#### Abstract

We show that each set of  $n \ge 2$  points in the plane in general position has a straightline matching with at least (5n + 1)/27 edges whose segments form a connected set, and such a matching can be computed in  $O(n \log n)$  time. As an upper bound, we show that for some planar point sets in general position the largest matching whose segments form a connected set has  $\lceil \frac{n-1}{3} \rceil$  edges. We also consider a colored version, where each edge of the matching should connect points with different colors.

Keywords: point sets; matchings for point sets; intersection graph

#### 1 Introduction

Consider a set P of n points in the plane in general position, meaning that no three points of P are collinear. A (straight line) matching M for P is a set of segments with endpoints in P such that no two segments share an endpoint. A matching M for P is connected (via their crossings) if the union of the segments of M forms a connected set. Equivalently, a matching is connected when the intersection graph of its segments is connected. The size of the matching M is the number of segments (or edges) in M. Note that whenever P has a connected matching of size  $m \ge 1$ , it also has a connected matching of size m - 1. Indeed, this is easy to see using the formulation via intersection graphs: in a connected graph, which is the intersection graph of the m segments of a matching M, we can always remove a vertex (which is an edge in M), and keep the graph connected.

In this paper, we study the following problem.

**Question 1** (Connected Matching). Find for each n the largest value f(n) with the following property: each set of n points in general position in the plane has a connected matching of size f(n).

It is also natural to consider a colored version of the problem. In this setting, the points are colored and each edge of the matching has to connect points with different colors. A balanced c-coloring of P is a partition of P into c subsets  $P_1, \ldots, P_c$  such that  $|P_i|$  and  $|P_j|$ 

<sup>\*</sup>A preliminary version of this work was presented at the 40th European Workshop on Computational Geometry (EuroCG2024).

differ by at most one, for each  $1 \leq i, j \leq c$ . In particular, if *n* is divisible by *c*, each set  $P_i$  has cardinality n/c. A matching for a balanced *c*-coloring  $P_1, \ldots, P_c$  is *polychromatic* if each segment connects two points with different colors. The bichromatic version of the problem corresponds to c = 2. We are also interested in the following question.

**Question 2** (Colored Connected Matching). Find for each  $c \leq n$  the largest value g(c, n) with the following property: each set of n points in general position in the plane with a balanced c-coloring has a connected polychromatic matching of size g(c, n).

The setting with c = n colors corresponds to the uncolored version because all edges are allowed in the matching. Therefore, f(n) = g(n, n).

In this work we provide upper and lower bounds for the functions f(n) and g(c, n). We show that  $\frac{5n+1}{27} \leq f(n)$  and a connected matching of this size can be computed in  $O(n \log n)$  time. We also show that  $f(n) \leq \lceil \frac{n-1}{3} \rceil$ . For the function g(n, c), we provide an upper bound only in the bichromatic setting, namely  $g(n, 2) \leq \lceil \frac{n-1}{4} \rceil$ . We also show that, for sufficiently large n,

$$g(n,c) \ge \begin{cases} \frac{c-3}{6c}n - \frac{1}{2} & \text{for } c > 7, \\ \frac{c-1}{9c}n - \frac{1}{3} & \text{for } 2 \le c \le 7. \end{cases}$$

For the bichromatic case, c = 2, this bound gives  $g(n, 2) \ge \frac{n}{18} - \frac{1}{3}$ . When c is very large, the lower bound becomes  $\frac{n}{6} - \Theta(1)$ . Again, polychromatic connected matchings attaining this size can be computed efficiently, namely in linear time.

The problem can be seen as a relaxation of the problem of crossing families of Aronov et al. [3], where one wants to find as many segments as possible with endpoints in P such that any pair of segments crosses in their interior. While in our setting we are asking for a connected subgraph in the intersection graph of the segments, the crossing families problem asks that the intersection graph is a complete graph. The best lower bound, showing an almost linear lower bound for crossing families, has been a recent breakthrough by Pach, Rubin and Tardos [10]. Aichholzer et al. [2] have the currently best upper bound.

The rest of the paper is organized as follows. In Section 2 we provide some basic subroutines that will be used in our algorithms. In Section 3 we discuss the existence and computation of a separator for points in the plane; the existence of such a separator is discussed by Ábrego and Fernández-Merchant [1]. In Section 4 we provide upper bounds for f(n) and g(n, c). In Section 5 we present a lower bound for f(n), the uncolored setting, while in Section 6 we give lower bounds for g(n, c), the colored setting. We finalize with a short discussion in Section 7

# 2 Algorithmic tools

Our algorithms are based on subroutines using classical techniques. We quickly explain these subroutines here.

We will employ algorithms for the k-selection problem: given n numbers and a value  $k \leq n$ , compute the element that would be in the kth position, if the numbers would be sorted non-decreasingly. It is well known that the k-selection problem can be solved performing a linear number of steps and comparisons between the input numbers; input numbers are only compared, and no arithmetic operations with them are performed. See Blum et al. [4] or the textbook [6, Section 9.3] for a description of the algorithm. Randomized variants are simpler [6, Section 9.2].

We also use that a linear program with 2 variables and n constraints can be solved optimally in O(n) time; see Megiddo [9] for a deterministic algorithm or the textbook [7, Chapter 4] for a simpler, randomized algorithm. Our use of linear programming is encoded in the following result. We use CH(P) to denote the convex hull of P.

**Lemma 3.** Given a set P of points in the plane and a ray  $\rho$  that intersects CH(P), we can find in linear time the last intersection of  $\rho$  with the boundary of CH(P).

Figure 1: Proof of Lemma 3. The pair (a, b) defining the blue line is a feasible solution to the linear program.

*Proof.* Making a rigid motion, if needed, we may assume that  $\rho$  is an upward vertical ray that starts at the origin. If all the points of CH(P) are on the same side of the *y*-axis, then  $\rho$  is tangent to CH(P) and a point of P is the last intersection of  $\rho$  with the boundary of CH(P). We can test in linear time whether we are in this scenario, and select the last point of P contained in  $\rho$ .

It remains the case when there are points of P on both sides of the y-axis. We then search for the line with equation y = ax + b with minimum value b such that all the points  $p = (p_x, p_y)$  of P lie below or on  $\ell$ . This is the following LP with real variables a, b:

$$b^* = \min\{b \mid \forall p \in P : ap_x + b \ge p_y\}.$$

The point  $(0, b^*)$  is the last intersection of the ray with CH(P). See Figure 1 for a schema. If  $(0, b^*)$  is not a vertex of CH(P), then the line  $y = a^*x + b^*$  defined by an optimal solution  $(a^*, b^*)$  supports an edge of CH(P). Since this is a linear program with 2 variables and n constraints, it can be solved in O(n) time.

Recall that a maximal matching is a matching where we cannot add any additional edge and keep having a matching. In other words, each edge of the graph has at least one vertex in common with some edge of the matching.

**Lemma 4.** Let  $\sigma$  be a segment and let  $\ell$  be its supporting line. Let A be a set of at most n points to one side of  $\ell$  and let B be a set of at most n points to the other side of  $\ell$ . In  $O(n \log n)$  time we can compute a maximal matching in the bipartite graph

$$G(A, B, \sigma) = (A \cup B, \{ab \mid a \in A, b \in B, ab intersects \sigma\}$$

*Proof.* Making a geometric transformation, we may assume that  $\sigma$  and  $\ell$  are vertical, that A is to the left of  $\ell$ , and B to the right. Let u and v be the endpoints of  $\sigma$  with v above u.

