only results based on IFS observations and with outflow velocities defined consistently with ours in SUPER, to allow for a proper comparison as homogeneous as possible. In all three panels of Fig. 11, SUPER results of type-2 and type-1 AGN are shown as red and blue filled markers, respectively, along with other IFS-based measurements of type-2 (red empty star; XID5395, Brusa et al. 2016) and type-1 (blue empty symbols; Cano-Díaz et al. 2012; Carniani et al. 2015; Vayner et al. 2021a) AGN at $z = 1 - 3$ from the literature. In orange, we highlight the measurements relative to red obscured AGN showing BLR emission (hence, optical type-1 systems), which should be considered as an intermediate class of objects between standard (blue) type-1 and (red) type-2 AGN. These are: the obscured quasar XID2028 at $z \sim 1.6$ (orange empty pentagon; Cresci et al. 2023; Veilleux et al. 2023), the powerful obscured ERQs from Perrotta et al. (2019) (orange empty circles); and the sample of obscured quasars from Vayner et al. (2021b) (orange diamonds), among which all but one (the lowest-velocity point) are selected as ERQs.

The first panel compares v_{out} measurements from SUPER and the literature based on v_{10}/v_{90} , as obtained by Vayner et al. (2021a,b) (blue/orange diamonds) and by Cresci et al. (2023) and Veilleux et al. (2023) consistently for XID2028; whereas higher percentile outflow velocities were used in Brusa et al. (2016) and Perrotta et al. (2019) (i.e. v_{05} and v_{02} , respectively). Therefore, we correct outflow velocities inferred in Brusa et al. (2016) and Perrotta et al. (2019) by a factor of 0.86 and 0.77,

respectively, corresponding to the mean ratio of $v_{10,90\text{-to-}v_{05,95}}$ and $v_{10,90\text{-to-}v_{02,98}}$ measured for SUPER type-2 AGN. We also add measurements from Cano-Díaz et al. (2012) and Carniani et al. (2015). Similarly, we re-scale v_{02} outflow velocities from Perrotta et al. (2019) by a factor of 1.2, as obtained from the mean $v_{\text{max-to-}v_{02,98}}$ ratio for SUPER type-2 AGN, and plot them in the $v_{\text{max}} - L_{\text{bol}}$ plane (middle panel), along with v_{max} measurements for SUPER type-2 (derived in Sect. 4.2.1) and type-1 AGN (Kakkad et al. 2020).

As shown in Fig. 11, standard blue (unobscured) type-1 and red (obscured) type-2 AGN from the literature lie close to SUPER type-1 and type-2 points, respectively. For instance, the obscured type-2 AGN XID5395 (empty red star; Brusa et al. 2016) exhibits outflow velocity and $v_{\text{out}}/L_{\text{bol}}$ ratio (i.e. ~ 130) comparable with those of SUPER type-2 systems, and a column density ($N_{\text{H}} \sim 10^{23}$ cm $^{-2}$) that places this source in the nuclear highly-obscured regime. Within the optical type-1 AGN population instead, we notice that ‘hybrid’ sources (i.e. optical type-1 but X-ray obscured AGN; orange markers) show higher outflow velocities, consistently with the picture proposed in this work. In fact, the hybrid type-1 AGN XID2028 (empty pentagon; Perna et al. 2015a; Cresci et al. 2023; Veilleux et al. 2023) behaves like the SUPER type-2 objects in terms of $v_{\text{out}} - L_{\text{bol}}$, while it is more similar to SUPER type-1 counterparts in the $v_{\text{out}}/L_{\text{bol}} - N_{\text{H}}$ parameter space, falling at the boundary of the obscured vs. unobscured regimes ($N_{\text{H}} \sim 10^{22}$ cm $^{-2}$).

Therefore, radiation pressure of dust might be the dominant mechanism explaining the presence of faster-ionised outflows in type-2 AGN, also at lower bolometric luminosity with respect to that typical of ERQs ($L_{\text{bol}} > 10^{47}$ erg s $^{-1}$) from Perrotta et al. (2019). Our analysis has furthermore revealed a clear type-1/type-2 dichotomy which fully reflects the X-ray unobscured/obscured classification based on obscuring material on nuclear scales. Interestingly, SUPER type-2 AGN are all X-ray highly obscured with $N_{\text{H}} \gtrsim 10^{23}$ cm $^{-2}$, which may explain the higher observed velocities of their ionised outflows, compared to those observed in SUPER type-1 AGN within the same luminosity range. Rather than being a consequence of projection effects, this result supports the scenario in which obscured optical type-2 AGN at $z \sim 2$ might indeed evolve towards the unob-

scured type-1 phase, as radiation-pressure driven outflows blow out obscuring material and unveil the central AGN and its BLR emission.

