(Dated: July 12, 2024)

We study measurement-induced phases of free fermion systems with U(1) symmetry. Following a recent approach developed for Majorana chains, we derive a field theory description for the purity and bipartite entanglement at large space and time scales. We focus on a multi-flavor one-dimensional chain with random complex hoppings and continuous monitoring of the local fermion density. By means of the replica trick, and using the number of flavors as a large parameter controlling our approximations, we derive an effective field theory made up of a SU(N) non-linear sigma model (NL σ M) coupled to fluctuating hydrodynamics. Contrary to the case of non-interacting Majorana fermions, displaying no U(1) symmetry, we find that the bipartite entanglement entropy satisfies an area law for all monitoring rates, but with a nontrivial scaling of entanglement when the correlation length is large. We provide numerical evidence supporting our claims. We briefly show how imposing a reality condition on the hoppings can change the NL σ M and also discuss higher dimensional generalizations.

I. INTRODUCTION

In this paper we analyze the entanglement structure of quantum trajectories of monitored free fermions with U(1) conservation: for example fermions hopping with a Hamiltonian $H = \sum_{\langle ij \rangle} J_{ij} c_i^\dagger c_j$ while an observer makes repeated measurements of the local densities $c_i^\dagger c_i$ [1–3]. The dynamics is nontrivial despite being noninteracting — i.e. despite the fact that the measurements preserve the Gaussianity of the state — because of the random ensemble of evolved states (trajectories) with different measurement outcomes.

For free fermions, any non-zero monitoring rate destroys volume-law entanglement [3], in contrast to monitored interacting systems which show a stable volume law phase [4, 5]. However, recent literature has shown that in some cases free fermion models (potentially without number conservation) exhibit non-trivial phase transitions, and phases with super-area-law entanglement [6–29].

Most previous work has focused on providing numerical evidence supporting the presence of phase transitions, while analytic results were restricted to certain special Majorana circuits [6, 22, 30] or simplified settings where the randomness of quantum measurements is eliminated by complete postselection of the outcomes [9, 18, 21, 31]. Very recently, however, analytic insight has been obtained using field-theoretic descriptions for monitored free fermions [32–34], see also [35]. The starting point of these works is to use the replica trick to average over the randomness, leading to an effective dynamics for N identical copies (or replicas) of the system. In analogy to the construction for monitored random circuits [36–38], which builds on replica approaches to unitary circuits [39] and tensor networks [40], and related mappings [41, 42], the replica trick introduces a symmetry.

For free fermions, the symmetry group allows for continuous rotations between replicas [8, 10, 38, 43]. The continuous replica symmetries give a simple way of understanding the very different phenomenology as compared to interacting systems [38], and in some cases the corresponding field theories allow controlled renormalization group approaches.

In this work we derive the replica continuum theory for fermions with number conservation [U(1) conservation] using the approach developed in Ref. 32 in the setting of Majorana chains. When applied to the U(1)-conserving case, this gives a controlled derivation of a field theory that includes an “entanglement sector” (a replica non-linear sigma model, or NL σ M) that is coupled to other fields describing the hydrodynamics of the conserved density.

This derivation clarifies some vexed points in the recent literature. The fate of U(1)-conserving chains was initially the subject of controversy (about an area law versus a critical state) [3, 7, 10, 17, 20]. Progress was made recently in Ref. 34, where it was appreciated that the ultimate fate of such chains is in fact an area law state, but with an exponentially large correlation length when the monitoring is weak. The SU(N) NL σ M that we derive for the entanglement sector was proposed previously in Ref. 34, using a different microscopic model: while we agree with the qualitative conclusions of that reference, we clarify when this NL σ M is appropriate. We find that the specific model studied in Ref. 34 (and in Refs. [44, 45]) in fact has a larger replica symmetry, leading to a different NL σ M. (See also the related discussion of symmetries in random tensor networks in Ref. [8].) We also analyze in more detail the effect of the conventional hydrodynamic charge mode on the entanglement sector.

In Ref. 32 the replica trick is used to map the dynamics of a model with random-in-time hoppings onto the imag-

inary time evolution of an effective spin chain. Using the number of flavors as a large parameter then allows a controlled continuum limit to be taken. For generic Majorana models, i.e. models without U(1) conservation, this led to a nonlinear sigma model (NL σ M) for an orthogonal $N \times N$ matrix, in the replica limit $N \rightarrow 1$ [32]. (The same field theory was also proposed on grounds of replica symmetry in Ref. [33].) Analysis of this continuum theory then gave an analytical demonstration of the existence of a stable nontrivial phase with $(\ln L)^2$ -scaling of the bipartite entanglement (L being the system size), separated from the area law phase by a transition that may be driven by dimerizing the measurement rates.

These conclusions of Ref. 32 crucially depend on the symmetries (or lack thereof) of the initial Hamiltonian and the measurement process. This is in analogy to Anderson localization, where there is a well-known symmetry classification [46], which has recently been extended to Gaussian tensor networks [8].

For a U(1)-conserving model with density measurements, and no further symmetry constraints, we obtain a continuum Lagrangian of the form (similar to that discussed in Ref. 34)

$$\mathcal{L} = \mathcal{L}_{\text{NL}\sigma\text{M}}[Q, \mathbf{n}] + \mathcal{L}_{\text{ferro}}[\mathbf{n}]. \quad (1)$$

Here $\mathcal{L}_{\text{NL}\sigma\text{M}}$ is a NL σ M for an SU(N) matrix $Q(x, t)$, as opposed to an SO(N) matrix in the Majorana case described above. The field $\mathbf{n}(x, t)$, which formally resembles the order parameter $\mathbf{n} = (n_x, n_y, n_z)$ of an SO(3) Heisenberg ferromagnet, encodes hydrodynamics of the charge (including fluctuations of the charge between different trajectories). The coupling between the two sectors is via the coupling constants of the NL σ M, which depend on the local charge density.

If the hopping amplitudes of the Hamiltonian obey a certain reality condition, then the replica symmetry is enhanced, and a different NL σ M applies. A gauge transformation shows that the reality condition is obeyed for any 1D nearest-neighbor chain with time-independent hoppings, or for any bipartite model with real hoppings. This includes the models of Refs. [34, 44, 45]. We give a more heuristic discussion of this case which suggests that the appropriate NL σ M is that on the manifold SU($2N$)/Sp($2N$) with $N \rightarrow 1$. (The corresponding $N \rightarrow 0$ theory is also discussed in Ref. [8].) It is worth noting that this does not qualitatively alter the physical conclusions of Ref. 34, since the SU($2N$)/Sp($2N$) NL σ M and the SU(N) NL σ M have similar properties when $N \rightarrow 1$.

Contrary to the Majorana case, the SU(N) NL σ M flows under RG to strong coupling, regardless of the monitoring rate. Therefore the NL σ M features no critical phase and, therefore, no phase transition. [Similarly for the SU($2N$)/SO($2N$) NL σ M.] Consistently, we predict that the bipartite entanglement entropy satisfies an area-law for all monitoring rates (in one dimension).

Nonetheless, the correlation length is exponentially large at small monitoring rate [34] or for a model with a

large number of flavors. When the system size is much smaller than the correlation length, the scaling of entanglement is nontrivial: following Ref. [32] we show how scaling forms for the bipartite entropy and for the purity can be obtained using ‘‘RG-improved’’ semiclassical computations of the path integral. In this regime we highlight that there can be a nontrivial effect of charge diffusion on the entanglement.

II. MICROSCOPIC MODEL

We will construct a free-fermion model with no global symmetries except charge conservation, and with a single dimensionless control parameter: the ratio Γ/\mathcal{J} of the monitoring rate Γ and the hopping strength \mathcal{J} . To make the model analytically tractable, we take the couplings in the Hamiltonian to fluctuate like white noise; we consider the limit of a continuous-time measurement process; and we consider the limit of a large number N_F of fermion “flavors”, which justifies a semiclassical derivation of the effective theory for any value of Γ/\mathcal{J} .

None of these choices affects the universal features of the results, which apply to a larger family of models with the same symmetry, including the single-flavor limit ($N_F \rightarrow 1$) of the model defined below, which takes the schematic form

$$H(t) = \sum_j \left(J_j(t) c_j^\dagger c_{j+1} + \text{h.c.} \right), \quad (2)$$

with complex hoppings, together with continuous-time measurements of the local densities $c_j^\dagger c_j$ at a rate Γ . In fact, if Γ/\mathcal{J} is small, then our derivation captures not only the universal physics of this single-flavor model but also the quantitative values of the couplings in the effective theory.

An important caveat is that if the Hamiltonian is fine-tuned, the effective description can be modified due to an enlargement of the replica symmetry. Surprisingly, this occurs for the 1D chain with nearest-neighbor hoppings J_j that are *constant* in time, regardless of the phases of these hoppings. We will discuss this alternative symmetry class in Sec. VII after discussing the more generic case represented by Eq. 2 and its $N_F > 1$ generalization below.

We consider a chain of sites $j = 1, \dots, L_{\text{sys}}$, each hosting N_F complex fermion orbitals, with creation operators $c_{j,\mu}^\dagger$ labelled by the flavor index $\mu = 1, \dots, N_F$. The unitary part of the dynamics is governed by the Hamiltonian

$$H(t) = \sum_{j,\mu,\nu} \left(J_j^{\mu\nu}(t) c_{j,\mu}^\dagger c_{j+1,\nu} + \text{h.c.} + h_j^{\mu\nu}(t) c_{j,\mu}^\dagger c_{j,\nu} \right). \quad (3)$$

The nearest-neighbor hopping matrix elements $J_j^{\mu\nu}$ and onsite matrix elements $h_j^{\mu\nu}$ are complex (with $h_j^{\mu\nu} = \overline{h_j^{\nu\mu}}$) and will be taken to be white noises. Initially the unitary dynamics is characterized by two parameters: a hopping rate \mathcal{J} , which sets the white-noise strength for the inter-site hoppings $J_j^{\mu\nu}$, and another white-noise strength for the on-site matrix elements $h_j^{\mu\nu}$.¹ However we will soon

¹ The mean values of J and h are zero. The nonzero variances are $\mathbb{E} [|dJ_j^{\mu\nu}|^2] = \mathcal{J} dt / N_F$ and $\mathbb{E} [|dh_j^{\mu\nu}|^2] = \mathfrak{h} dt / N_F$, where e.g. $dJ = \int_t^{t+dt} J(t') dt'$. Note that \mathcal{J} and \mathfrak{h} have the dimensions of frequency, i.e. they can be viewed as rates.

take the limit where the variance for the on-site matrix elements $h_j^{\mu\nu}$ tends to infinity, so that the unitary dynamics is characterized only by the typical hopping rate \mathcal{J} .

We note that the onsite matrix elements $h_j^{\mu\nu}$ only have a nontrivial effect for $N_F > 1$: for $N_F = 1$ these terms commute with the measured operators, and as a result they can be gauged away by redefining the inter-site hoppings. This is why they were not written in Eq. 2.