We define the function  $(\varphi_1, \varphi_2) = \varphi \colon \mathbb{R}^2 \setminus \ell \to \mathbb{R}^2$  by

 $\varphi_1(p) =$  slope of the line supporting pu,  $\varphi_2(p) =$  slope of the line supporting pv. For points a to the left of  $\ell$  we have  $\varphi_1(a) < \varphi_2(a)$ , while for points b to the right of  $\ell$  we have  $\varphi_1(b) > \varphi_2(b)$ . Therefore, each number in the interval  $[\varphi_1(a), \varphi_2(a)]$  corresponds to a slope such that the line through a with that slope intersects  $\sigma = uv$ . A similar statement holds for b.

Figure 2: Proof of Lemma 4. The definition of the transformation  $\varphi = (\varphi_1, \varphi_2)$ .

Using that a is to the left of  $\ell$  and b to the right, we note that ab intersects uv if and only if  $\varphi_1(a) \leq \varphi_1(b) \leq$  and  $\varphi_2(a) \geq \varphi_2(b)$ . See Figure 2. One way to see this is noting that  $ab \cap uv \neq \emptyset$  if and only if the line supporting au can be rotated counterclockwise around uuntil it becomes the line supporting ub, and the line supporting av can be rotated clockwise around v to turn it into the line supporting bv. This mapping  $\varphi$  and an application is discussed in Cabello and Milinković [5, Lemma 3], using point-line duality as an intermediary step in the discussion.

Define the point set  $P_B = \varphi(B) = \{\varphi(b) \mid b \in B\}$ . For each point  $a \in A$  define the quadrant  $Q_a = \{(x, y) \in \mathbb{R}^2 \mid x \geq \varphi_1(a), y \leq \varphi_2(a)\}$ . This is a bottom-right quadrant with apex at  $\varphi(a)$ . Set  $Q_A = \{Q_a \mid a \in A\}$ . Note that  $\varphi(b) \in Q_a$  if and only if *ab* intersects  $\sigma$ . Therefore, we have reduced the problem to computing a maximal matching in the incidence graph of the point set  $P_B$  and the set of quadrants  $Q_A$ , where all the quadrants have the same orientation, bottom-right. For computing such a maximal matching we can employ a simple sweep line algorithm, which we explain next. We mix the points A, B and the transformed setting with  $Q_A$  and  $P_B$ .

We sweep the plane with a vertical line x = t from left to right. For each value of  $t \in \mathbb{R}$ , let

$$A_t = \{a \in A \mid \varphi_1(a) \leq t\} = \{a \in A \mid \text{ the vertical line } x = t \text{ intersects } Q_a\}$$
$$B_t = \{b \in B \mid \varphi_1(b) \leq t\}.$$

At any given moment, we maintain a maximal matching  $M_t$  in  $G(A_t, B_t, \sigma)$ , the subgraph of  $G(A, B, \sigma)$  induced by  $A_t \cup B_t$ . Let  $A'_t$  be the points of  $A_t$  that are currently not matched. We also maintain a dynamic binary search T tree for the points  $A'_t$  with the key  $\varphi_2(a)$ . When x = t passes over  $\varphi_1(a)$ , which means that a becomes a new element of  $A_t$ , we add a to the tree T with key  $\varphi_2(a)$ . When x = t passes over  $\varphi_1(b)$ , which means that b becomes a new element of  $B_t$ , we query T to get a point  $a' \in A'_t$  stored in T with  $\varphi_2(a') \ge \varphi_2(b)$ ; this is a predecessor query in T. If we get such a point a', we have an incidence between  $\varphi(b)$  and the quadrant  $Q_{a'}$ , we add a'b to the matching  $M_t$ , and remove a' from T. If there is no such point a' in T, because  $\varphi_2(b) > \varphi_2(a')$  for all a' in T, then b will stay unmatched. This happens when all the quadrants  $Q_a$  for  $a \in A_t$  that contain  $\varphi(b)$  are already matched.

A standard inductive argument shows that we indeed maintain a maximal matching between  $A_t$  and  $B_t$ . When we sweep over the last point of B, we finish. The events in the algorithm are the points  $\varphi(A) \cup \varphi(B)$ , and they can be sorted by x-coordinate in  $O(n \log n)$ time. This suffices to know in which order the points have to be treated. At each point we make O(1) operations, some of them in a dynamic binary search, and thus we spend  $O(\log n)$ time per event. In total, the running time is  $O(n \log n)$ .

# 3 Balanced separation with a short path

In this section we provide a structural result about splitting the convex hull of a point set with a single edge or with a 2-edge path in such a way that both sides contain a large fraction of the point set. This will be used later in our proofs of lower bounds. A very similar result can be found in Ábrego and Fernández-Merchant [1, Lemma 2]. We include a proof because their bound has a small error<sup>1</sup>, our approach is slightly different in the treatment of the triangular case (Theorem 5), we develop a colored version (Lemma 11 and Lemma 13), and because we discuss the algorithmic counterpart, a part that is not considered in [1] and that forces us to rework a proof.

We first consider the case when the convex hull is a triangle and the partition can be with different numbers of points. This will be a tool for the general case. See Figure 3 to visualize the following statement.

Figure 3: Statement in Theorem 5.

**Theorem 5.** Assume that we have a triangle with vertices  $p_0$ ,  $p_1$ , and  $p_2$  and in its interior there is a set P of  $m \ge 1$  points such that  $P \cup \{p_0, p_1, p_2\}$  is in general position. For any integer weights  $w_0, w_1, w_2$  such that  $0 \le w_0, w_1, w_2 < m$  and  $\ell := w_0 + w_1 + w_2 > 2m - 3$ , there exist at least  $\ell - 2m + 3 > 0$  points  $q \in P$  such that, for each  $i \in \{0, 1, 2\}$ , the triangle  $\triangle(p_i q p_{i+1})$  contains at most  $w_{i+2}$  points of P in its interior, where all indices are modulo 3. We can find  $\ell - 2m + 3$  points with this property in linear time.

*Proof.* In this proof, all indices are modulo 3. For  $i \in \{0, 1, 2\}$ , consider a ray  $r_i$  that starts at  $p_{i-1}$  and goes through  $p_i$ . We rotate  $r_i$  around  $p_{i-1}$  in the direction towards  $p_{i+1}$  until we pass  $r_i$  over  $m - w_i - 1$  points of P. See Figure 4, left, to visualize the case i = 1. For any of

<sup>&</sup>lt;sup>1</sup>Lemma 2 in [1] is not correct for n = 4 because a ceiling was missing in the bound. The authors have an updated, corrected version in arXiv.

the points  $q \in P$  we did not scan over, the triangle  $\triangle(p_{i-1}qp_{i+1})$  contains at most  $w_i$  points of P in its interior; note that q is not in the interior of  $\triangle(p_{i-1}qp_{i+1})$ .

Figure 4: Left: rotating  $r_1$  until we pass over  $m - w_1 - 1$  points. Any point not scanned by  $r_1$  defines with  $p_0$  and  $p_2$  a triangle with at most  $w_1$  points. Right: the part of the triangle that is not shadowed contains at least  $\ell - 2m + 3$  points.

Some points of P may be scanned more than once, but in total we scan at most  $3m - w_1 - w_2 - w_3 - 3 = 3m - \ell - 3$  points. So there are at least  $m - (3m - \ell - 3) = \ell - 2m + 3 > 0$  points remaining, and each of them satisfies the desired property. See Figure 4, right.