Despite previous studies already pointed to individual sources as likely ‘blow-out’ candidates (e.g. Brusa et al. 2016), SUPER has provided observational evidence of such an evolutionary scenario in a larger AGN sample, and also pointed to an optical type-1/type-2 AGN dichotomy in outflow velocity, for the first time, in a sample of moderate-luminous AGN at $z \sim 2$ (i.e. $L_{\text{bol}} \sim 10^{44.8-46.5} \text{ erg s}^{-1}$). As a comparison, the ERQ sample at $z = 2-3$ studied by Perrotta et al. (2019) consists of highly luminous AGN ($L_{\text{bol}} > 10^{47} \text{ erg s}^{-1}$), all showing BLR emission (hence, optical type-1 systems). On another side, the published results from the KASHz survey (Harrison et al. 2016) relative to X-ray-selected AGN ($L_{2-10 \text{ keV}} > 10^{42} \text{ erg s}^{-1}$) at $z = 0.6 - 1.7$, shows no evidence for more extreme gas kinematics in obscured (type-2) objects than in unobscured (type-1) counterparts (see left panel of Fig. 8). We point out that this is likely consequence of the lower S/N of KASHz data compared to SUPER, which hampers the detection of any extended [O III] line wing. This is indeed the case for cid_1143 and cid_451, among the targets in common to both surveys (Scholtz et al., in prep.), where the shallower KMOS data completely miss the broad [O III] wing due to the outflow, thus underestimating its velocity.

7. Conclusions

In this paper we presented SINFONI H - and K -band observations of the SUPER type-2 AGN sample, thus complementing the results previously on the type-1 systems (Kakkad et al. 2020, 2023). The spectral analysis of SINFONI datacubes (Sect. 3.1) allowed us to study the spatial distribution and kinematics of ionised gas via [O III] line emission (Sect. 4.1), and found evidence for ionised outflows in all seven examined type-2 AGN, moving at $v_{\text{out}} > 600 \text{ km s}^{-1}$. The detected outflows are spatially resolved in six objects and extend up to 2–4 kpc from the centre, while marginally resolved in the remaining source (XID614, $R_{\text{out}} < 1.9 \text{ kpc}$). We also compute outflow mass rates from dust-corrected [O III] outflow luminosity (Sect. 4.2.2).

In Sect. 5, we investigated outflows velocity as a function of AGN bolometric luminosity, aiming at unveiling any difference between the type-1 and type-2 AGN populations in SUPER. The key result of this paper is presented in Sect. 5.1 and clearly shown in Fig. 8, where the outflow velocity is plotted against L_{bol} : SUPER type-2 AGN host faster winds than the type-1 systems within the same luminosity range (i.e. $L_{\text{bol}} = 10^{44.8-46.5} \text{ erg s}^{-1}$). Interestingly, these type-2 AGN (namely, all type-2 systems with high-S/N [O III] detection in our SINFONI observations) are all highly obscured systems ($N_{\text{H}} \gtrsim 10^{23} \text{ cm}^{-2}$). By separately stacking integrated type-1 and type-2 spectra, we found a 2.7σ difference in the blue wing of the [O III] line profile, which appears to be more prominent in type-2 AGN than in type-1 counterparts (Fig. 9). We interpret this as a consequence of the larger amount of obscuring material ($N_{\text{H}} \gtrsim 10^{24} \text{ cm}^{-2}$ in all examined type-2 AGN), which favours the acceleration of winds via radiation-pressure on dust (e.g. Ishibashi & Fabian 2015; Costa et al. 2018).

SUPER survey has hence provided observational evidence of an evolutionary origin of the type-1/type-2 dichotomy at $z \sim 2$, consistently with theoretical predictions and with previous observational evidence, whereas orientation effects might play a minor role. Within this picture, type-2 AGN - even at lower luminosity - represent the blow-out phase (e.g. Hopkins et al. 2008), whose obscured environment favours the acceleration of

fast winds via radiation pressure on dust. Such an interpretation was already proposed for obscured AGN at $z \sim 2$ (e.g. Brusa et al. 2015, 2016; Perna et al. 2015b; Zakamska et al. 2016), but not clearly associated with the type-2 optical class, with some of these examined X-ray obscured AGN being optical type-1 systems (e.g. Perna et al. 2015a; Perrotta et al. 2019). Moreover, the ionised outflows overall detected in SUPER AGN galaxies have velocities compatible with the escape speed of their DM halo (Fig. 10, left panel), pointing to no type-1/type-2 discrepancy though. Unfortunately, the uncertainties and the simplified assumptions of our dynamical model prevent us from testing definitely the ejective feedback scenario. However, we found that, although possibly unable to successfully escape the DM halo of their galaxy, these ionised outflows are likely to reach 30–50 kpc scales (Fig. 10, right panel), where they can still provide effective feedback by sweeping away gas and/or injecting energy in the galaxy medium (‘preventive’ mode), thus halting the formation of new stars.