Monitoring modifies this unitary dynamics. The monitored observables are taken to be the local densities $\hat{n}_j^\mu = c_{j,\mu}^\dagger c_{j,\mu}$. A “quantum trajectory” is labelled by the time-series $M_j^\mu(t)$ of random measurement outcomes for each density. Given the hoppings and measurement outcomes, the evolution of the state is

$$\rho(t) = \frac{K(t) \rho_0 K^\dagger(t)}{\text{Tr} [K(t) \rho_0 K^\dagger(t)]}, \quad (4)$$

where the Kraus operator $K(t) = \mathcal{T} e^{-i \int_0^t dt' H_{\text{meas}}(t')}$ is the time-ordered exponential of a *non-Hermitian* “Hamiltonian”:²

$$H_{\text{meas}}(t) = H(t) + i \sum_{j,\mu} M_j^\mu(t) \left(c_{j,\mu}^\dagger c_{j,\mu} - \frac{1}{2} \right) - i \frac{\Gamma N_F L_{\text{sys}}}{4} \quad (5)$$

Given a realization of the couplings, the probabilities for the measurement outcomes M are given by Born’s rule. The physical Born-rule averages $\mathbb{E}[\bullet]$ may be expressed in terms of simpler Gaussian averages $\mathbb{E}_G[\bullet]$:

$$\mathbb{E}[\bullet] = \mathbb{E}_G \left[\bullet \text{Tr} (K(t) \rho_0 K^\dagger(t)) \right]. \quad (6)$$

The quantity \bullet may depend on the full trajectory up to time t , but we will usually take it to be a function of the state at time t . In the Gaussian average, the complex variables J and h and the real variable M are all treated as white noise, with respective variances proportional to³ \mathcal{J} , \mathfrak{h} (which we take to infinity) and Γ . Here Γ is the measurement rate. For more details on the above formalism see Ref. [32]; an alternative formulation is via the stochastic Schrödinger equation (see App A).

III. EFFECTIVE SPIN CHAIN

In the present limit of large variance for the onsite terms $h_j^{\mu\nu}$, we effectively perform Haar-random onsite $U(N_F)$ rotations in every infinitesimal time-step. This on-site randomization simplifies the replica description below. For a pedagogical introduction to the replica formalism in a similar setting, see Ref. 32: here we give a very brief outline.

² The shift of the number operators by $-1/2$ and the constant $-i\Gamma L_{\text{sys}} N_F / 4$ ensure that the Kraus operator are properly normalized: $\mathbb{E}_G [K^\dagger(t) K(t)] = \mathbb{I}$.

³ See the previous footnote for variances of J and h . For M we take $\mathbb{E}_G [(dM_j^\mu)^2] = \Gamma dt$.

For notational convenience we treat the initial density matrix ρ_0 as a *wavefunction* for a “doubled” system, denoting it $|\rho_0\rangle$. We define an averaged evolution for the N th tensor power of this density matrix:⁴

$$\mathbb{E}_{\mathbb{G}} \left[(K(t) \otimes K(t)^*)^{\otimes N} \right] |\rho_0^{\otimes N}\rangle = e^{-tN_F \mathcal{H}} |\rho_0^{\otimes N}\rangle. \quad (7)$$

The average on the left is the simple Gaussian average. On the right, we have taken the average explicitly to give an effective evolution, which involves a time-independent effective Hamiltonian \mathcal{H} that we specify below.⁵ (The constant N_F has been extracted for convenience.) Note that the effective evolution resembles what would usually be called “imaginary time” evolution, although the physical evolution we consider is in real time.

Eq. 7 allows physical averages at time t (taking account of Born’s rule, Eq. 6) to be written as analytic continuations $N \rightarrow 1$ of transition amplitudes $\langle \mathcal{C} | e^{-tN_F \mathcal{H}} | \rho_0^{\otimes N} \rangle$. The required final state $\langle \mathcal{C} |$ depends on the quantity of interest. Ultimately these amplitudes may be written as path integrals for fields with specified boundary conditions [32].

Now we consider the effective Hamiltonian \mathcal{H} . Each physical fermion orbital $c_{j\mu}$ gives rise to $2N$ “replicated” orbitals $c_{j\mu}^\alpha$. We label these by $\alpha = (\sigma, a)$ with $\sigma = \pm$ and $a = 1, \dots, N$, where σ distinguishes between replicas associated with K and K^* operators in Eq. 7. A choice of convention is required, as for example we are free to make a particle-hole transformation on the $\sigma = -$ replicas. In our convention (details in App. B) the total number of replicated fermions on a given site, $\aleph_j = \sum_{\alpha, \mu} c_{j\mu}^{\alpha\dagger} c_{j\mu}^\alpha$, will be a constant of motion of \mathcal{H} , and fixed to NN_F by the initial condition in Eq. 7. By contrast $\sum_{\alpha, \mu} \sigma_\alpha c_{j\mu}^{\alpha\dagger} c_{j\mu}^\alpha$, which differs by the sign factor σ_α , is a dynamical degree of freedom that we relate below to moments of the physical charge density \hat{n}_j .

The effective Hamiltonian \mathcal{H} is quartic in the fermions as a result of the Gaussian averaging in Eq. 7. In the limit of interest where the on-site noise in (3) is strong, \mathcal{H} may be written in terms of bosonic “spin” operators

$$S_j^{\alpha\beta} = \frac{1}{N_F} \left(\sum_{\mu} c_{j\mu}^{\alpha\dagger} c_{j\mu}^\beta - \frac{\delta^{\alpha\beta}}{2N} \aleph_j \right). \quad (8)$$

These operators are $\text{su}(2N)$ generators, normalized so that $[S_j^{\alpha\alpha'}, S_j^{\beta\beta'}] = N_F^{-1} (\delta_{\alpha',\beta} S_j^{\alpha\beta'} - \delta_{\alpha\beta'} S_j^{\beta\alpha'})$. Defining $\hat{\Gamma} := \Gamma N_F / (N_F + 1)$, the effective Hamiltonian is (re-

peated indices summed):

$$\mathcal{H} = \sum_j \left[-\frac{\mathcal{J}}{2} S_j^{\alpha\beta} S_{j+1}^{\beta\alpha} + \frac{\hat{\Gamma} \sigma_\alpha \sigma_\beta}{2} (S_j^{\alpha\beta} S_j^{\beta\alpha} - S_j^{\alpha\alpha} S_j^{\beta\beta}) \right]. \quad (9)$$

The strong on-site noise has projected the dynamics into a subspace of the original replicated Hilbert space: each site hosts a $\text{su}(2N)$ spin in a definite representation, corresponding to a rectangular Young tableau with N rows and N_F columns.⁶ A derivation of \mathcal{H} is given in App. C, including an additive constant that is omitted in Eq. 9 and which ensures that the ground state energy of \mathcal{H} is exactly zero when $N = 1$, as required for the generator of a quantum channel.

For $N = 1$, Eq. 9 retains full $\text{su}(2N) = \text{su}(2)$ symmetry for any measurement rate,⁷ but for general N and $\hat{\Gamma}$ it preserves only $\text{su}(N) \oplus \text{su}(N) \oplus u(1)$, as will be clear in sub-block representation below.

A. Semiclassical ground states

While they remain finite in the limit $N_F \rightarrow \infty$, the operators $S_j^{\alpha\beta}$ commute in this limit. The choice of representation also imposes kinematic constraints on these matrices of the form⁸ $S_j^{\alpha\beta} S_j^{\beta\gamma} = \frac{\delta^{\alpha\gamma}}{4} \mathbb{1} + O(1/N_F)$, which specify the semi-classical phase space.

Given that the average over noise and measurement outcome turns the time-evolution problem into the imaginary time evolution generated by \mathcal{H} , we are interested in understanding the nature of the ground state of \mathcal{H} . For this purpose, we consider first the classical ground states and will later characterize quantum fluctuations on top of them.

At the classical level S_j is a Hermitian matrix which we may decompose as

$$S_j = \begin{pmatrix} L_j + d_j \mathbb{1} & q_j Q_j \\ Q_j^\dagger q_j^* & R_j - d_j \mathbb{1} \end{pmatrix}. \quad (10)$$

⁴ Eq. 7 assumes a choice of local basis, in order to define the complex conjugation of K and in order to map density matrices to states, but the final results are independent of this choice. We discuss the replicated Hilbert space more carefully in App. B.

⁵ In the stochastic Schrödinger picture, these effective Hamiltonians are the association N replica Lindbladians (up to an additive constant).

⁶ These states are invariant under the action of the $\text{su}(N_F)$ flavor (as opposed to replica) symmetry. The $\text{su}(N_F)$ generators are $T_{\mu\nu} = \sum_\alpha c_\mu^{\dagger\alpha} c_\nu^\alpha - \frac{\delta_{\mu\nu}}{N_F} \aleph$. They commute with the $\text{su}(2N)$ generators. With this representation, large N_F gives a semiclassical limit [47].

⁷ Because the $\hat{\Gamma}$ term reduces to a constant at $N = 1$.

⁸ A simple check on this constraint consists in verifying it when acting on the on-site identity state, i.e. checking $S_j^{\alpha\beta} S_j^{\beta\gamma} |\mathbb{I}\rangle = \frac{\delta^{\alpha\gamma}}{4} |\mathbb{I}\rangle + O(N_F^{-1})$, and then arguing that any state with $\aleph_j = NN_F$ is in the $\text{SU}(2N)$ -orbit of $|\mathbb{I}\rangle$. Here $|\mathbb{I}\rangle$ is (up to a choice of normalization) the replicated infinite-temperature density matrix, represented as a ket in the way discussed around Eq 7: see App. G.

These variables satisfy $\text{tr } L_j = \text{tr } R_j = 0$ and $\det Q_j = 1$,⁹ as well as the kinematic constraint above, which reads

$$L_j Q_j + Q_j R_j = 0, \quad (11)$$

$$(L_j + d_j \mathbb{1})^2 + |q_j|^2 Q_j Q_j^\dagger = \mathbb{1}/4, \quad (12)$$

up to $O(1/N_F)$ corrections.

The variable d_j is related to the physical charge $n_j = N_F^{-1} \sum_\mu c_{j\mu}^\dagger c_{j\mu}$ in the unreplicated theory. This is best seen in terms of the quantum operator $\hat{d}_j = \sum_\alpha \sigma_\alpha S_j^{\alpha\alpha} / (2N)$ corresponding to the classical variable d_j , which satisfies

$$\lim_{N \rightarrow 1} \langle \mathbb{1} | \hat{d}_j^k | \rho^{\otimes N} \rangle = \text{Tr} \left[\rho \left(n_j - \frac{1}{2} \right)^k \right]. \quad (13)$$

We will refer to the variables (d, q) as the charge sector and (Q, L, R) as the entanglement sector.

Inserting the block decomposition, the Hamiltonian (9) takes the simple form (up to a constant)

$$\mathcal{H} = \sum_j \left[-\frac{\mathcal{J}}{2} \text{tr} (S_j S_{j+1}) + \hat{\Gamma} \text{tr} (L_j^2 + R_j^2) + 2N \hat{\Gamma}_N d_j^2 \right]. \quad (14)$$

with $\hat{\Gamma}_N = \hat{\Gamma}(1-N)$. Due to the first — ferromagnetic — term, the classical ground states are translation-invariant and, because of the second term, they satisfy $L = R = 0$. This gives the manifold

$$Q^\dagger Q = \mathbb{1}, \quad L = R = 0, \quad d^2 + |q|^2 = 1/4, \quad (15)$$

i.e. $Q \in \text{SU}(N)$. The variables (d, q) in the charge sector parameterize a sphere: in the limit $N \rightarrow 1$, all points on this sphere become degenerate. We will also parameterize this sphere using a unit vector $\mathbf{n} = (q + q^*, i(q^* - q), 2d)$. In a translationally-invariant state the value of d is fixed by the charge density, $d = \sum_j (n_j - 1/2) / L_{\text{sys}}$.

IV. MAPPING TO $\text{SU}(N)$ SIGMA MODEL

The variables Q , d , and q , which parameterize the classical ground states, are the slow modes. Starting from a coherent state path-integral and integrating out the gapped modes L and R , one could obtain the effective Lagrangian describing the large-scale fluctuations of (d, q, Q) . As a shortcut, we shall infer the effective Lagrangian from the semiclassical equations of motion (as in Ref. 32). The derivation is quantitatively controlled in the semi-classical limit $N_F \gg 1$, but we expect that the universal consequences hold for all N_F , as they are largely determined by the symmetries of the effective model.

⁹ The decomposition is not fully unique as for $N > 1$ we can multiply q^{-1} and Q by an N th root of unity, but this will not affect the perturbative analysis of the sigma model below.