To show the *algorithmic claim*, we note that, for each  $i \in \{0, 1, 2\}$ , the points scanned by the rotation of  $r_i$  can be computed in linear time. To see this, we associate the number  $\alpha(q) = \measuredangle(p_i p_{i-1}q)$  to each point  $q \in P$ . We then compute the point  $q_i$  of P solving the  $(m - w_i - 1)$ -selection problem with respect to  $\{\alpha(q) \mid q \in P\}$ , which takes linear time. All points  $q \in Q$  with  $\alpha(q) \leq \alpha(q_i)$  are marked as scanned. Note that we do not need to compute actual angles and that it suffices to use orientation tests to compare angles. After performing this for i = 0, 1, 2, the points that remain unmarked have the desired property.

As a special case we state the following corollary, which might be of its own interest.

**Corollary 6.** Let  $\Delta$  be a triangle with a set P of  $m \ge 1$  points in its interior. Then there is a point of P that splits  $\Delta$  into three triangles, such that none of these triangles contains more than  $\lceil (2m-2)/3 \rceil$  points of P in its interior.

*Proof.* Perturb the points to general position, if needed, without changing the positive or negative orientation of any triple of points. Use now Theorem 5 with  $w_0 = w_1 = w_2 = \lceil (2m-2)/3 \rceil$ , which satisfy  $w_0 + w_1 + w_2 = 3\lceil (2m-2)/3 \rceil > 2m-3$ , to obtain a point q. Each triangle defined by q and any two vertices of  $\Delta$  contains at most  $\lceil (2m-2)/3 \rceil$  of P in its interior. Undoing the perturbation, some points may move to the boundary of some of the triangles, but the number of points in the interior of a triangle cannot increase.

This result resembles the classical Centerpoint Theorem [8, Section 1.4], which tells that for each set P of n points in the plane there exists a so-called centerpoint q with the property that each open halfplane that does not contain q has at most 2n/3 of the points of P inside. However, the centerpoint does not need to be a point of P, it exists independently of the shape of the convex hull, and for some point sets it cannot be an element of P.

Recall that CH(P) denotes the convex hull of P. A point  $p \in P$  is *extremal* for (or an extreme point of) P if it lies on the boundary of CH(P). A *k*-separating path for P is a plane path  $\pi$  spanned by vertices of P and connecting two different extremal points of P

such that  $CH(P) \setminus \pi$  has two parts, each containing at least k points; note that the points on the path are counted in no part. The larger is k, the more balanced is the separation. See Figure 5. The *length* of such a path is its number of edges.

Figure 5: Left: 5-separating path of length 1. Right: 7-separating path of length 2.

**Theorem 7.** Let P be a set of  $n \ge 2$  points in general position in the plane. Then there exists a  $\lceil \frac{n-4}{3} \rceil$ -separating path of length 1 or 2. Such a separating path can be found in time linear in n.

*Proof.* For  $n \leq 4$  the statement is trivially true. So for the reminder of the proof assume that  $n \geq 5$ . Let us set  $r = \lceil (2(n-3)-2)/3 \rceil = \lceil (2n-8)/3 \rceil$ . The intuition is that r is the bound of Corollary 6 for  $n-3 \geq 1$  points; in our current setting, n is also counting the vertices of the triangle. We also set  $k = \lceil (n-4)/3 \rceil \geq 1$  as  $n \geq 5$ . Note that  $n-4 \leq r+k \leq n-3$ . The task is to show the existence of a k-separating path of length 1 or 2.

Choose an extremal point  $q_0 \in P$  with the smallest y-coordinate. Let  $q_1, \ldots, q_{n-1}$  be the points  $P \setminus \{q_0\}$  sorted increasingly by the angle  $\overline{q_0q_i}$  makes with the horizontal rightward ray from  $q_0$ . See Figure 6, left.

Figure 6: Proof of Theorem 7.

If between  $q_k$  and  $q_{n-k}$  there is some extremal point  $q_j$  for P, which implies that k < j < n-k, then the segment  $q_0q_j$  is a k-separating path of length 1 and we are done. See Figure 6, right. Otherwise, the rays  $q_0q_k$  and  $q_0q_{n-k}$  intersect the same edge e of CH(P). Let  $q_aq_b$  be the edge e, with a < b. This means  $a \leq k < n-k \leq b$  and the triangle  $\triangle(q_0q_aq_b)$  has exactly b-a-1 points in its interior. See Figure 7, left. Note that we may have a = k and b = n-k. We have  $n-2 \geq b-a \geq n-2k$ .

We want to apply Theorem 5 to  $\triangle(q_0q_aq_b)$  and the  $m = b - a - 1 \ge n - 2k - 1 = n - 2\lceil (n-4)/3 \rceil - 1 \ge n - 2(n-2)/3 - 1 = (n+1)/3 \ge 1$  points of P in its interior. To this

Figure 7: Continuation of the proof of Theorem 7.

end, set  $p_0 = q_0$ ,  $p_1 = q_a$ ,  $p_2 = q_b$ ,  $w_0 = r$ ,  $w_1 = r - (n - b - 1)$ , and  $w_2 = r - (a - 1)$ . See Figure 7, right. To apply Theorem 5, we must verify that  $w_0 + w_1 + w_2 > 2m - 3$ :

$$w_{0} + w_{1} + w_{2} = r + (r - (n - b - 1)) + (r - (a - 1))$$
  

$$= 3r - n + b - a + 2$$
  

$$\geqslant 3r - n + b - a + 2 + (b - a - n + 2) \qquad \text{using } n - 2 \geqslant b - a$$
  

$$= 3\lceil (2n - 8)/3 \rceil - 2n + 2(b - a) + 4 \qquad \text{using } r = \lceil (2n - 8)/3 \rceil$$
  

$$\geqslant (2n - 8) - 2n + 2(m + 1) + 4 \qquad \text{using } m = b - a - 1$$
  

$$> 2m - 3.$$

Theorem 5 guarantees the existence of a point  $q \in P$  in the interior of  $\triangle(p_0p_1p_2) = \triangle(q_0q_aq_b)$ that splits it into three triangular pieces such that the interior of the triangle  $\triangle(p_{i-1}qp_{i+1})$ has at most  $w_i$  points of P (for i = 0, 1, 2 and indices modulo 3).

We split CH(P) into three parts  $A_0, A_1, A_2$  by removing the segments  $qq_0 = qp_0, qq_a = qp_1$ , and  $qq_b = qp_2$ ; the part  $A_i$  is the one whose closure is disjoint from the relative interior of  $qp_i$  (for i = 0, 1, 2). See Figure 7, right. The points  $q, q_0, q_a, q_b$  belong to no part, while all the other points of P belong to exactly one part. From the choices of weights  $w_i$ , each part contains at most r points of P. For example,  $A_1$  contains at most  $(n - b - 1) + w_1 = r$  points.

Let B be a part  $A_j$  that contains the most points of  $P \setminus \{q, p_0, p_1, p_2\}$ . Let  $\pi$  be the separating path of length 2 that separates  $A_j = B$  from  $CH(P) \setminus A_j$ ; the path  $\pi$  is the concatenation of  $p_{j-1}q$  and  $qp_{j+1}$  (indices modulo 3). Let B' be the other part of  $CH(P) \setminus \pi$ ; it contains  $A_{j-1}$ ,  $A_{j+1}$  and its common boundary (indices modulo 3).

By the pigeonhole principle, B contains at least  $\lceil (n-4)/3 \rceil = k$  points. On the other hand, B contains at most r points, which means that B' contains  $(n-3) - r \ge k$  points. It follows that  $\pi$  is a k-separating path of length 2.