To confirm this novel result found in SUPER, in future we will need larger samples of high-redshift type-1 and type-2 AGN. The new generation of IFS facilities, both from space (e.g. NIRSpec on *JWST*) and on the ground with AO (e.g. ERIS at VLT), will allow us to exploit as much as possible the power of spatially resolved observations, to finally take the next step to fully understand feedback mechanisms and AGN evolution at the Cosmic Noon.

Appendix A: Further comparison of outflow properties with AGN/host parameters

In this appendix we further search for any dependence of outflow properties on AGN/host galaxy parameters, yet finding no result as interesting as that shown in Fig. 8. In Fig. A.1 we plot v_{out} against M_* and SFR in the left and right panel, respectively, for those SUPER AGN sources with available M_* and SFR estimates (or upper limits) from SED fitting (Circosta et al. 2018). As pointed in Sect. 5.2, constraining (or at least placing upper limits to) stellar properties might be particularly challenging in bright type-1 AGN, where the dominant AGN emission outshines the fainter stellar counterpart. For this reason, whereas the seven SUPER type-2 AGN galaxies have all M_* and SFR estimates (or upper limits), only six and seven type-1 systems have estimates (or upper limits) of M_* and SFR available, respectively. Errors on M_* and SFR estimates are the total uncertainty, including both statistical (from SED fitting) and typical systematic uncertainties (~ 0.1 dex in M_* and 0.3 dex in SFR, Pacifici et al. 2023). Colours and symbols are the same as in Figs. 8 and 10. We point out that these M_* and SFR values derived by Circosta et al. (2018) are consistent within the uncertainty with the updated SED fitting results (Bertola et al. 2024) obtained with CIGALE (Noll et al. 2009; Yang et al. 2020), recently implemented to fit also X-ray data. Unlike Fig. 8, we find no clear trend of v_{out} with either M_* or SFR, with type-1 and type-2 measurements scattered together across the two planes. All this overall suggests no connection of v_{out} with host galaxy stellar properties, which is instead well known to increase with AGN luminosity (e.g. Bae & Woo 2014; Woo et al. 2016; Rakshit & Woo 2018). However, we argue that the modest number of measurements and the difficulty in constraining stellar properties of AGN galaxies (especially for type-1 AGN hosts) might conceal some link between these quantities.

Considering the interesting type-1/type-2 dichotomy found by comparing outflow velocity with bolometric luminosity (see Fig. 8), we check whether the same discrepancy between the SUPER type-2 and type-1 samples is also present in terms of outflow mass rates. To compare type-1 and type-2 measurements as homogeneously as possible, we re-compute outflow mass rates for the type-1 sample consistently with the prescriptions adopted on v_{out} and R_{out} in this work (see Sect. 4.2), still using values inferred in Kakkad et al. (2020). As discussed in Sect. 4.2.1, v_{10} and v_{90} indeed provide a more suitable definition of v_{out} than w_{80} , being less sensitive to the line shape which may be driven by dust extinction. Regarding the value of R_{out} to use in Eq. 2, the type-1 outflow mass rates were all computed at a fixed radius of 2 kpc (Kakkad et al. 2020), since [O III] line emission is unresolved in most of type-1 observations, as opposed to type-2 datasets. Therefore, for the few type-1 AGN with clear detection of spatially resolved outflows, we consistently take as outflow radius R_{out} the maximum distance of [O III] outflow emission (Kakkad et al. 2020). For all other unresolved type-1 AGN, we use the maximum distance (or corresponding upper limit) from the central AGN where is found the bulk of the ionised gas, as resulted from spectroastrometry analysis (Kakkad et al. 2020). With these values of v_{out} and R_{out} , we obtain \dot{M}_{out} type-1 mass rates, consistent with the type-2 estimates.

In Fig. A.2, we plot outflow mass rates as a function of L_{bol} for the full SUPER sample. The upper panel shows the \dot{M}_{out} values (same coloured markers as in Fig. 8), derived according to our trust prescriptions (see Sect. 4.2), most of which are lower limits (triangles) due to an upper limit to R_{out} and/or a lower limit to A_V (see Table 3). Similarly, the lower panel shows the \dot{M}_{max}

values obtained by using v_{max} values (Rupke et al. 2005) in Eq. 2, which can be compared with the scaling relations by Fiore et al. (2017) (dotted line) and Musiimenta et al. (2023) (dashed). To allow a proper comparison, both scaling relations have been rescaled to our adopted $n_e \sim 500 \text{ cm}^{-3}$, whereas all \dot{M}_{max} points have been corrected for a factor 2, since the scaling relations have been obtained by considering outflow mass rates computed from the flux of broad Gaussian components. The factor 2 corresponds to the approximated mean ratio of [O III] luminosity from broad Gaussian components to that from line channels at $|v| > 300 \text{ km s}^{-1}$, obtained separately for both type-2 and type-1 AGN (Kakkad et al. 2020).