The semiclassical equations are obtained as the classical limit of the Heisenberg equations in App. E. Because of the large parameter N_F , the continuum limit can be taken in a controlled way.¹⁰ This amounts to expanding the equations of motion both in spatial derivatives and in powers of the “massive” modes L and R : details are given in App. E. For convenience we make a Wick rotation during this intermediate step, $t = i\tilde{t}$, so that the time evolution resembles Schrodinger evolution in the \tilde{t} coordinate; below, $\dot{Q} = \partial_{\tilde{t}} Q$ etc.

The Heisenberg equations are first order in time derivatives: that for Q is of the form¹¹ $\dot{Q} = 4i\hat{\Gamma} L Q + O(\partial_x^2)$ together with an expression for \dot{L} . Eliminating L by taking another time derivative, the equation of motion for the entanglement sector is

$$Q^\dagger \left[\ddot{Q} - 4\mathcal{J}\hat{\Gamma} \partial_x (|q|^2 \partial_x Q) \right] - \text{h.c.} = 0. \quad (16)$$

The equations of motion for the charge sector are

$$\begin{aligned} i\dot{q} &= \mathcal{J} (q \partial_x^2 d - d \partial_x^2 q) + qd \left[\frac{\mathcal{J}}{N} \text{tr} \partial_x Q^\dagger \partial_x Q - 4\hat{\Gamma}_N \right], \\ i\dot{d} &= \frac{\mathcal{J}}{2} (q^* \partial_x^2 q - q \partial_x^2 q^*), \end{aligned} \quad (17)$$

plus terms of order $O(\partial_x^3, L \partial_x^2)$ in both equations.

Equations (16,17) are the equations of motion of an action which comprises a nonlinear sigma model for the unitary matrix $Q \in \text{SU}(N)$, together with the action for a ferromagnetic spin chain in the charge sector.¹² Returning to the physical time coordinate t , writing the path integral weight as $\exp(-\int dt dx \mathcal{L})$, and writing (q, d) in terms of the unit vector \mathbf{n} ,

$$\mathcal{L} = \mathcal{L}_{\text{NL}\sigma\text{M}}[Q, q] + \mathcal{L}_{\text{ferro}}[\mathbf{n}]. \quad (18)$$

The NL σ M Lagrangian is given by

$$\mathcal{L}_{\text{NL}\sigma\text{M}} = \frac{1}{2g_B} \text{tr} \left(v^{-1} \partial_t Q^\dagger \partial_t Q + v \partial_x Q^\dagger \partial_x Q \right), \quad (19)$$

with a “bare” local coupling constant g_B and local velocity v that depend on $|q|^2$:

$$g_B = \frac{2\sqrt{\hat{\Gamma}}}{N_F |q| \sqrt{\mathcal{J}}}, \quad v = 2|q| \sqrt{\hat{\Gamma} \mathcal{J}}. \quad (20)$$

¹⁰ The parameter N_F stands outside the action in a coherent states path integral. As a result, fluctuations of “massive” modes L and R are small ($L^2 \sim R^2 \sim N_F^{-1}$). Similarly, large-momentum fluctuations of the “Goldstone” modes are strongly suppressed.

¹¹ Above, we neglect the $O(\partial_x^2)$ term because $\partial_t Q$ is of the same order as $\partial_x Q$, as will be clear below; see App. E for a more careful derivation.

¹² The overall coefficient of \mathcal{L} cannot be inferred from the equations of motion, but is fixed by noting that the terms without time derivatives are inherited directly from the Hamiltonian in the coherent states approach [48].

Using Eq. 15, and writing d in terms of the local charge density n via $d = n - 1/2$ (see eq.(13)), we may further write

$$|q| = \sqrt{n(1-n)}. \quad (21)$$

The dependence of Eqs. 20 on $|q|^2$ constitutes the interaction between the charge and entanglement sectors. The Lagrangian for the ferromagnet in (18) is

$$\mathcal{L}_{\text{ferro}} = \frac{NN_F}{2} \left[i(1-n_z)\dot{\varphi} + \frac{\mathcal{J}}{4} |\partial_x \mathbf{n}|^2 + \hat{\Gamma}_N n_z^2 \right]. \quad (22)$$

The first term is the Berry phase for a chain of $\text{su}(2)$ spins of size $NN_F/2$ and unit lattice spacing, expressed in terms of φ — the angle between (n_x, n_y) with the x -axis. Note that $\lim_{N \rightarrow 1} \hat{\Gamma}_N = 0$, so that $\text{su}(2)$ symmetry of the charge sector is recovered in the replica limit. This matches the well-known formulation of charge transport in the classical symmetric exclusion process via the $\text{su}(2)$ ferromagnet [49–52].

Above we obtained precise quantitative results for the couplings by taking $N_F \gg 1$. In fact, we expect that these results remain quantitatively accurate (at sufficiently large scales) even when $N_F = 1$, if we impose the additional condition $\Gamma \ll \mathcal{J}$. This is because in the unitary limit $\Gamma = 0$ the spin chain Hamiltonian (9) becomes an $\text{su}(2N)$ symmetric ferromagnet, whose ground states are simple polarized product states. For small Γ , the low-energy-density states remain locally almost-polarized, so large polarized blocks act like effective spins with a large effective N_F .¹³

If we impose neither $N_F \gg 1$ nor $\Gamma \ll \mathcal{J}$ then the quantitative (bare) values of g and v cannot be assumed to be accurate, but nevertheless the universal consequences of the above theory, discussed below, remain valid. On grounds of replica symmetry, the effective description obtained above applies for “generic” monitored free fermion models with particle number conservation.

The $\text{SU}(N \rightarrow 1)$ NL σ M in the limit $N \rightarrow 1$ was obtained for a microscopic model in a different regime in Ref. [34]. While we agree that this is the correct replica

symmetry class for generic conserved fermion models, in fact we find that it does not apply to the specific model studied in Ref. [34], as a result of the hopping amplitudes in that model being real. Imposing constraints on the phase of the hoppings can lead to an enlarged $\text{su}(2N)$ replica symmetry which we discuss in Sec. VII. Related symmetry observations were made for the $N \rightarrow 0$ limit in Ref. [8].

V. CONSEQUENCES OF THE FIELD THEORY

We start with a schematic overview of the consequences of the continuum description in Eqs. 19, 22, with some details to follow.

A. Regimes of scales and RG flows

The first point to note is that the nonlinear sigma model coupling g is small if either $N_F \gg 1$ or $\Gamma/J \ll 1$ holds. This guarantees that there is a large regime of length and time scales where the theory can be treated “semiclassically” (more precisely, by an RG-improved semiclassics discussed below and in Ref. [32]).

In this “semiclassical” regime, various von Neumann entropies/entanglement entropies can be computed essentially by solving the classical equations of motion. The simplest setting is where the charge density is homogeneous. In this case it is possible to argue that we may deal only with translationally invariant equations for the Q sector. More generally, we must solve the saddle point equations both for the charge and for the entanglement. However, this simplifies considerably for the calculation of the von Neumann entropy: because the matrix Q becomes trivial in the limit $N \rightarrow 1$, the entanglement sector does not feed back on the charge sector, and the latter reduces to standard classical hydrodynamics (App. F).

Although entropies scale nontrivially in the semiclassical regime, this is an intermediate lengthscale effect: the dynamics is ultimately in the *disentangling* phase, because — as discussed in Ref. [34] — the NL σ M flows to strong coupling [46, 54]:

$$\frac{dg}{d\tau} = \frac{N}{4\pi} g^2 + O(g^3). \quad (23)$$

Here τ is the logarithm of the observation lengthscale. Below we will denote lengthscales by L : this should not be confused with the operators L_j discussed above, which will not appear again below. The coupling to the charge fluctuations is irrelevant for this RG flow: see the end of Sec. VB. Integrating this equation for $N = 1$,

$$\frac{1}{g(\ln L)} = \frac{1}{g_B} - \frac{\ln L}{4\pi}, \quad (24)$$

shows that the running coupling $g = g(\ln L)$ becomes of

¹³ Recall that in the usual $\text{su}(2)$ ferromagnet, semiclassics is accurate at low energy densities even in the absence of any other small parameter [53]. The heuristic reason for this is quoted above. Formally, we can make a coarse-graining argument in which we obtain a large parameter b outside the coherent states action by rescaling lengths by a factor of b (and times by a factor b^2). If $\Gamma \ll \mathcal{J}$, the same argument shows that the present spin chain resembles a pure ferromagnet on lengthscales smaller than $b_* \sim \sqrt{\mathcal{J}/\Gamma}$ (at which point the Γ term becomes comparable with the other terms in the action). By coarse-graining to the scale b_* , we acquire an effective “ N_F ” given by b_* . This justifies the derivation given in the text, even if microscopically N_F is equal to 1. (Note that, although in this discussion Γ is assumed to be small, the fact that it is nonzero is important, since on scales $\gtrsim b_*$ it gives a mass to the L and R modes and leads to the effective description in the text.)

order 1 at a lengthscale

$$\xi \asymp \exp\left(\frac{4\pi}{g_B}\right). \quad (25)$$

The standard assumption is that on scales larger than ξ the NL σ M flows to a massive phase [34]. (This is consistent with numerics in Sec. VI.) As a result, the pure states produced by the dynamics at asymptotically late times are *area law* states [3], for any value of Γ/\mathcal{J} , though with a correlation length ξ that is extremely large if the bare value of g is small.¹⁴

The various regimes are illustrated by the form of the bipartite von Neumann entanglement entropy, for a pure state at asymptotically late times in the dynamics. We consider a system of size L , with non-periodic boundary conditions, cut into two halves (Sec. VB). When L is large compared to microscopic scales¹⁵ but still much smaller than ξ , we find

$$S_{\text{vN}}(L) \simeq \frac{\pi \ln L}{3g_B} - \frac{(\ln L)^2}{24} \quad (L \ll \xi). \quad (26)$$

On scales much larger than ξ , $S_{\text{vN}}(L)$ plateaus at an area-law entanglement value of order $\lim_{L \rightarrow \infty} S_{\text{vN}}(L) \propto 1/g_B^2$ (which is of order $g_B^{-1} \ln \xi$).

Note that Eq. 26 takes into account the RG flow of g . Neglecting this flow corresponds to a straightforward saddle-point calculation using the bare action: this gives the first term, $S_{\text{vN}} \propto g_B^{-1} \ln L$. The latter result is valid only when $[\ln L]/[\ln \xi] \ll 1$, which is a more restrictive condition than the $L/\xi \ll 1$ assumed in Eq. 26.

As another example, the decay of (mixed state) entropy density s [55] for a high-entropy initial state (in the thermodynamic limit) takes the form

$$s \simeq \frac{\pi^2}{3} \frac{1}{g(\ln vt)} \frac{1}{vt} \quad (t \ll \xi/v). \quad (27)$$

Again, we have assumed that t is large compared with an appropriate ‘‘microscopic’’ timescale (Footnote 15).

On timescales much larger than ξ/v the sigma model is massive, and the entropy density decays exponentially.

B. Computing entropies

The calculation of entropies was discussed in Ref. [32] in a closely related setting, so here we mention only the new features.

¹⁴ It would be interesting to have a rigorous proof of the existence of a stable area law phase, for example by working with the lattice model in the opposite regime of $\Gamma \gg \mathcal{J}$, $N_F = 1$.

¹⁵ If Γ/\mathcal{J} is of order 1 then it is sufficient to assume $L \gg 1$ (in order for the long-wavelength theory to be valid). In the weak-measurement limit $\Gamma/\mathcal{J} \ll 1$ then we must assume $L \gg \sqrt{\mathcal{J}/\Gamma}$, as a result of the crossover from the unitary theory discussed in Footnote 13 (similarly, for Eq. 27 we require $vt \gg \sqrt{\mathcal{J}/\hat{\Gamma}}$). Ref. [34] considers fermions that are ballistic at small scales, also leading to a crossover phenomenon.