It remains to show the algorithmic claim. Finding  $q_0$  takes linear time by scanning the point set. The points  $q_k$  and  $q_{n-k}$  can be found in linear time because it is the k- and (n-k)-selection problem of P with respect to the angle  $q_0q_i$  makes with the horizontal rightward ray from  $q_0$ . One does not need to compute the angle and can just use orientation tests. Using Lemma 3, we find in linear time the last intersection of the rays  $q_0q_k$  and  $q_0q_{n-k}$  with the boundary of CH(P). Let  $\ell$  be the line supporting those two intersections.

We test whether  $\ell$  has all the points of P on the same side. If the test fails, we find the extremal point  $q_j \in P$  swept by the line  $\ell$  when we move it away from  $q_0$ . See Figure 8, left. The point  $q_j$  is then a vertex of CH(P) and it lies in the cone defined by  $q_k q_0 q_{n-k}$ . In this case we are in the first scenario and  $q_0 q_j$  is the desired separator.

Figure 8: Algorithmic part of Theorem 7.

If the test is successful, that is, if all the points of P lie on the same side of  $\ell$ , then  $\ell$  supports an edge of CH(P). This edge of CH(P) is defined by the two points u, v of P that lie on the line  $\ell$ , and they can be found in linear time. We then count how many points are in each region, that is, we figure out the indices a and b such that  $u = q_a$  and  $v = q_b$ . We also compute the points in the interior of the triangle  $q_0q_aq_b$ , and use Theorem 5 to find in linear time the point q used to split  $\Delta(q_0q_aq_b)$ . The rest of the proof is constructive and can be done in linear time by scanning and counting points.

# 4 Upper bounds

In the following we provide upper bounds on the maximal size of connected matchings that exist for any given set of n points.

We start with an upper bound for the uncolored case. Consider n points split into three sets  $A_0, A_1, A_2$  of size  $\sim \frac{n}{3}$ , where each  $A_i$  lies on its own slightly curved blade of a three-bladed windmill; see Figure 9, left. We use indices modulo three in the discussion. We can form such a configuration so that each line determined by two points of  $A_i$  separates  $A_{i+1}$ from  $A_{i+2}$ , and no segment connecting one point of  $A_i$  with one point of  $A_{i+1}$  crosses any segment connecting two points of  $A_{i+1}$ . Hence, the set of all segments is separated into three parts where each part consists of segments connecting two points of  $A_i$  or one point of  $A_i$ and one point of  $A_{i+1}$ , and segments from different parts do not cross. Clearly, the size of the largest matching spanning  $A_i \cup A_{i+1}$ , if their sizes differ by at most one, is min{ $|A_i|, |A_{i+1}|$ }, and the largest of those values over  $i \in \{0, 1, 2\}$  gives the largest connected matching. To be careful with the modulus of n, we note that there is a connected matching of maximum size  $\lceil \frac{n}{3} \rceil$  when at least two of the sets have that size; when only one set has that size, the largest connected matching has size  $\lfloor \frac{n}{3} \rfloor$ . Thus, for each  $n \ge 1$  we have constructed a point set where the maximum connected matching has size  $\lceil \frac{n-3}{3} \rceil$ .

Now, we provide an upper bound for the size of a connected matching in the balanced 2-colored case. We consider a similar configuration. Recall that the coloring is balanced: the cardinalities of each color class differ at most by one. We split the points into four sets  $A_0, A_1, A_2, A_3$  of size  $\sim \frac{n}{4}$  so that each  $A_i$  lies on its own slightly curved blade of a four-bladed windmill. The sets  $A_0$  and  $A_2$  contain only blue points, while  $A_1$  and  $A_4$  only red ones. See Figure 9, right. In this configuration, bichromatic segments connecting points of  $A_i$  with points of  $A_{i+1}$  do not cross any other segments (indices modulo 4), so the size of the largest connected matching is  $\frac{n}{4}$ . A maximum connected matching of size  $\lceil \frac{n}{4} \rceil$  is attainable when two sets of different colors have that cardinality, that is, when  $n \equiv 2, 3 \pmod{4}$ . Thus, for each  $n \ge 1$  we have constructed a 2-colored point set where the maximum connected matching has

Figure 9: Upper bounds for (colored) connected matchings. Left: uncolored. Right: balanced 2-colored.

size  $\left\lceil \frac{n-1}{4} \right\rceil$ .

# 5 Lower bound for uncolored sets

We first consider the following special setting, depicted in Figure 10, left.

Figure 10: Left: Situation in Lemma 8. Right: edges added to the matching when A has four points not in convex position.

**Lemma 8.** Assume that we have a horizontal segment uv, a set A of a points above the line supporting uv, and a set B of  $b \leq a$  points below the line supporting uv such that, for all  $(a,b) \in A \times B$ , the segment ab intersects uv, and  $A \cup B \cup \{u,v\}$  consists of a + b + 2 points in general position. Then,  $A \cup B \cup \{u,v\}$  has a connected matching of size at least

$$m(a,b) := \begin{cases} 1+b & \text{if } b \leq a \leq 2b+3, \\ (a+3b+2)/5, & \text{if } 2b+3 \leq a \leq 7b+3, \\ 1+2b, & \text{if } a \geq 7b+3. \end{cases}$$

Such a connected matching can be computed in  $O(1 + a \log a)$  time.

*Proof.* We first make two easy observations that will come in handy to follow the discussion:

- (a) A matching of B onto A with b edges together with the edge uv to "connect" them is a connected matching of size b + 1. We want to improve upon this when the sides are unbalanced, in particular when a is larger than  $2b \pm O(1)$ .
- (b) If A has a large subset A' in convex position, then we can get a connected matching of size  $\lfloor \frac{|A'|}{2} \rfloor$ , for example by connecting "antipodal" points along the boundary of CH(A').

We construct a connected matching M iteratively as follows. At the start we add uv to M. While |A| > |B| > 0 and A has four points  $p_0, p_1, p_2, q$  such that q is in the interior of  $\triangle(p_0p_1p_2)$ , we take an arbitrary point  $r \in B$ , add the edge qr to M, and add to M the edge pp' of  $\triangle(p_0p_1p_2)$  crossed by qr. See Figure 10, right. Note that  $\{pp', uv, qr\}$  is a connected matching. Then we remove p, p', q from A, and r from B. With each repetition of this operation, we increase the size of the matching by two, remove three points from A, and remove a point from B. We repeat this operation until B is empty,  $|A| \leq |B|$ , or A is in convex position, whatever happens first. Let k be the number of repetitions of this operation, let A' and B' be the subsets of A and B, respectively, that remain at the end. Therefore, M currently is a connected matching with 1 + 2k edges, A' has a - 3k points, and B' has b - k points.

We now consider the different conditions that hold at the end:

- Condition (1) If we finish because B' is empty, then k = b and the matching M has 1 + 2b edges. This scenario can happen only when  $a \ge 3b$ , because otherwise we run out of points of A earlier.
- **Condition (2)** If we finish because  $|A'| \leq |B'|$ , we match the remaining points of A' to B' arbitrarily and add those |A'| edges to M; since they cross uv, M keeps being a connected matching. Because the cardinality of A decreases at steps of size 3 and the cardinality of B decreases at steps of size 1, this means that  $|A'| \leq |B'| \leq |A'| + 1$ , which implies that  $a 3k \leq b k \leq a 3k + 1$ , or equivalently, we have  $a 2k \leq b \leq a 2k + 1$ . From this, because k is an integer, we obtain that  $k = \lceil (a b)/2 \rceil$ . The size of the connected matching M is now  $1 + 2k + (a 3k) = 1 + a k = 1 + a \lceil (a b)/2 \rceil = 1 + \lfloor (a + b)/2 \rfloor$ . This scenario can happen for any  $3b \geq a \geq b$ .
- Condition (3) If we finish because A' does not have any 4 points with the desired condition, the key observation is to note that A' is in convex position. (This is also true if  $|A'| \leq 3$ .) We consider two connected matchings and take the best of both.