As opposed to Fig. A.2, the large number of inferred lower limits to mass rates hampers any accurate comparison within the low-luminosity range previously selected ($L_{\text{bol}} \sim 10^{44.8-46.5}$; orange shading). However, excluding lower limits, we find mean values of $\dot{M}_{\text{out}} \sim 5 M_{\odot} \text{ yr}^{-1}$ and $\dot{M}_{\text{max}} \sim 7 M_{\odot} \text{ yr}^{-1}$ for type-2 AGN, and $\dot{M}_{\text{out}} \sim 5 M_{\odot} \text{ yr}^{-1}$ and $\dot{M}_{\text{max}} \sim 15 M_{\odot} \text{ yr}^{-1}$ for low- L_{bol} selected type-1 AGN. Compared to Fig. 8, here it is harder to establish whether a separation between type-2 and type-1 AGN is actually present or not, due to the large uncertainty on outflow mass rates. Indeed, as explained in Sect. 4.2.2, mass rate estimates require several quantities to be assumed (e.g. n_e , [O/H], ionisation), and strongly depend on the accuracy of the other measured parameters (e.g. A_V , R_{out}). All this uncertainty contributes to increasing the scatter in the resulting mass rate values, which might hide any possible type-1/type-2 dichotomy, visible instead in terms of outflow kinematics. Finally, we argue that the larger scatter in \dot{M}_{out} measurements further complicates any search for trends with M_* and SFR estimates, which are more uncertain than L_{bol} , as discussed at the beginning of this appendix.

Fig. A.1. Outflow velocity v_{out} as a function of host galaxy stellar mass (M_* , left panel) and star formation rate (SFR, right panel), for those SUPER AGN sources with available SED-based estimates or upper limits (Circosta et al. 2018). Errorbars on M_* and SFR values represent the total uncertainty, including both statistical and typical systematic uncertainties (~ 0.1 dex in M_* and 0.3dex in SFR, Pacifici et al. 2023). Colours and symbols are the same as in Figs. 8 and 10. The two panels show neither clear trend of v_{out} with the host stellar properties nor separation between type-1 and type-2 measurements, which appear scattered together across the two planes.

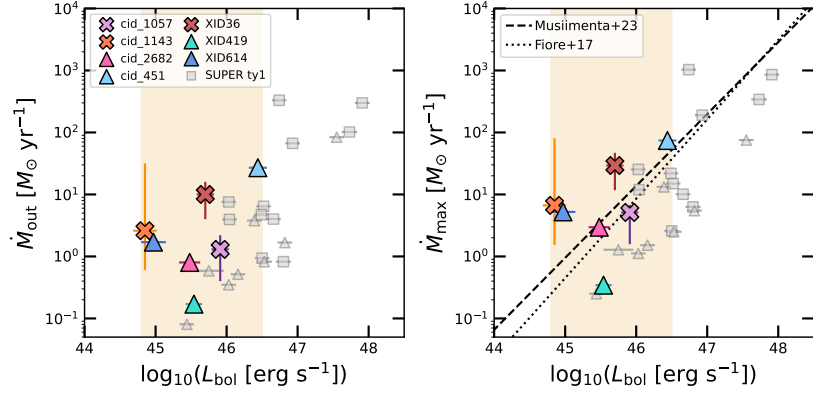

Fig. A.2. Outflow mass rates as a function of L_{bol} for the full SUPER sample. Upper and lower panels show our trust \dot{M}_{out} values and \dot{M}_{max} mass rates, derived using v_{max} in Eq. 2. Triangles indicate lower limits to mass rates. In the lower panel, scaling relations from Fiore et al. (2017) and Musiimenta et al. (2023) are shown as dotted and dashed lines, after being re-scaled to $n_e = 500$ adopted for our targets, while values of \dot{M}_{max} have been multiplied by a factor of 2 to match definitions adopted in Fiore et al. (2017) and Musiimenta et al. (2023). Compared to Fig. 8, the distribution of measurements is more scattered, with no clear discrepancy between the type-1 and type-2 samples. The comparison is furthermore hampered by the large number of lower limits to mass rates.