For simplicity let us first consider the regime $\ln L \ll \ln \xi$. In this regime the running coupling (24) is approximately equal to the bare coupling: therefore we can neglect the nontrivial RG flow, and do semiclassics using the bare stiffness $1/g_B$. Let us also first consider the case where the charge density n is uniform (on scales much larger than the lattice spacing).

Computations of entropies (either the mixed state entropy or the entanglement entropy) require us to compute the partition function of the field theory with appropriate boundary conditions for both Q and \mathbf{n} , discussed in App. G and Ref. [32]. For concreteness, consider the mixed state entropy. We must then compute the $N \rightarrow 1$ limit of a partition function with $Q = \mathbf{1}$ at the initial time, and with $Q = Q_{\text{vN}}$ at the final time where

$$Q_{\text{vN}} \equiv \begin{pmatrix} 0 & 0 & \cdots & 0 & +1 \\ -1 & 0 & \cdots & 0 & 0 \\ 0 & -1 & \cdots & 0 & 0 \\ \cdots & & & & \\ 0 & 0 & \cdots & -1 & 0 \end{pmatrix}. \quad (28)$$

(Up to signs, this matrix represents a cyclic permutation of the N replicas.) In the present setup, the charge sector has a trivial saddle-point solution, in which $|q| = \sqrt{n(1-n)}$ is a constant that simply sets g and v in the NL σ M action. The only nontrivial saddle-point equation is then (16), Wick-rotated back to the physical t coordinate:

$$Q^\dagger \left[\partial_t^2 Q + 4\mathcal{J}\hat{\Gamma} \partial_x (|q|^2 \partial_x Q) \right] - \text{h.c.} = 0. \quad (29)$$

Further, for the present boundary conditions, Q is real. As a result, the solution lies in the submanifold $\text{SO}(N) \subset \text{SU}(N)$, and reduces to that discussed in [32]: $Q = Q(t)$ interpolates smoothly between the initial and final conditions. Evaluating the action of this saddle point and taking the replica limit (see Sec. VI of [32]) gives the result in Eq. 27. Similar considerations give the bipartite entanglement entropy in the present regime of lengthscales ($\ln L \ll \ln \xi$).

An additional subtlety in comparison to Ref. [32] is that, for general initial conditions, we must also solve the saddle-point equations for the charge sector [51, 56, 57]. For general N , these are affected by the entanglement sector. However, we argue that, in the calculation of the von Neumann entropy, the replica limit is straightforward for the charge equations of motion. We may directly set $N = 1$ in these equations, and use the fact that Q becomes a trivial constant in this limit ($Q = 1$).

We note that this simplification holds for the von Neumann entropy — for which the boundary conditions have a straightforward $N \rightarrow 1$ limit — but may not hold identically for other observables, such as the averaged purity.¹⁶

¹⁶ For the boundary conditions appropriate to the von Neumann

The charge equations of motion are then those of the (“imaginary time”) ferromagnet [51, 57], and are discussed in App. F. For all the cases that we discuss, they reduce to conventional hydrodynamics of the physical charge density n :¹⁷

$$\partial_t n = \frac{\mathcal{J}}{2} \partial_x^2 n. \quad (30)$$

Above we have restricted to cases where n is simply constant, but the approach applies more generally. Note that charge transport takes place diffusively (dynamical exponent $z_n = 2$), while the entanglement sector has the dynamical exponent $z_Q = 1$.

So far we have considered pure semiclassics. On larger scales (even when $L \ll \xi$) we must take into account the running of the coupling. This is described in Ref. [32]. For the purification setup (27) it is sufficient to run RG up to the lengthscale vt , and then do semiclassics using the renormalized coupling at this scale (24). For the bipartite entropy, we must integrate over lengthscales at increasing distances from the entanglement cut, using the renormalized coupling appropriate to each scale. This integral gives Eq. 26.

Finally, we comment on the role of the charge sector in the renormalization group flow of the NL σ M. We argue that the coupling between the two sectors is in fact RG-irrelevant, so that we are justified in using the standard beta function for the NL σ M (23). Indicating the space-time coordinate by $\mathbf{y} = (x, t)$, the coupling between the two theories in Eq. 19 is of the form $\int d\mathbf{y} n_z^2(\mathbf{y}) \mathcal{O}(\mathbf{y})$ with $\mathcal{O} = \text{tr}[(\partial_x Q^\dagger) \partial_x Q]$. We can imagine integrating out \mathbf{n} to obtain a Lagrangian involving only Q . By the cumulant expansion, this generates terms of the form

$$\int d^2\mathbf{y}_1 \dots d^2\mathbf{y}_k \Delta^{(k)}(\mathbf{y}_1, \dots, \mathbf{y}_k) \mathcal{O}(\mathbf{y}_1) \dots \mathcal{O}(\mathbf{y}_k), \quad (31)$$

where $\Delta^{(k)}(\mathbf{y}_1, \dots, \mathbf{y}_k)$ is the *connected* k -point correlation function for n_z (computed using the Lagrangian of

entropy, Q becomes a trivial constant ($Q = 1$) in the $N \rightarrow 1$ limit. [The quantity $\text{tr}(\partial_x Q^\dagger) \partial_x Q$ is of order $N - 1$ for the solutions we consider (App. F).] For other observables the replica limit may be more complex. The average purity is an example: in that case, the N -dependent boundary condition for Q is a matrix that is defined for $N > 1$ but not for $N = 1$. In that case, a priori we should solve the saddle-point equations for both sectors in full for $N > 1$ and analytically continue only after obtaining the action. There may be a physical reason for this difference. The average of the purity is the average of e^{-S_2} , where S_2 , the second Rényi entropy, is proportional to $1/g_B \asymp N_F$ in the regime we are discussing. Since this large factor appears in the exponent, inserting the purity into the average may bias the ensemble of quantum trajectories [58] away from those that are typical. This effect is probably subleading at large scales, however, since S_2 scales at most logarithmically with scale in the present model, while imposing a rare charge fluctuation on a large scale incurs a polynomial cost.

¹⁷ More general final-time boundary conditions (e.g. conditioning on a final-time charge profile as well as an initial-time profile) lead to two nontrivial equations [51, 56, 57], see App. F.

the charge sector) which decays as a power law at large times/distances. (In fact these correlations are Gaussian at leading order and match standard classical fluctuating hydrodynamics for a conserved density.¹⁸) Since \mathcal{O} is a marginal operator at the $g = 0$ fixed point, all these terms are *irrelevant*, except for the first one, $\langle n_z^2 \rangle \mathcal{O}(\mathbf{y})$, which simply forms part of the standard translation-invariant NL σ M action. Thus we are justified in considering only the RG for the pure NSLM, in which $\langle n_z^2 \rangle$ — which at large N_F is also approximately equal to $\langle n_z \rangle^2$ — appears only as a parameter setting the bare couplings.

C. Higher-dimensional models

The derivation we have given for the continuum field theory extends immediately to higher-dimensional versions of the models in Eqs. 2, 3. In higher dimensions the NL σ M has a phase transition between a nontrivial phase and an area-law phase [44, 59]. (In $d = 1 + \epsilon$ spatial dimensions, we can see the presence of a phase transition at a critical point g_* by including the tree level term, “ $-\epsilon g$ ”, on the right-hand-side of Eq. 23.) The nontrivial phase at $g < g_*$ is the one in which the NL σ M flows to weak coupling, which means that the scaling forms obtained by straightforward semiclassics are valid on asymptotically large lengthscales. For $g > g_*$ the NL σ M flows to a massive area-law phase.

In d spatial dimensions this leads to a bipartite entanglement entropy scaling as $\frac{1}{g_B} L^{d-1} \ln L$ in the nontrivial phase [44, 59]. This scaling also holds for a stable phase in a simpler model of projectively measured Majoranas above one dimension [6], for similar reasons [38].

At the higher-dimensional critical point for U(1) fermions, we must check the relevance/irrelevance of coupling between charge fluctuations and the entanglement sector. The equivalent issue has been examined recently for the measurement-induced critical point in *interacting* quantum circuits [60], where charge fluctuations are generically RG-*relevant* in 1+1D.

Here, we saw above that charge fluctuations can couple to local SU(N)-invariant operators: in particular, the microscopic derivation shows that there is a coupling between the charge density and $\mathcal{O} = \text{tr}[(\nabla Q^\dagger) \nabla Q]$. At the critical point (and at long wavelengths), \mathcal{O} is equivalent to the relevant operator which drives the phase transition between trivial and nontrivial phases. As in the inter-

¹⁸ Writing $n_z = \langle n_z \rangle + \delta n_z$, one convenient rewriting of the charge Lagrangian is in terms of $h(x, t) = \int_0^x dx' \delta n_z(x')$. After integrating out the angle in the (n_x, n_y) plane, h has a free field action with dynamical exponent $z_n = 2$. As an aside: above we have discussed the case where the charge is at equilibrium. But even if the charge is driven out of equilibrium by connecting to boundary reservoirs at different chemical potentials, this leads to a current of order $1/L$ at large L , so that in the limit $L \rightarrow \infty$ the RG flow for g will be unaffected.

acting case, the Harris criterion shows that the charge-entanglement coupling is irrelevant if $\nu > 2/d$, where ν is the correlation length exponent [60].¹⁹

The one-loop result in the $d = 1 + \epsilon$ expansion is $\nu = 1/\epsilon$, so that the charge coupling is formally irrelevant for very small epsilon. It requires simulations to establish what happens for $d = 2$ or $d = 3$.

In Refs. [44, 59], models in $d = 2$ spatial dimensions were simulated, and Ref. [44] found a critical point with $\nu \approx 1.4$. In Sec. VII we argue that, because of a symmetry constraint, the models in Refs. [44, 59] are described by the sigma model on the target space $SU(2N)/Sp(2N)$, rather than the sigma model on $SU(N)$ as was believed previously. Therefore these lattice models are slightly different from the models we have been discussing so far in this section. Nevertheless, we expect a similar effective field theory, coupling charge and entanglement degrees of freedom, in the $SU(2N)/Sp(2N)$ symmetry class.

At first sight, the result $\nu \approx 1.4$ then indicates that the charge-entanglement coupling is irrelevant in that symmetry class in $d = 2$ spatial dimensions. This seems very plausible, since ν values larger than 1 are encountered for many related Anderson localization sigma models. Strictly, however, to draw this conclusion one would need to check that the critical point found numerically is the one governed by the pure $SU(2N)/Sp(2N)$ model, and not by a different fixed point that is influenced by charge fluctuations. Evidence that the dynamical exponent was unity would be an indication that the transition is indeed governed by the pure $NL\sigma M$.

The discussion above applies to the critical point. One could further ask if the $\mathbf{n}\text{-}Q$ coupling can affect the entanglement scaling in the ordered phase (the nontrivially entangled phase). Proceeding as in footnote 19, it is easy to check that the $\mathbf{n}\text{-}Q$ coupling is irrelevant in the ordered phase.

VI. NUMERICAL RESULTS

In this section, we confirm the drift towards $g \rightarrow \infty$ numerically by simulating the stochastic Schrodinger equation for $N_F = 1$ using the technique of Ref. [3]. We give an explicit proof of the validity of the method in App. H.

Starting from a product state of alternating filled and empty sites (i.e. half-filling on average), we study the bipartite entanglement scaling for various values of Γ/\mathcal{J} . We analyze the scaling of the bipartite entanglement entropy in the states produced by the dynamics at late

times, in order to compare with Eq. 26 and the surrounding discussion.