The first matching is obtained by adding to M a matching between all the vertices of B' and any subset of A' with |B'| points. The second matching, which we denote by M', is obtained by taking a connected matching of the points A', that is in convex position. Note that this is a matching within A. We take the larger matching of M and M'.

The connected matching M has size 1 + 2k + (b - k) = 1 + b + k. The other connected matching, M', has  $\lfloor \frac{|A'|}{2} \rfloor = \lfloor \frac{a-3k}{2} \rfloor \ge \frac{a-3k-1}{2}$  edges. Therefore, in this outcome we get a connected matching of size

$$\max\left\{1+b+k,\frac{a-3k-1}{2}\right\}.$$

The first term increases with k, the second term decreases with k, and the two terms are equal when k takes the value  $k_0 := (a - 2b - 3)/5$ . At  $k = k_0$  the expression takes

the value (a + 3b + 2)/5. However, we have some additional constraints, as follows.

$$\begin{split} k &\leqslant a/3: \qquad k_0 \leqslant a/3 \iff 2a \geqslant -6b-9, \text{ always true.} \\ k &\leqslant b: \qquad k_0 \leqslant b \iff a \leqslant 7b+3. \\ k \geqslant 0: \qquad k_0 \geqslant 0 \iff a \geqslant 2b+3. \end{split}$$

Therefore, if a < 2b + 3, then  $k_0 < 0$  and the maximum is always attained at the function 1 + b + k, which in the worst case takes value 1 + b. If a > 7b + 3, then  $k_0 > b$  and for all values of k ( $k \leq b$ ) the maximum is given by  $\frac{a-3k-1}{2}$ ; its minimum value is at k = b, giving  $\frac{a-3b-1}{2}$ . Summarizing this outcome, we get a connected matching whose size is bounded from below by the following function

$$m(a,b) := \begin{cases} 1+b & \text{if } b \leq a \leq 2b+3, \\ (a+3b+2)/5, & \text{if } 2b+3 \leq a \leq 7b+3, \\ (a-3b-1)/2, & \text{if } a \geq 7b+3. \end{cases}$$

Note that this function is "continuous" at the boundary cases, which is a "good indication".

Since we have given a construction that can finish with 3 different conditions, we have to consider the worst case among those scenarios, and show that in each case m(a, b) is a lower bound on the size of the connected matching.

We first compare the outcomes under Conditions (1) and (3) and see that actually m(a, b) describes the worst case among them.

$$\begin{array}{ll} \text{If } b \leqslant a < 2b+3: & 1+b \leqslant 1+2b \quad \text{always} \\ \text{If } 2b+3 \leqslant a \leqslant 7b+3: & \frac{a+3b+2}{5} \leqslant 1+2b \quad \Longleftrightarrow \quad a \leqslant 7b+3 \\ \text{If } a \geqslant 7b+3: & \frac{a-3b-1}{2} \geqslant 1+2b \quad \Longleftrightarrow \quad a \geqslant 7b+3 \end{array}$$

It remains to compare the outcome under Condition (2) and m(a, b); we will see that the worst case is never in this outcome. In some cases we compare against  $(a+b+1)/2 \leq 1+\lfloor (a+b)/2 \rfloor$ , as it suffices and it is easier to manipulate.

$$\begin{split} \text{If } b &\leqslant a < 2b + 3: \qquad 1 + b \leqslant 1 + \left\lfloor \frac{a + b}{2} \right\rfloor &\iff a \geqslant b \quad \text{always} \\ \text{If } 2b + 3 &\leqslant a \leqslant 7b + 3: \qquad \frac{a + 3b + 2}{5} \leqslant \frac{a + b + 1}{2} \iff b \leqslant 3a + 1 \quad \text{always} \\ \text{If } a \geqslant 7b + 3: \qquad 1 + 2b \leqslant \frac{a + b + 1}{2} \iff a \geqslant 3b + 1 \end{split}$$

We conclude that m(a, b) indeed gives a lower bound on the size of a connected maximum matching.

It remains to discuss the *algorithmic claim*. We only discuss the case of  $a \ge 1$ . Since  $a \ge b$ , we have O(a) points in total. The proof is constructive and most of it is just simple book keeping of the sizes of the sets. The only complicated aspect of the algorithm is finding the 4 points of A that are not in convex position, or recognize that A is in convex position. For this we employ an incremental algorithm to compute CH(A) by adding the points by increasing x-coordinate. Let  $p_1, \ldots, p_a$  be the points of A sorted by increasing x-coordinate. For each index i, let  $A_i$  be the prefix  $\{p_1, \ldots, p_i\}$ .

We maintain a connected matching M and a subset  $X_i \subseteq A_i$  such that: (i)  $X_i$  is in convex position, and (ii)  $A_i \setminus X_i$  are endpoints of the connected matching we maintain. This

Figure 11: Algorithmic part of Lemma 8. Two cases may arise when inserting  $p_{i+1}$ : we may match  $p_{i+1}$  to B (left) or we may match the other three points that together with  $p_{i+1}$  form a non-convex 4-tuple. Crosses denote points that are deleted.

means that  $X_i \cup \{p_{i+1}, \ldots, p_a\}$  is the set of points A maintained through the iterations of the constructive proof. For  $X_i$  we maintain its convex hull,  $CH(X_i)$ , as a linked list with a finger to its rightmost point; in general,  $p_i$  is *not* the rightmost point of  $X_i$  because it may have been matched.

When we add the next point,  $p_{i+1}$ , we compute  $CH(X_i \cup \{p_{i+1}\})$  from  $CH(X_i)$ . If in the process we do not delete any point of  $X_i$ , meaning that all points of  $X_i \cup \{p_{i+1}\}$  are extremal, we just set  $X_{i+1} = X_i \cup \{p_{i+1}\}$ , move the finger to  $p_{i+1}$  because it is the rightmost point of  $X_{i+1}$ , and move to the next point,  $p_{i+2}$ . If in the process we delete some point q or  $X_i$ , let q' and q'' the neighbors of q along the boundary of  $CH(X_i)$ . The triangle  $\Delta(p_{i+1}q'q')$  contains q in its interior. See Figure 11. In this case we make once the operation described in the constructive proof: select any point r from B, add to the matching qr and the edge e of  $\Delta(pq'q'')$  it crosses. Now we have to remove the points q and two other points of e. For this we undo the changes we made to  $CH(X_i)$ , so that we get  $CH(X_i)$  back. We remove the points of  $\{q, q', q''\} \cap X_i$  that were matched, which takes constant time; we may have to update the finger to the point with largest x-coordinate. If  $p_{i+1}$  is to be removed because it was matched, we have finished and move to the next point,  $p_{i+2}$ ; this is the case in the left of Figure 11. Otherwise, we try to reinsert  $p_{i+1}$  again, which may trigger another iteration adding another two edges to the matching; this is the case on the right of Figure 11.

After sorting the points of A, we spend O(1) time per point, if we do not add any edge to the matching, and O(1) time per edge added to the matching. Therefore, in total we spend  $O(a \log a)$  time.