We first compute the (trajectory-averaged) von Neumann entropy $S_{vN}(t, L)$ as a function of time after the “quench”. For a given system size L , $S_{vN}(t, L)$ eventually plateaus. We define $S_{vN}(L)$ by averaging $S_{vN}(t, L)$ over t in an interval $[t_{\text{plateau}}, t_{\text{max}}]$, where t_{plateau} is determined by eye and t_{max} is the maximum time we reach in our simulations. We checked that our results are not sensitive to the choice of t_{plateau} or the time step δt used to discretize the stochastic Schrodinger equation. Raw data is shown in App. I.

In Fig. 1, $S_{vN}(L)$ is reported as a function of $\ln L$. Recall that if the steady-state ensemble was scale-invariant, these plots would become straight lines. Our theoretical expectation is that the curves will instead bend downwards and give a finite value of $\lim_{L \rightarrow \infty} S_{vN}(L)$.

For $\Gamma/\mathcal{J} \lesssim 1$ we already see that S_{vN} curves downward and for $\Gamma/\mathcal{J} = 2$, S_{vN} reaches a constant value (within error bars) at $L = 64$.

For a more quantitative examination of the curvature, in Fig. 2 we report the discrete logarithmic derivative

$$\Delta S_{vN}(L) = \frac{S_{vN}(L) - S_{vN}(L/2)}{\ln 2} \quad (32)$$

as a function of $\ln L$. For comparison, Eq. 26 predicts that, in the regime (of small renormalized coupling) where ΔS_{vN} is large,

$$\Delta S_{vN}(L) \approx \frac{\pi}{3} g_B^{-1} - \frac{1}{12} \ln L \quad (33)$$

plus terms of order 1. We see that our simulations are not in the regime $g_B \ll 1$, so are far away from the region where the perturbative calculation of $\frac{dg}{d \ln L}$ is applicable. Thus, we cannot expect (26) to be accurate. Nonetheless, we see that the behaviour is qualitatively similar to the predicted one, and even the observed slope of ΔS_{vN} is not far from the limiting value $-1/12$ at large g_B^{-1} .

To quantitatively check the universal $1/12$ coefficient in Eq. 33 it would be necessary to achieve a larger g_B^{-1} , either through larger N_F , or through smaller Γ/\mathcal{J} . The latter requires large length and time scales, because of the crossover from the unitary behavior which obtains for $\Gamma = 0$.

VII. ENLARGED REPLICIA SYMMETRY FOR FIXED-PHASE HOPPING

Above we considered models where the phases of the hoppings J_j change randomly in time. The resulting symmetry class also includes sufficiently generic models with time-independent hoppings. Formally, this is because both kinds of model have the same replica symmetry.

However, it was appreciated in Ref. [8] in the closely-related setting of non-unitary circuits that imposing constraints on the hoppings can lead to a larger replica symmetry and a different $NL\sigma M$. (Ref. [8] noted for example that this enlarged replica symmetry applied to the

¹⁹ In the language of Eq. 31, we may obtain this condition by examining the scaling dimension of the term with $k = 2$, taking into account the scaling dimension $x = d + 1 - 1/\nu$ of the relevant operator driving the transition [61]. Since the dynamical exponent for the charge is $z = 2$ whereas the entanglement critical point has $z = 1$ we approximate the charge as static, i.e. we approximate $\Delta^{(2)}$ as a time-independent spatial delta function.

Figure 1. S_{vN} averaged over the time interval $[t_{\text{plateau}}, t_{\text{max}}]$ (see text). The statistical errors associated with each dot are not visible on the plot scale.

Figure 2. ΔS_{vN} reported a function of $\ln L$. The behavior is approximately linear, in qualitative agreement with (26). A gray dashed line reports the slope expected from Eq. (26). The statistical errors associated with each dot are not visible on the plot scale.

nonunitary circuit in Ref. [23].) To complement the algebraic analysis in Ref. [8], we give a simple discussion for a general free-fermion Hamiltonian system with monitoring of occupation numbers. Note that enlarged replica symmetry was also discussed in setting of monitored Majorana chains in Ref. 32.

The extended replica symmetry holds on a general lattice (in any number of dimensions) iff, after a gauge transformation of the physical fermion operators,²⁰ all the hopping amplitudes J_{ij} can be made imaginary. This

is equivalent to saying that for every plaquette P of the lattice (or generally for every loop made of bonds) the “gauge flux” $\phi_P = \sum_{(i,j) \in P} \arg J_{ij}$ takes the value $\phi_P = \pi n_P$ (modulo 2π), where n_P is the number of edges of P .

In particular, this includes all nearest-neighbor chains in which the phase of the hoppings is time-independent, including the models in Refs. [7, 14, 20, 23, 34]. Other notable cases are bipartite lattices with real hopping amplitudes [44, 45].

When the above condition holds, the effective Hamiltonian commutes with a set of $\text{su}(2N)$ generators even in the presence of measurement, rather than just $\text{su}(N) \oplus \text{su}(N)$ as in the more generic setting discussed in the rest of this paper. This $\text{su}(2N)$ symmetry becomes apparent after making a particle-hole transformation for the replicas with $\sigma = -$, see Appendix J.

We do not here derive the effective field theory for the case with enlarged replica symmetry, though this could be approached using similar methods to the present ones, for a model with e.g. random imaginary hoppings J_{ij} . However, we can guess the appropriate $\text{NL}\sigma\text{M}$ manifold by considering the action of $\text{SU}(2N)$ symmetry on the replicated infinite-temperature state. This is discussed in App J and gives the manifold $\text{SU}(2N)/\text{Sp}(2N)$. This $\text{NL}\sigma\text{M}$ manifold is consistent with the symmetry considerations for the $N \rightarrow 0$ limit in [8].

Although the $\text{NL}\sigma\text{M}$ on $\text{SU}(2N)/\text{Sp}(2N)$ is different to the one on $\text{SU}(N)$ discussed in the rest of this paper, the qualitative features of the renormalization group flow in the limit $N \rightarrow 1$ are similar, because although the beta functions of the two models are not identical, both have a positive sign for the $O(g^2)$ term when $N \rightarrow 1$. Therefore we expect a similar physical picture: the monitored system is in an area-law phase, but if the bare $\text{NL}\sigma\text{M}$ coupling is small there is a semiclassical regime with (loosely speaking) logarithmic scaling of entanglement. In this semiclassical regime, the “entanglement” degrees of freedom will again be sensitive to the charge density.

VIII. CONCLUSIONS & FUTURE DIRECTIONS

In this paper we have given a precise derivation of the effective continuum field theory for monitoring of charge-conserving free fermions. This derivation illuminates the effect of conserved charge modes (hydrodynamics) on the entanglement entropy. It also clarifies the symmetry of the nonlinear sigma model, which has not been so straightforward to fix in other approaches [34, 44, 59].

The present approach is controlled by a simple large parameter (N_F), and allows us to take into account the initial states and boundary conditions relevant to computations of entanglement entropies. Using these results we have given scaling forms that are universal in the “renormalized semiclassical” regime of lengthscales $L \ll \xi$ that are much smaller than the typical lengthscale for entan-

²⁰ A redefinition $c_j \rightarrow e^{-i\chi_j} c_j$, with time-independent χ_j .

gement. Recall that in 1+1 dimensions ξ can be exponentially large in microscopic parameters such as N_F or the inverse measurement rate Γ^{-1} (and in higher dimensions ξ can be infinite).

The continuum theory derived here is applicable to essentially any observable that is nonlinear in the density matrix, such as the statistics of charge fluctuations [34], relevant to “charge sharpening” [62].²¹

More generally, the replica field theory approach could be used to study the detailed fluctuating hydrodynamics of charge in both unitary and nonunitary noisy dynamics of free fermions. In the unitary case this will involve studying Goldstone fluctuations in a Lagrangian analogous to Eq. 22 for an $\text{su}(2N)$ ferromagnet [52].

Monitored fermion systems give a new class of phase transitions to explore. It will be interesting to study the zoology of critical points in $N \rightarrow 1$ NLSMs both in 1+1 and in higher dimensions, and to explore the analogies/contrasts with critical points both at $N > 1$ (i.e. conventional ground state phase transitions in spin models [48]) and at $N \rightarrow 0$ (i.e. Anderson localization transitions [46] or transitions in random Gaussian tensor networks [8]). It would also be worthwhile to develop a simple understanding, for completely general free fermion measurement problems, of how physical symmetries or constraints on the Hamiltonian and the monitored operators determine the $\text{NL}\sigma\text{M}$ symmetry class [8]. See Sec. VII above for the case of $\text{U}(1)$ -conserving fermions with measurements of the local density, where we have contrasted generic hopping Hamiltonians from those which give rise to “real” Kraus operators and therefore an enlarged replica symmetry, and see Sec. VIII of [32] for the analogous issue in the case of Majoranas.

Another natural question is whether there are generic differences between the $N \rightarrow 1$ and $N \rightarrow 0$ classes of sigma models that are imposed by the different replica group theory structure. For the models discussed here, with target spaces $\text{SU}(N)$ or $\text{SU}(2N)/\text{Sp}(2N)$, it is worth noting that while the $N \rightarrow 1$ sigma models are ultimately massive in 1+1D, the $N \rightarrow 0$ sigma models are critical [8, 46]. (This is related to the factor of N in the beta function in Eq. 23.) Intuitively, this difference is consistent with the fact that in the limit of strong continuous-time measurement of local densities we clearly obtain an area-law state with well-localized fermions [3], whereas continuous-time *forced* measurement of local densities does not effectively localize fermions. This also has a single-particle analog [63]. The role played by the charge sector of the effective field theory is also quite different at $N \rightarrow 0$ and at $N \rightarrow 1$, since it is only in the latter case that this sector has diffusive scaling.

In the future it would be possible to study the effect of out-of-equilibrium charge hydrodynamics on the von Neumann entropy in more detail by finding solutions to

the saddle-point equations²² in Eq. 30 for, say, nontrivial initial charge profiles or for boundary driving [64–66]. The results could then be compared to the effect of charge flow on the mutual information of the Quantum Symmetric Simple Exclusion Process (i.e. in the unitary case) [64]. As noted above, the regime in which this semiclassical approach is valid can extend over a very large range of scales even in one dimension if g_B is small, and over arbitrarily large scales in higher dimensions. Since the dynamical exponent for charge diffusion is 2 — whereas the natural dynamical exponent for the entanglement sector is 1 — the saddle-point problem may simplify in some settings where we can approximate the charge density profile as static.

Another interesting topic is the crossover induced by *interactions* between the physical fermions. Adding 4-fermion terms to the physical Hamiltonian breaks the continuous replica symmetry of the entanglement sector down to a discrete symmetry. The simplest setting is the Majorana model of Ref. [32], where the analog of the matrix Q is a real $\text{SO}(N)$ matrix obeying a nonlinear sigma model action (and there is no charge sector to consider). Weak 4-Majorana terms lead to an additional potential which reduces the continuous ground state manifold of the sigma model, $\text{SO}(N)$, to a discrete set. It would be interesting to analyze semiclassical solutions in this model, extending the analysis for the ($N = 2$) unitary case in Ref. [57]. This is a route to an effective theory for interacting monitored systems that differs from previous approaches [67, 68].

In passing, we note that, while we have focussed on monitored dynamics, formally similar problems arise if we measure the physical degrees of freedom in the bulk of a 2D random PEPS wavefunction or similar. Again the $N \rightarrow 1$ limit arises naturally to handle Born’s rule and in the free fermion case we expect an $\text{NL}\sigma\text{M}$ description. This context allows for a larger family of tensor networks that do not represent Kraus operators [68], so allows for additional tuning parameters.

Progress could also be made on the formalism for the free fermion dynamics problems. In the context of Anderson localization it is well known that an alternative to replicas is the “supersymmetry” method [69], in which the path integral is formulated using bosons and fermions. In the present model, the replica spin chain (9) would become a chain of interacting superspins [70–72]. It would be interesting to see how the separation of the charge and entanglement sectors works in this formalism. The supersymmetric formalism might also give a simple picture for the strongly disentangled limit, in terms of a product ground state of the superspin chain.

Finally, we note that at present there is a lack of

²¹ We thank S. Gopalakrishnan for discussions of this point.

²² For more general final-time boundary conditions we must use the equations in App. F. In general we must also use the appropriate scale-dependent $\text{NL}\sigma\text{M}$ coupling in solving the saddle-point equations.

mathematically rigorous results for the phase structure of monitored many-body systems (we lack even proofs of the stability of “trivial” disentangled phases). The formal analogies with Anderson localization give hope that the free fermion setting may be simpler in this regard than the interacting case.

Appendix A: Stochastic formulation of quantum trajectories and their linearisation

We explain here the link between the $N \rightarrow 1$ replica trick and the stochastic formulation of quantum trajectories. The latter are non-linear, quadratic, stochastic differential equations (SDE). They can be linearized at the price of changing the measure and applying Girsanov’s theorem in a way similar to the $N \rightarrow 1$ replica trick.

Let us start with the simplest case of quantum trajectories with a single monitored operator. For a quantum system with density matrix ρ_t and hamiltonian H , and a monitored operator $Q + Q^\dagger$, these equations are:²³

$$d\rho_t = -i[H, \rho_t]dt + \mathcal{L}_Q(\rho_t)dt \quad (\text{A1})$$

$$+ (Q\rho_t + \rho_t Q^\dagger - \rho_t \text{tr}(Q\rho_t + \rho_t Q^\dagger))dB_t ,$$

$$dY_t = \text{tr}(Q\rho_t + \rho_t Q^\dagger)dt + dB_t , \quad (\text{A2})$$

with $\mathcal{L}_Q(\rho) = Q\rho Q^\dagger - \frac{1}{2}(\rho Q^\dagger Q + Q^\dagger Q\rho)$ the Lindbladian associated to the so-called jump operator Q . Here B_t is a normalized Brownian motion w.r.t. some measure that we denote \mathbb{E} , $dB_t^2 = dt$ (we shall call a \mathbb{E} -Brownian motion a Brownian motion w.r.t. the measure \mathbb{E}), and Y_t is the output signal of the “monitored” (not measured) operator $Q + Q^\dagger$.

In the case considered in the main text, Q is Hermitian and proportional to a fermion occupation number, but here we allow for a more general monitoring protocol. For instance, if we would like to monitor the current $j_k := i(c_k^\dagger c_{k+1} - c_{k+1}^\dagger c_k)$ we could choose $Q = ic_k^\dagger c_{k+1}$.

The linearization of those quantum trajectories, and hence the replica trick, amounts to showing that these equations are equivalent to the following linear equations for an un-normalized matrix $\check{\rho}_t$,

$$\rho_t = \check{\rho}_t / \text{tr}\check{\rho}_t, \quad (\text{A3})$$

$$Y_t = X_t, \quad (\text{A4})$$

$$d\check{\rho}_t = -i[H, \check{\rho}_t]dt + \mathcal{L}_Q(\check{\rho}_t)dt + (Q\check{\rho}_t + \check{\rho}_t Q^\dagger)dX_t, \quad (\text{A5})$$

with X_t a normalized Brownian motion w.r.t. to another measure \mathbb{E}_0 , provided we define the previous measure by

$$\mathbb{E}[\dots] = \mathbb{E}_0[(\text{tr}\check{\rho}_t)(\dots)] . \quad (\text{A6})$$

In particular,

$$\mathbb{E}[\rho_t \otimes \dots \otimes \rho_t] = \mathbb{E}_0[(\text{tr}\check{\rho}_t) \frac{\check{\rho}_t}{\text{tr}\check{\rho}_t} \otimes \dots \otimes \frac{\check{\rho}_t}{\text{tr}\check{\rho}_t}] , \quad (\text{A7})$$

as in the setup for the replica trick, where we would go on to write this formula (for the case where there are k factors of ρ_t on the left-hand side) as

$$\mathbb{E}[\rho_t \otimes \dots \otimes \rho_t] = \lim_{N \rightarrow 1} \mathbb{E}_0[(\text{tr}\check{\rho}_t)^{N-k} \check{\rho}_t^{\otimes k}] . \quad (\text{A8})$$

The proof of Eq. A3-A6 is based on Girsanov’s theorem (see e.g. [73, 74]). Let us start with (A5) for $\check{\rho}_t$ and recall that X_t is an \mathbb{E}_0 -Brownian motion. We let $Z_t := \text{tr}(\check{\rho}_t)$, with $Z_{t=0} = 1$, and $M_t Z_t := \text{tr}(Q\check{\rho}_t + \check{\rho}_t Q^\dagger)$. Note that $M_t := \text{tr}(Q\rho_t + \rho_t Q^\dagger)$ with $\rho_t = \check{\rho}_t / \text{tr}\check{\rho}_t$. We let $\mathcal{L}(\rho) := -i[H, \rho] + \mathcal{L}_Q(\rho)$.

First (about the change of measure), Z_t is bounded and satisfies $dZ_t = Z_t M_t dX_t$ so that Z_t is \mathbb{E}_0 -martingale. In particular, $\mathbb{E}_0[Z_t] = 1$ is time independent. We deform the measure \mathbb{E}_0 by $\mathbb{E}[\dots] = \mathbb{E}_0[(Z_t)(\dots)]$, as in (A6). By Girsanov’s theorem, B_t defined by $dB_t = dX_t - M_t dt$ is then a \mathbb{E} -Brownian motion. That is:

$$dX_t = M_t dt + dB_t , \quad (\text{A9})$$

with B_t a \mathbb{E} -Brownian motion (but not a \mathbb{E}_0 -Brownian motion).

Second (about the SDE), since $dZ_t = Z_t M_t dX_t$ we have $dZ_t^{-1} = -Z_t^{-1} M_t dX_t + Z_t^{-1} M_t^2 dt$, via Ito calculus. Define $\rho_t := Z_t^{-1} \check{\rho}_t = \check{\rho}_t / \text{tr}\check{\rho}_t$. We have

$$d\rho_t = Z_t^{-1} d\check{\rho}_t + (dZ_t^{-1})\check{\rho}_t + (dZ_t^{-1})d\check{\rho}_t ,$$

via Ito calculus. Expanding yields

$$d\rho_t = \mathcal{L}(\rho_t)dt + (Q\rho_t + \rho_t Q^\dagger)(dX_t - M_t dt) - \rho_t M_t (dX_t - M_t dt) . \quad (\text{A10})$$

Using $dX_t = M_t dt + dB_t$ and $M_t = \text{tr}(Q\rho_t + \rho_t Q^\dagger)$, this reproduces (A1) and (A2).

The quantum trajectory equations (A1) and (A2), and the statement about their linearization, can clearly be generalized with a collection of operators $Q \rightsquigarrow Q_j$ and Brownian motions $dB_t \rightsquigarrow dB_t^j$, as in the problem studied in the main text. It can also be generalized with $-i[H, \rho_t] \rightsquigarrow -i[H, \rho_t] + \mathcal{L}_{\text{sys}}(\rho_t)$ for some system Lindbladian \mathcal{L}_{sys} .

²³ There is another version with Poisson noise.

Appendix B: Fermionization of the replicas

In this section, we introduce a replicated Hilbert space for the problem. This issue was already solved in a number of context [32, 52, 75, 76], nonetheless, we summarize it here to make the manuscript self-contained and to fix the notation.

Loosely speaking, the replicated is a tensor product of N copies of the Hilbert space of a single chain. However, subtleties arise due the fact that tensor product of fermionic Fock spaces are non-trivial to define. We circumvent this problem by transforming the original fermionic Fock space into a standard Hilbert space, for which replicas can be trivially defined, and, finally, by reintroducing fermionic operators in the replicated Hilbert space.

On a single copy we write the fermionic operators in terms of spin-1/2 operators through a Jordan-Wigner transformation.

$$c_k = \left(\prod_{k' < k} Z_{k'} \right) S_k^+, \quad c_k^\dagger = \left(\prod_{k' < k} Z_{k'} \right) S_k^-. \quad (\text{B1})$$

In terms of the bosonic (spin) Hilbert space \mathcal{H}_B , we can consider tensor products and map operators to states in a doubles Hilbert space

$$O = \sum_{i,j} O_{ij} |i\rangle \langle j| \quad \mapsto \quad |O\rangle = \sum_{i,j} O_{ij} |i\rangle \otimes |j\rangle. \quad (\text{B2})$$

Note that the isomorphism above is basis-dependent, but the actual choice of basis is inconsequential for our treatment. N replicas of a density matrix can be then identified with states in $\mathcal{H}_{2N} = (\mathcal{H}_B)^{\otimes 2N}$. In this space we can define replicated Pauli operators

$$V_k^{(+a)} = \mathbb{I}^{\otimes 2a} \otimes V_k \otimes \mathbb{I}^{\otimes 2N-2a-1} \quad (\text{B3})$$

$$V_k^{(-a)} = \mathbb{I}^{\otimes 2a+1} \otimes V_k \otimes \mathbb{I}^{\otimes 2(N-a-1)} \quad (\text{B4})$$

with $V = X, Y, Z$ and \mathbb{I} denoting the identity on the space \mathcal{H}_B . Our final aim is to define fermionic operators in this space. As an intermediate step, we introduce the operators $\chi_k^{(\sigma a)}$:

$$\chi_k^{(+a)} = \mathbb{I}^{\otimes 2a} \otimes c_k \otimes \mathbb{I}^{\otimes 2N-2a-1} \quad (\text{B5})$$

$$\chi_k^{(-a)} = \mathbb{I}^{\otimes 2a+1} \otimes c_k^T \otimes \mathbb{I}^{\otimes 2(N-a-1)} \quad (\text{B6})$$

with c_k^T denoting the transpose of c_k w.r.t. the basis used in defining the isomorphism (B2). Note that by virtue of this convention we effectively performed a particle-hole transformation on the backward replicas. This will help to make certain symmetries of our model explicit.