Note that the bound m(a, b) of Lemma 8 is monotone increasing in a and in b, also when we take a and b as real values (with  $b \leq a$  always.) Moreover, when a + b remains constant, then m(a, b) is larger for larger b. This means  $m(a, b) \leq m(a - 1, b + 1)$  whenever  $b \leq a - 2$ .

**Theorem 9.** Let P be a set of  $n \ge 2$  points in general position in the plane. Then P has a connected matching of size at least (5n + 1)/27 which can be computed in  $O(n \log n)$  time.

*Proof.* By Theorem 7 we know that there is a  $\lceil \frac{n-4}{3} \rceil$ -separating path P of length 1 or 2 for P. Let A and B be the sets of points of P on each side of  $\pi$ , such that  $|A| \ge |B|$ . Note that the vertices of  $\pi$  do not go to any of the sides, which means that  $n-3 \le |A|+|B| \le n-2$ . Therefore we have

$$\left\lceil \frac{n-4}{3} \right\rceil \hspace{0.2cm} \leqslant \hspace{0.2cm} |B| \hspace{0.2cm} \leqslant \hspace{0.2cm} |A| \hspace{0.2cm} \leqslant \hspace{0.2cm} n-3 - \left\lceil \frac{n-4}{3} \right\rceil \hspace{0.2cm} = \hspace{0.2cm} \left\lfloor \frac{2n-5}{3} \right\rfloor.$$

Each edge connecting a point of A to a point of B crosses  $\pi$ .

If  $\pi$  consists of a single edge e, then we match all points of B to points of A arbitrarily, and include e also in the matching. Since all these edges intersect e, they form a connected matching of size  $1 + |B| \ge \lfloor \frac{n-1}{3} \rfloor \ge \frac{5n+1}{27}$ . (This last inequality holds for  $n \ge 2$ .)

For the remainder of this proof we assume that  $\pi$  has length two, and denote its edges by  $e_1$  and  $e_2$ . We build a maximal matching  $M_1$  from  $B_1 \subseteq B$  to  $A_1 \subseteq A$  with edges that cross  $e_1$ . This means that  $|A_1| = |B_1|$  and there is no point in  $A \setminus A_1$  that can be connected to a point in  $B \setminus B_1$  by crossing  $e_1$ . Set  $A_2 = A \setminus A_1$  and  $B_2 = B \setminus B_1$ ; Each segment connecting a point in  $A_2$  to a point of  $B_2$  must cross  $e_2$  because it does not cross  $e_1$ . We make an arbitrary matching  $M_2$  connecting each point of  $B_2$  to points of  $A_2$ ; this can be done because  $|B_2| = |B| - |M_1| \leq |A| - |M_1| = |A_2|$ . We add  $e_1$  to  $M_1$  and  $e_2$  to  $M_2$  so that  $M_1$  and  $M_2$ become connected matchings with  $|M_1| + |M_2| = 2 + |B|$ .

If  $M_1$  or  $M_2$  has size at least  $\frac{5n+1}{27}$ , then we are done. Therefore, we can restrict our attention to the case when  $|M_1|, |M_2| \leq \frac{5n+1}{27}$ . Since  $|A_1| = |B_1| = |M_1| - 1 \leq \frac{5n-26}{27}$ , we have

$$|B_2| = |B| - |B_1| \ge \left\lceil \frac{n-4}{3} \right\rceil - \frac{5n-26}{27} \ge \frac{4n-10}{27}.$$

We apply Lemma 8 to the segment  $e_2$  with  $A_2$  and  $B_2$  to get a connected matching, where  $a = |A_2|$  and  $b = |B_2|$ . Since the lower bound m(a, b) of Lemma 8 is monotone increasing in b, even when a + b is fixed, we get a worst-case lower bound by evaluating it at

$$b := \frac{4n - 10}{27} \leq |B_2|$$
  

$$a := \frac{13n - 19}{27} = (n - 3) - 2 \cdot \frac{5n - 26}{27} - \frac{4n - 10}{27}$$
  

$$\leq (n - 3) - |A_1| - |B_1| - b = |A_2| + |B_2| - b,$$

because  $a + b \leq |A_2| + |B_2|$ . Note that for this choice of a and b we indeed have  $b \leq a$  for  $n \geq 2$ . To evaluate the function m(a, b) of Lemma 8, the values  $a = \frac{13n-19}{27}$  and  $b = \frac{4n-10}{27}$  fall in the regime  $2b + 3 \leq a \leq 7b + 3$ , when  $n \geq 16$ , because

$$2b+3 = \frac{8n+61}{27} \leqslant \frac{16\leqslant n}{27} = a \leqslant \frac{28n+11}{27} = 7b+3.$$

In this case, when  $n \ge 16$ , we obtain the worst-case lower bound

$$\frac{a+3b+2}{5} = \frac{1}{5} \cdot \left(\frac{13n-19}{27} + 3 \cdot \frac{4n-10}{27} + 2\right) = \frac{1}{5} \cdot \frac{25n+5}{27} \ge \frac{5n+1}{27}.$$

For  $2 \leq n \leq 15$ , we have to evaluate the function m(a, b) of Lemma 8 in the regime  $b \leq a \leq 2b + 3$ , and the lower bound we obtain is

$$1+b = 1 + \frac{4n-10}{27} = \frac{4n+17}{27} \qquad \stackrel{16 \ge n}{\geqslant} \qquad \frac{5n+1}{27}.$$

This covers all options for n and concludes the proof of the lower bound (5n+1)/27.

It remains to discuss the *algorithmic claim*. The computation of the separating path via Theorem 7 takes O(n) and the computation of the maximal matching takes  $O(n \log n)$  using Lemma 4. Lemma 8 takes  $O(n \log n)$  time. The remaining tasks are simple book keeping of cardinalities of sets.

#### 5.1 Sets with deep points

We define the depth d(p) of a point  $p \in P$  as the minimum number of points that need to be removed from P so that p lies on the boundary of the convex hull of the remaining points. This implies that any line through p has at least d(p) points of S on both of its sides. If the set P of points is in convex position, then d(p) = 0 for all  $p \in P$ . However, for some point sets in general position, we may have some point at depth (n-2)/2.

**Theorem 10.** Let P be a set of n points in general position in the plane and let p be a point of P with the largest depth d(p) in P. Then P has a connected matching of size at least d(p).

*Proof.* Let  $\ell$  be a line that passes through p and an arbitrary extremal point a of P. Without loss of generality we may assume that pa is horizontal with a to the right of p. The edge e = pa is our first matching edge and we will construct additionally d(p) - 1 matching edges that all intersect e. See Figure 12.

Figure 12: Proof of Theorem 10. The segment  $u_i v_{d(p)-i}$  intersects ap for each i with  $1 \leq i < d(p)$ .

Label the points strictly above  $\ell$  as  $v_1, \ldots, v_k$  in counterclockwise order around p, from a onwards. Note that  $k \ge d(p)$ . Label the points strictly below  $\ell$  as  $u_1, \ldots, u_{k'}$  in clockwise order around p, from a onwards. Note that  $k' \ge d(p)$ , Let  $\ell_i$  be the oriented line passing through  $u_i$  and then p. For each i with  $1 \le i < d(p)$ , the points  $v_1, \ldots, v_{d(p)-i}$  are to the right of  $\ell_i$ . This is so because otherwise to the right of the  $\ell_i$  we would have  $\{a, u_1, \ldots, u_{i-1}\}$  and a subset of  $\{v_1, \ldots, v_{d(p)-i-1}\}$ , which in total has 1 + (i-1) + d(p) - i - 1 = d(p) - 1 points, contradicting the fact that p is at depth d(p). Moreover, because  $v_{d(p)-i}$  is to the right of  $\ell_i$  and a is an extreme point of CH(P), the segment  $u_i v_{d(p)-i}$  intersects the segment e = pa. It follows that the segments  $u_1 v_{d(p)-1}, u_2 v_{d(p)-2}, \ldots, u_{d(p)-1} v_1$  together with e = pa form a connected matching of size d(p).