Finally, we note that the operators χ do not anticommute when in different replicas. To fix this, we introduce the Klein factors

$$F^{(\sigma a)} = \prod_{k=1}^{LN_F} \exp \left(i\pi \left(\chi_k^{(+a)} \right)^\dagger \chi_k^{(+a)} \right) \quad (\text{B7})$$

and in terms of these the fermionic operators on the replicated Hilbert space

$$c_k^{(+a)} = i \left(\prod_{a' < a} F^{(+a')} F^{(-a')} \right) F^{(+a)} \chi_k^{(+a)} \quad (\text{B8})$$

$$c_k^{(-a)} = \left(\prod_{a' < a} F^{(+a')} F^{(-a')} \right) F^{(+a)} \chi_k^{(-a)}. \quad (\text{B9})$$

It is straightforward to verify that these operators satisfy the canonical anticommutation relation

$$\{ (c_l^\alpha)^\dagger, c_m^\beta \} = \delta_{\alpha,\beta} \delta_{l,m}. \quad (\text{B10})$$

Finally, note that this convention can also be obtained by re-expressing the complex fermions in terms of Majoranas γ_k , introducing Majorana operators $\gamma_k^{(\sigma a)}$ in the replicated space as in Refs. 32 and 75, and finally writing complex fermions in the replicated space as

$$c_j^{(\sigma a)} = \frac{\gamma_{2j+1}^{(\sigma a)} - i\gamma_{2j+2}^{(\sigma a)}}{2}. \quad (\text{B11})$$

Appendix C: Derivation of the spin Hamiltonian

In this Appendix we derive the effective spin Hamiltonian generating the time evolution $\mathbb{E}_G[(K \otimes K^*)^{\otimes N}]$ in the replicated space. The starting point is the non-Hermitian Hamiltonian (5) generating K . In the space with N forward-evolving replicas and N backward-evolving replicas, using the convention detailed in the previous section the operator $(K \otimes K^*)^{\otimes N}$ is generated by

$$H_{\text{meas}}^{(N)} = H_{\text{hop}}^{(N)} + H_{\text{flav}}^{(N)} + H_{\text{nH}}^{(N)} - i\Gamma L N_F N \quad (\text{C1a})$$

$$H_{\text{hop}}^{(N)} = \sum_{j,\mu,\nu,\alpha} J_j^{\mu\nu}(t) c_{j,\mu}^{(\alpha)\dagger} c_{j+1,\nu}^{(\alpha)} + \text{h.c.} \quad (\text{C1b})$$

$$H_{\text{flav}}^{(N)} = \sum_{j,\mu,\nu,\alpha} \left(h_j^{\mu\nu}(t) c_{j,\mu}^{(\alpha)\dagger} c_{j,\nu}^{(\alpha)} - \frac{1}{2} \delta_{\mu\nu} \right) \quad (\text{C1c})$$

$$H_{\text{nH}}^{(N)} = i \sum_{j,\mu,\alpha} M_{j,\mu}(t) \sigma_\alpha \left(c_{j,\mu}^{(\alpha)\dagger} c_{j,\mu}^{(\alpha)} - \frac{1}{2} \right). \quad (\text{C1d})$$

Finally, the Gaussian average over J, h , and M can be easily obtained through a cumulant expansion, and using the convention detailed in the main text's footnotes, yielding

$$\begin{aligned} N_F \mathcal{H} &= \frac{\mathcal{J}}{2N_F} \sum_{\substack{j,\mu,\nu \\ \alpha,\beta}} (c_{j,\mu}^{\alpha\dagger} c_{j+1,\nu}^\alpha c_{j+1,\nu}^{\beta\dagger} c_{j,\mu}^\beta + [j \leftrightarrow j+1]) \\ &+ \frac{\mathfrak{h}}{2N_F} \sum_{j,\mu,\nu} \left[\left(\sum_\alpha c_{j,\mu}^{\alpha\dagger} c_{j,\nu}^\alpha \right) - N \delta_{\mu\nu} \right]^2 \\ &- \frac{\Gamma \sigma_\alpha \sigma_\beta}{2} \sum_{j,\mu,\alpha,\beta} c_{j,\mu}^{\alpha\dagger} c_{j,\mu}^\alpha c_{j,\mu}^{\beta\dagger} c_{j,\mu}^\beta \\ &+ \frac{\Gamma L N N_F}{2}. \end{aligned} \quad (\text{C2})$$

This can be most easily expressed in terms of S_j and T_j : the local generators of $SU(2N)$ and $SU(N_F)$ rotations respectively:

$$S_j^{\alpha\beta} = \frac{1}{N_F} \sum_{\mu} c_{j\mu}^{\alpha\dagger} c_{j\mu}^{\beta} - \frac{\delta^{\alpha\beta}}{2NN_F} \aleph, \quad (\text{C3})$$

$$T_{j;\mu\nu} = \sum_{\alpha} c_{j\mu}^{\alpha\dagger} c_{j\nu}^{\alpha} - \frac{\delta^{\mu\nu}}{N_F} \aleph, \quad (\text{C4})$$

where we recall that \aleph is the $U(1)$ generator

$$\aleph_j = \sum_{\alpha,\mu} c_{j\mu}^{\alpha\dagger} c_{j\mu}^{\alpha}. \quad (\text{C5})$$

Then

$$\begin{aligned} N_F \mathcal{H} = & \sum_j \left[-N_F \mathcal{J} \text{tr}(S_j S_{j+1}) \right. \\ & + \frac{\hbar}{2N_F} \left(\text{tr} T_j^2 + \frac{1}{N_F} (\aleph_j - NN_F)^2 \right) \\ & - \frac{\Gamma \sigma_{\alpha\sigma\beta}}{2} \sum_{\mu} c_{j\mu}^{\alpha\dagger} c_{j\mu}^{\alpha} c_{j\mu}^{\beta\dagger} c_{j\mu}^{\beta} \\ & \left. - N_F \mathcal{J} \frac{\aleph_j \aleph_{j+1} - NN_F (\aleph_j + \aleph_{j+1})}{2NN_F^2} \right] \\ & + \frac{\Gamma L N N_F}{2}. \end{aligned} \quad (\text{C6})$$

In the limit $\hbar \rightarrow \infty$ the conditions $\text{Tr} T_j^2 = 0$ and $\aleph_j = N_F N$ are enforced. In particular, due to $\text{Tr} T_j^2 = 0$ each site is projected onto a $SU(N_F)$ singlet. Therefore in this limit we need the Hamiltonian projected onto this sector. This allows us to simplify the measurement term. Projection is equivalent to Haar-averaging the operator over $U(N_F)$ transformations $c_{\mu}^{\alpha} \rightarrow \sum_{\nu} U_{\mu\nu} c_{\nu}^{\alpha}$ (a site index j is left implicit)

$$\begin{aligned} & \sum_{M,\mu,\nu,\lambda,\kappa} \mathbb{E} [U_{M\mu}^* U_{M\nu} U_{M\lambda}^* U_{M\kappa}] c_{\mu}^{\alpha\dagger} c_{\nu}^{\alpha} c_{\lambda}^{\beta\dagger} c_{\kappa}^{\beta} \\ & = \frac{1}{N_F + 1} \sum_{\mu,\nu} (c_{\mu}^{\alpha\dagger} c_{\mu}^{\alpha} c_{\nu}^{\beta\dagger} c_{\nu}^{\beta} + c_{\mu}^{\alpha\dagger} c_{\nu}^{\alpha} c_{\nu}^{\beta\dagger} c_{\mu}^{\beta}) \end{aligned} \quad (\text{C7})$$

In this way, we finally obtain that, in the sector with $\text{tr} T_j^2 = 0$ and $\aleph_j = NN_F$, the projected Hamiltonian is

$$\begin{aligned} \mathcal{H} = & -\mathcal{J} \sum_j \left[\text{tr}(S_j S_{j+1}) - \frac{N}{2} \right] \\ & - \frac{\hat{\Gamma}}{2} \sum_j \left[\sum_{\alpha,\beta} \sigma_{\alpha\sigma\beta} (S_j^{\alpha\alpha} S_j^{\beta\beta} - S_j^{\alpha\beta} S_j^{\beta\alpha}) + \frac{N}{2} \right] \\ & + \frac{L\Gamma N}{2}, \end{aligned} \quad (\text{C8})$$

where we introduced $\hat{\Gamma} = \Gamma N_F / (N_F + 1)$.

Appendix D: On-site representation

The aim of this Appendix is to explain why the on-site $\text{su}(2N)$ representation is that with a Young tableau of N rows and N_F columns: for example, in the case $N = 3$, $N_F = 4$:

$$\begin{array}{|c|c|c|c|} \hline & & & \\ \hline & & & \\ \hline & & & \\ \hline & & & \\ \hline \end{array} \quad (\text{D1})$$

First, it is easy to check that $\text{su}(N_F)$ and $\text{su}(2N)$, with generators $S^{\alpha\beta}$ and $T_{\mu\nu}$, are two commuting sub-algebras of $\text{su}(2NN_F)$. Recall from the main text that these generators are defined by

$$N_F S^{\alpha\beta} = \sum_{\mu=1}^{N_F} c_{\mu}^{\alpha\dagger} c_{\mu}^{\beta} - \frac{\delta^{\alpha\beta}}{2N} \aleph, \quad (\text{D2})$$

$$T_{\mu\nu} = \sum_{\alpha=1}^{2N} c_{\mu}^{\alpha\dagger} c_{\nu}^{\alpha} - \frac{\delta^{\mu\nu}}{N_F} \aleph, \quad (\text{D3})$$

with total fermion number $\aleph = \sum_{\mu} \sum_{\alpha} c_{\mu}^{\alpha\dagger} c_{\mu}^{\alpha} = NN_F$ in the sector of interest.

We are interested in the $\text{su}(2N)$ representation which is the $\text{su}(2N)$ orbit of the replicated identity map (replicated N_F times), which in our notation is denoted as a *state*, $|\mathbb{I}\rangle$. It is easy to check that it is made of $\text{su}(N_F)$ scalars.

For $N_F = 1$, the identity belongs to the $\text{su}(2N)$ irreducible representation of anti-symmetric N -tensors, with Young tableau made of one column of length N .²⁴ Within this $\text{su}(2N)$ representation there is a state v which is a $\text{su}(2N)$ highest weight vector (for the given selected Borel sub-algebra).

For $N_F > 1$, the $\text{su}(2N)$ action is the diagonal one on the N_F -fold tensor product of the above $N_F = 1$ representation. The state $v \otimes \dots \otimes v$ (N_F times) is thus in the orbit of the replicated identity under the $\text{su}(2N)$ action. Because the $\text{su}(2N)$ action is the diagonal one, it is also an $\text{su}(2N)$ highest weight vector. Its highest vector is N_F times that of v . Hence it is the highest weight vector of the representation with Young tableau made of N_F column and N lines. That is: the irreducible $\text{su}(2N)$ representation containing the identity map is that with Young tableau made of N_F column and N lines.

If one is not at ease with this general argument, one may check it on the first few cases. For $N_F = 2$, $2N = 2$: the sector with $\aleph = 2$ has dimension 6, and is made of $\text{su}(4)$ anti-symmetric 2-tensors.²⁵ Projecting it on the

²⁴ Denoting the fermion vacuum (which is manifestly invariant under Eqs. D2, D3) by $|\Omega\rangle$, the sector with $\aleph = NN_F$ is given by filling NN_F fermion modes. For $N_F = 1$, this gives states $A_{\alpha_1, \dots, \alpha_N} c^{\alpha_1\dagger} \dots c^{\alpha_N\dagger} |\Omega\rangle$, where A is an antisymmetric tensor.

²⁵ Similarly to the discussion in Footnote 24, this sector is obtained by filling $\aleph = 2$ fermion modes, so contains states of the form $A_{IJ} c_I^{\dagger} c_J |\Omega\rangle$, where I, J are multi-indices running over $2NN_F$ values, and A is an antisymmetric tensor.

$\mathfrak{su}(N_F)$ invariant subspace yields a vector space of dimension 3 which is an irreducible triplet w.r.t. $\mathfrak{su}(2N)$ (recall $2N = 2$). That is: in this case, fixing $\mathfrak{N} = NN_F$ and projecting on $SU(N_F)$ -scalars selects an $\mathfrak{su}(2N)$ irreducible representation. One can check directly (on a small piece of paper) that this also works for $N_F = 3, 2N = 2$ as well as for $N_F = 2, 2N = 4$. In all these cases the resulting $\mathfrak{su}(2N)$ irreducible representation is that with rectangular Young tableau with N lines and N_F columns. It is also easy to prove along these lines that the identity belongs to this representation and that it is part of the $\mathfrak{su}(N_F)$ invariant with $\mathfrak{N} = NN_F$. We can thus restrict to it.

Appendix E: From the Heisenberg equations to the $NL\sigma M$ action

As explained in the main text, the Hamiltonian H_N has modes associated to L and R that have an explicit mass, and modes associated to the slow variation of Q and (in the $N \rightarrow 1$ limit) of d and q that are Goldstone modes in the ultraviolet.

Our aim is then to integrate out L and R to derive an effective Lagrangian $\mathcal{L}[Q, d, q]$ for the other modes. To do this we will exploit the semiclassical limit $N_F \gg 1$. Here we can integrate out the gapped modes at the level of the equations of motion and then reconstruct the Lagrangian from those.