Note that the bound is tight for four points, when one of them is in the interior of the convex hull.

# 6 Lower bound for colored sets

For this section, P denotes a set of n points in general position in the plane with a balanced c-coloring. This means that each of the c color classes has roughly n/c points. To avoid carrying floors and ceilings, which make the computation more cumbersome, in our results we will not optimize additive constants.

For colored sets we will prove our lower bounds using separating paths, as in the uncolored case. The main difference is that we want that each edge of the separating path connects

points with different colors, as otherwise they can not be used as matching edges. For this, we say that a *polychromatic k-separating path* is a *k*-separating path where each edge of the path connects points with different colors. To show the existence of polychromatic *k*-separating path, for a suitable k, we use Theorem 5 in such a way that there are enough candidate points to split the triangle into the required weighted subtriangles. A sufficiently large number of points allow us to have flexibility of choosing the color of the points in the separating path.

We start by showing colored variants of Theorem 7. We provide two results, each of them better for a different range of c.

**Lemma 11.** For  $c \ge 4$  and sufficiently large n, there exists a polychromatic  $\left(\frac{(c-3)n}{3c}-3\right)$ -separating path for P of length 1 or 2. Such a separating path can be found in time linear in n.

*Proof.* We closely follow the proof of Theorem 7. As it was done there, we set  $k = \lceil (n-4)/3 \rceil$ , which means that  $\frac{n-4}{3} \leq k \leq \frac{n-2}{3}$ , and define  $q_0, q_1, \ldots, q_{n-1}$  by sorting the points angularly with respect to an extremal point  $q_0$  with minimal x-coordinate.

Consider first the case where between the points  $q_k$  and  $q_{n-k}$  there is an extremal point  $q_j$ . If  $q_0$  and  $q_j$  have different colors, then we take  $q_0q_j$  as the separating path, which is a k-separating path for  $k \ge \frac{n-4}{3} \ge \frac{(c-3)n}{3c} - 3$ , whenever  $c \ge 2$ . Otherwise, we take a point  $q_\ell$  with  $\frac{n}{4} - 1 \le \ell \le \frac{3n}{4} + 1$  such that  $q_\ell$  has a color different than  $q_0$  and  $q_j$ . See Figure 13, left. Such a point exists because there are at least  $(\frac{3n}{4} + 1) - (\frac{n}{4} - 1) - 1 = \frac{n}{2} + 1$  points, and no color class has more than  $\frac{n}{2} + 1$  points. Note that  $q_j$  is also from this interval of points, but as  $q_0$  has the same color as  $q_j$  there is at least one point with a different color among the  $\frac{n}{2} + 1$  points. Then, the path  $q_0q_\ell q_j$  is a  $(\frac{n}{4} - 2)$ -separating path of length 2: it has at least  $\ell - 1 \ge \frac{n}{4} - 2$  on one side, and at least  $k \ge \frac{n-4}{3}$  on the other side. Finally, we note that  $\frac{n}{4} - 2 \ge \frac{(c-3)n}{3c} - 3$  for  $c \ge 2$ . (It may be that  $q_\ell$  is an extreme point, and therefore  $q_0q_\ell q_j$  splits CH(P) into three parts, but then two of them are on the same side of the path.)

Figure 13: Proof of Lemma 11. Left: Schema where  $\ell$  satisfies  $\frac{n}{4} - 1 \leq \ell \leq n - k$ . Right: All the points in Q give a good enough partition, and Q has points with at least 4 colors.

Now we turn to the case where between  $q_k$  and  $q_{n-k}$  there is no extremal point. This means that there is an edge  $q_a q_b$  of CH(P) such that  $q_k$  and  $q_{n-k}$  are in the triangle  $\triangle(q_0 q_a q_b)$ , which also means that  $a \leq k < n-k \leq b$ . The triangle  $\triangle(q_0 q_a q_b)$  has  $m = b - a - 1 \leq n - 3$  points in the interior. We set  $p_0 = q_0$ ,  $p_1 = q_a$ ,  $p_2 = q_b$ ,

$$w_0 = \left\lceil \left(\frac{1}{c} + \frac{2}{3}\right)n \right\rceil, \quad w_1 = w_0 - (n - b - 1), \text{ and } w_2 = w_0 - (a - 1).$$

We first note that

$$w_0 > 0,$$
  

$$w_1 = w_0 - (n - b - 1) \ge \left(\frac{1}{c} + \frac{2}{3}\right)n - k + 1 > \frac{2n}{3} - \frac{n - 2}{3} + 1 > 0,$$
  

$$w_2 = w_0 - (a - 1) \ge \left(\frac{1}{c} + \frac{2}{3}\right)n - k + 1 > 0,$$

and then we note that

$$w_{0} + w_{1} + w_{2} \ge 3\left(\frac{1}{c} + \frac{2}{3}\right)n - (n - b - 1) - (a - 1)$$

$$= 2n + \frac{3n}{c} - n + b - a + 2$$

$$\geqslant \frac{3n}{c} + n + b - a + 2$$

$$\geqslant \frac{3n}{c} + (m + 3) + (m + 1) + 2$$

$$\Rightarrow \frac{3n}{c} + 2m + 6.$$
using  $m = b - a - 1$  and  $n - 3 \ge m$ 

This means that, using Theorem 5 we get a set  $Q \subset P$  of at least  $w_0 + w_1 + w_2 - 2m + 3 \ge \frac{3n}{c} + 9$ points such that each  $q \in Q$  satisfies the conclusion of Theorem 5: the interior of each triangle  $\triangle(p_{i-1}qp_{i+1})$  has at most  $w_i$  points of P (for i = 0, 1, 2 and indices modulo 3). See Figure 13, right.

Since each color class has at most  $\lceil \frac{n}{c} \rceil \leq \frac{n}{c} + 1$  points, Q has points with at least four different colors. Let q be a point of Q with a color different than  $p_0, p_1, p_2$ . We can now use  $qp_0, qp_1, qp_2$  to split CH(P), as it was done in the proof of Theorem 7, and to select the piece B with the largest number of points. As it happened there, B has at least  $\frac{n-4}{3}$  points by the pigeonhole principle, and it has at most  $w_0 \leq \left(\frac{1}{c} + \frac{2}{3}\right)n$  points by construction, which means that the other side has at least

$$n - 3 - w_0 \ge n - 3 - \left(\frac{1}{c} + \frac{2}{3}\right)n = \frac{(c - 3)n}{3c} - 3$$

points.

The algorithm to compute the separating path is very similar to the algorithm in Theorem 7.  $\hfill \Box$ 

**Theorem 12.** Assume that  $c \ge 4$  and n is sufficiently large. Let P be a set of n points in general position in the plane with a balanced c-coloring. Then P has a polychromatic connected matching of size at least  $\frac{(c-3)n}{6c} - \frac{1}{2}$  which can be computed in O(n) time.

Proof. We use Lemma 11 to compute a polychromatic  $\left(\frac{(c-3)n}{3c}-3\right)$ -separating path  $\pi$  for P of length 1 or 2. Let A and B be the sets on one side and the other side of  $\pi$ , and set  $k = \min\{|A|, |B|\} \ge \frac{(c-3)n}{3c} - 3$ . We can compute a polychromatic matching M of size k between A and B greedily: at each step, we match a point from A and a point of B with different colors from the two most popular color classes; in this way, different color classes differ by at most one through the whole procedure, and all the points in the smallest side get matched. Since each edge of M crosses  $\pi$ , at least one of the two (or fewer) edges of  $\pi$ , say e, is intersected by |M|/2 edges of M. The edges of M intersecting e together with e form a polychromatic matching of size at least  $1 + \frac{k}{2} \ge 1 + \frac{(c-3)n}{6c} - \frac{3}{2} = \frac{(c-3)n}{6c} - \frac{1}{2}$ . The computation in linear time is easy after obtaining the separating path of Lemma 11.

**Lemma 13.** For  $c \ge 2$  and sufficiently large n, there exists a polychromatic path  $\pi$  with at most 3 edges, and two sets  $P', P'' \subset P$ , each with at least  $\frac{(c-1)n}{3c} - 4$  points, such that each edge connecting a point from P' to a point of P'' intersects  $\pi$ .

*Proof.* The path  $\pi$  we are searching for is essentially a polychromatic (k)-separating path of length at most 3, but now the path may selfintersect and the regions are not obvious.

We closely follow the proof of Lemma 11. The only difference is that we set

$$w_0 = \left\lceil \left(\frac{1}{3c} + \frac{2}{3}\right)n \right\rceil, \quad w_1 = w_0 - (n - b - 1), \text{ and } w_2 = w_0 - (a - 1)$$

(In the proof of Lemma 11 we had  $\frac{1}{c}$  instead of  $\frac{1}{3c}$ .) Like before, we note that

$$w_0 > 0,$$
  

$$w_1 = w_0 - (n - b - 1) \ge \left(\frac{1}{3c} + \frac{2}{3}\right)n - k + 1 > \frac{2n}{3} - \frac{n - 2}{3} + 1 > 0,$$
  

$$w_2 = w_0 - (a - 1) \ge \left(\frac{1}{3c} + \frac{2}{3}\right)n - k + 1 > 0,$$

and then we note that

$$w_{0} + w_{1} + w_{2} \ge 3\left(\frac{1}{3c} + \frac{2}{3}\right)n - (n - b - 1) - (a - 1)$$

$$= 2n + \frac{n}{c} - n + b - a + 2$$

$$\ge \frac{n}{c} + n + b - a + 2$$

$$\ge \frac{n}{c} + (m + 3) + (m + 1) + 2$$

$$\Rightarrow \frac{n}{c} + 2m + 6.$$
using  $m = b - a - 1$  and  $n - 3 \ge m$ 

$$\ge \frac{n}{c} + 2m + 6.$$

This means that, using Theorem 5 we get a set  $Q \subset P$  of at least  $w_0 + w_1 + w_2 - 2m + 3 \ge \frac{n}{c} + 9$ points such that each  $q \in Q$  satisfies the conclusion of Theorem 5: the interior of each triangle  $\triangle(p_{i-1}qp_{i+1})$  has at most  $w_i$  points of P (for i = 0, 1, 2 and indices modulo 3). Recall Figure 13, right.

Since each color class has at most  $\lceil \frac{n}{c} \rceil \leq \frac{n}{c} + 1$  points, Q has points with at least *two* different colors. Let  $q_1 q_2$  be points of Q with different colors. If one of them has a color different than the three points  $p_0, p_1, p_2$ , we can continue as usual. Otherwise, we connect each point  $p_i$  (i = 1, 2, 3) with a point  $q_j$  (j = 1 or j = 2) that has a different color. We also connect  $q_1q_2$ . See Figure 14. These four edges define 3 regions; they may overlap because two (and only two) of the edges may cross. Nevertheless, the same argument as shown before can be used to show that each of the regions defined by the edge  $p_{i-1}p_{i+1}$  contains at most  $w_i$  points. Now a region is bounded by a 3-edge path, which is defined by 4 points.

We can now use these regions to cover CH(P) with three pieces, possibly with an overlap, and to select the piece B with the largest number of points. Let  $\pi$  be the path that together with a portion of the boundary of CH(P) defines B. As it happened in the proof of Lemma 11, B has at least  $\frac{n-5}{3}$  points (instead of  $\frac{n-4}{3}$ ) by the pigeonhole principle, and it has at most  $w_0 \leq (\frac{1}{3c} + \frac{2}{3}) n$  points by construction, which means that the complement has at least

$$(n-4) - w_0 \ge n-4 - \left(\frac{1}{3c} + \frac{2}{3}\right)n = \frac{(c-1)n}{3c} - 4$$

points. (Now we have n - 4, instead of n - 3, because a bounding path has 4 points instead of 3.) We take P' to be the points inside B and P'' the points outside B and not on  $\pi$ . Since

Figure 14: Proof of Lemma 13. Left: Two points  $q_1, q_2$  from Q with different colors. Center and right: two possible configurations and the regions they define. In the right, all three regions share a triangle.

 $\pi$  connects two points on the boundary of CH(P), each edge connecting a point from P' to a point of P'' crosses  $\pi$ .

**Theorem 14.** Assume that  $c \ge 2$  and n is sufficiently large. Let P be a set of n points in general position in the plane with a balanced c-coloring. Then P has a polychromatic connected matching of size at least  $\frac{(c-1)n}{9c} - \frac{1}{3}$  which can be computed in O(n) time.

*Proof.* The proof is very similar to the proof of Theorem 12, but we use Lemma 13. We start using Lemma 13 to obtain the path  $\pi$  and the point sets P' and P'' claimed there. Set  $k = \min\{|P'|, |P''|\} \ge \frac{(c-1)n}{3c} - 4$ . We construct a polychromatic matching M of size k between P' and P'' greedily, as discussed in the proof of Theorem 12. Since each edge of M crosses  $\pi$ , at least one of the three (or fewer) edges of  $\pi$ , say e, is intersected by |M|/3 edges of M. The edges of M intersecting e together with e form a polychromatic matching of size at least  $1 + \frac{k}{3} \ge 1 + \frac{(c-1)n}{9c} - \frac{4}{3} = \frac{(c-1)n}{9c} - \frac{1}{3}$ .

Finally, we compare the bounds of Theorem 12 and Theorem 14. For this, we want to know for which c we have

$$\frac{(c-3)n}{6c} - \frac{1}{2} \geqslant \frac{(c-1)n}{9c} - \frac{1}{3}$$

The first bound is better for c > 7. (For c = 7 we get  $\frac{2n}{21} - \frac{1}{2}$  against  $\frac{2n}{21} - \frac{1}{3}$ ).

# 7 Discussion and Future Work

We have studied the problem of finding a largest connected matching defined by a set of points in the plane. Our upper and lower bounds do no match, and the most obvious open problem is closing the gap.

The problem of crossing families asks for finding a matching in the intersection graph of segments defined by a set of points. In our problem we were only concerned about connectivity. A problem in between is the following:

Question 15. Consider matchings such that the resulting intersection graph is k-connected.

For  $k = \Theta(n)$ , the problem approaches the problem of crossing families. We can also search for matchings whose intersection graph has additional substructures, such as containing a largest star, a Hamiltonian path or a Hamiltonian cycle. Finally, one can consider the algorithmic problem of finding a largest connected matching (or related structures) for a given point set. Acknowledgments. Research on this work has been initiated at the 17th European Geometric Graph Week which was held from August 15th to 19th in Leipzig. We thank all participants for the good atmosphere as well as for inspiring discussions on the topic. Moreover, we thank Florian Thomas for pointing us to a variant of Question 1 which initiated our research.