We define the operators in the Heisenberg picture (recall from the main text that we Wick rotate $t = i\tilde{t}$ so that the equations of motion have the conventional form)

$$\dot{\mathcal{O}} = iN_F[\mathcal{H}, \mathcal{O}], \quad (\text{E1})$$

so that on a finite system it gives

$$\mathcal{O}(\tilde{t}) = e^{iN_F\mathcal{H}\tilde{t}}\mathcal{O}e^{-iN_F\mathcal{H}\tilde{t}}. \quad (\text{E2})$$

We find that, at the operator level, the blocks of S_j ,

$$S_j = \begin{pmatrix} \tilde{L}_j & \tilde{Q}_j \\ \tilde{Q}_j^\dagger & \tilde{R}_j \end{pmatrix}, \quad (\text{E3})$$

satisfy

$$\begin{aligned} -i\dot{\tilde{Q}}_j &= \frac{\mathcal{J}}{2} \left[\tilde{L}_j(\tilde{Q}_{j-1} + \tilde{Q}_{j+1}) - (\tilde{Q}_{j-1} + \tilde{Q}_{j+1})\tilde{R}_j \right] \\ &\quad - \frac{\mathcal{J}}{2} \left[(\tilde{L}_{j-1} + \tilde{L}_{j+1})\tilde{Q}_j - \tilde{Q}_j(\tilde{R}_{j-1} + \tilde{R}_{j+1}) \right] \\ &\quad + 2\hat{\Gamma}(\tilde{L}_j\tilde{Q}_j - \tilde{Q}_j\tilde{R}_j) - \hat{\Gamma} \left\{ \text{tr} \left(\tilde{L}_j - \tilde{R}_j \right), \tilde{Q}_j \right\}, \end{aligned} \quad (\text{E4a})$$

$$\begin{aligned} -i\dot{\tilde{L}}_j &= \frac{\mathcal{J}}{2} \left[\tilde{Q}_j(\tilde{Q}_{j-1}^\dagger + \tilde{Q}_{j+1}^\dagger) - (\tilde{Q}_{j-1} + \tilde{Q}_{j+1})\tilde{Q}_j^\dagger \right] \\ &\quad - \frac{\mathcal{J}}{2} \left[(\tilde{L}_{j-1} + \tilde{L}_{j+1})\tilde{L}_j - \tilde{L}_j(\tilde{L}_{j-1} + \tilde{L}_{j+1}) \right], \end{aligned} \quad (\text{E4b})$$

$$\begin{aligned} -i\dot{\tilde{R}}_j &= \frac{\mathcal{J}}{2} \left[\tilde{Q}_j^\dagger(\tilde{Q}_{j-1} + \tilde{Q}_{j+1}) - (\tilde{Q}_{j-1}^\dagger + \tilde{Q}_{j+1}^\dagger)\tilde{Q}_j \right] \\ &\quad - \frac{\mathcal{J}}{2} \left[(\tilde{R}_{j-1} + \tilde{R}_{j+1})\tilde{R}_j - \tilde{R}_j(\tilde{R}_{j-1} + \tilde{R}_{j+1}) \right]. \end{aligned} \quad (\text{E4c})$$

Let us parametrize \tilde{Q} as $\tilde{Q} = qQ$ with $\det Q = 1$ and $\tilde{L} = L + d\mathbb{1}$ and $\tilde{R} = R - d\mathbb{1}$ with $\text{tr} L = \text{tr} R = 0$. In the continuous limit, the first equation then becomes

$$\begin{aligned} -i(\dot{q} + \dot{Q}Q^{-1}) &= \mathcal{J} \left[d\partial_x^2(qQ)Q^{-1} - q\partial_x^2q \right] \\ &\quad + 4\hat{\Gamma}L + 4\hat{\Gamma}(1 - N)d. \end{aligned} \quad (\text{E5})$$

where we neglect terms of order N_F^{-1} (arising from order- N_F^{-1} corrections to the kinematic constraints in Eq. 11) or $O(\tilde{L}\partial_x^3\tilde{Q}, \tilde{R}\partial_x^3\tilde{Q}, \tilde{Q}\partial_x^3\tilde{L}, \tilde{Q}\partial_x^3\tilde{R})$. Throughout, we organize terms by the number of spatial derivatives, i.e. by the order in ∂_x .

We now extract the trace and the traceless part of the above equation. The condition $\det Q = 1$ implies that $\text{tr}(Q^{-1}\delta Q) = 0$ for any infinitesimal variation. In particular $Q^{-1}\dot{Q}$ and $Q^{-1}\partial_x Q$ are traceless. Thus we get

$$\begin{aligned} -iN\dot{q} &= \mathcal{J} \left[N(d\partial_x^2q - q\partial_x^2q) + dq \text{tr}(\partial_x^2Q Q^{-1}) \right] \\ &\quad + 4\hat{\Gamma}(1 - N)Nd, \end{aligned} \quad (\text{E6a})$$

$$-i\dot{Q}Q^{-1} = +4\hat{\Gamma}L + \mathcal{J}d\mathcal{A}, \quad (\text{E6b})$$

with

$$\mathcal{A} = \partial_x^2(qQ)Q^{-1} - \frac{1}{N} \text{tr}(\partial_x^2(qQ)Q^{-1}).$$

In Eq. E6b we neglect \mathcal{A} compared to L , because it is a higher-derivative contribution. To see this: the equation below for \dot{L} shows that \dot{L} scales as $O(\partial_x^2)$. Therefore L , without the time derivative, is much larger than $O(\partial_x^2)$, which is the order of \mathcal{A} .

We thus get

$$\begin{aligned} -iN\dot{q} &= \mathcal{J} \left[N(d\partial_x^2q - q\partial_x^2d) + dq \text{tr}(\partial_x^2Q Q^{-1}) \right] \\ &\quad + 4\hat{\Gamma}(1 - N)Nd, \end{aligned} \quad (\text{E7a})$$

$$-i\dot{Q}Q^{-1} = 4\hat{\Gamma}L, \quad (\text{E7b})$$

Note that since L is hermitian and traceless this last equation is compatible with Q being unitary, $QQ^\dagger = \mathbf{1}$. In other words, the long-wavelength fluctuations of Q preserve the unitarity of Q that is a property of the classical ground states. Therefore we now impose unitarity.

We get the evolution equation for L and d by looking at Eq. E4b. This yields

$$-i(\dot{L} + \dot{d}) = \frac{\mathcal{J}}{2}[qQ\partial_x^2(q^*Q^\dagger) - \partial_x^2(qQ)Q^\dagger q^*]. \quad (\text{E8})$$

Extracting the trace and the traceless part gives

$$i\dot{d} = \frac{\mathcal{J}}{2}(q^*\partial_x^2 q - q\partial_x^2 q^*), \quad (\text{E9})$$

$$i\dot{L} = -\frac{\mathcal{J}}{2}\left[|q|^2(Q\partial_x^2 Q^\dagger - (\partial_x^2 Q)Q^\dagger) + 2((q\partial_x q^*)Q\partial_x Q^\dagger - \text{h.c.})\right]. \quad (\text{E10})$$

We may combine Eqs. E7b, E10 to get the equation for \tilde{Q} in the main text:

$$Q^\dagger \left[\tilde{Q} - 4\mathcal{J}\hat{\Gamma} \partial_x (|q|^2 \partial_x Q) \right] - \text{h.c.} = 0. \quad (\text{E11})$$

We may write the equation for q in the form

$$i\dot{q} = \mathcal{J}(q\partial_x^2 d - d\partial_x^2 q) + qd \left[\frac{\mathcal{J}}{N} \text{tr} \partial_x Q^\dagger \partial_x Q - 4\hat{\Gamma}_N \right] \quad (\text{E12})$$

by using the fact $\text{tr}(Q^{-1}\partial_x Q) = 0$, together with the unitarity of Q , which imply

$$\text{tr}(\partial_x^2 Q Q^\dagger) = -\text{tr}(\partial_x Q \partial_x Q^\dagger) = \text{tr}(Q \partial_x^2 Q^\dagger)$$

and similarly for the \tilde{t} -derivatives.

One can easily check that the equations of motion (16) and (17) are reproduced by the action (18). First, one needs to impose that the action is extremal w.r.t. variations of the form $Q \mapsto Q(1 + ih)$, with $h = h^\dagger$ and $\text{tr} h = 0$. For this purpose, note that, if $\text{tr}(Xh) = 0$ for all such h , then $X \propto \mathbf{1}$. The local variation of $S_{\text{NL}\sigma\text{M}}$ is of the form $\text{tr}(Xh)$ with

$$X \propto Q^\dagger \left[\partial_{\tilde{t}} \left(\frac{1}{g_B v} \dot{Q} \right) - \partial_x \left(\frac{v}{g_B} Q' \right) \right] - \text{h.c.} \quad (\text{E13})$$

By the identities above, this is traceless, so it must vanish, giving the equation of motion $X = 0$. Finally, substituting in Eq. 20 for g_B and v as functions of $|q|$ recovers the equation of motion (16) in the main text.

Finally, in order to extremize the action in the main text w.r.t. \mathbf{n} , it is useful to note that

$$\delta \left[\int dx dt (1 - n_z) \dot{\varphi} \right] = \int dx dt \delta \mathbf{n} \cdot (\dot{\mathbf{n}} \times \mathbf{n}). \quad (\text{E14})$$

Appendix F: Semiclassical equations of motion

In this appendix we discuss the saddle-point solutions contributing to the amplitude

$$\langle \text{fin} | e^{-N_{\text{F}} t \mathcal{H}} | \text{ini} \rangle \quad (\text{F1})$$

where $|\text{ini}\rangle$ and $\langle \text{fin}|$ are determined by the initial density matrix of the system and the observable being computed respectively.

The saddle-point solutions are given by the semiclassical equations of the action (18). In general there will be a coupled set of equations for both the charge degrees of freedom \mathbf{n} and the entanglement degrees of freedom in Q . However we argue below that, when computing the Von Neumann entropy using the $N \rightarrow 1$ limit, one can neglect the feedback of Q on the mode \mathbf{n} .

The saddle-point solutions for Q are similar to the ones discussed in Ref. 32. Here the final and initial state specify two time-like boundary conditions for Q , and, given that the equations of motion for Q are second-order in time, this uniquely specifies a solution. The solution for the charge sector \mathbf{n} can be more subtle since it involves boundary conditions at both initial and final times, despite the fact that the equations of motion are only first-order in time [51, 56, 57]. The resolution to the apparent paradox is that the saddle-point equations for the charge sector involve two independent fields (as will be clear below): one has its boundary condition imposed at the final time, and the other has its boundary condition imposed at the initial time.

It is convenient to represent \mathbf{n} through stereographic projection of \mathbf{n} from the point $(0, 0, 1)$ onto the plane $\{(x, y, -1) | x, y \in \mathbb{R}\}$, so that

$$\mathbf{n} = \frac{1}{1 + z\bar{z}} \begin{pmatrix} z + \bar{z} \\ i(\bar{z} - z) \\ 1 - z\bar{z} \end{pmatrix}. \quad (\text{F2})$$

This corresponds to the coherent states representation of the spins as

$$|z\rangle = \frac{1}{\sqrt{1 + \bar{z}z}} \begin{pmatrix} 1 \\ z \end{pmatrix}, \quad (\text{F3})$$

in the case of spin-1/2 (i.e. for $N = N_F = 1$) or as [56]

$$|z\rangle \propto \exp(zS_-) |S, +S\rangle \quad (\text{F4})$$

for a general spin S (where the ket on the right-hand-side is the state with maximum n_z).

Substituting this into \mathcal{L} , we find that, up to a constant, the Lagrangian (the convention for the path integral weight is $e^{-\int dt dx \mathcal{L}}$) has the form $\mathcal{L} = \frac{NN_F}{2} \mathcal{L}_1$ with

$$\mathcal{L}_1 = \frac{\bar{z}\partial_t z - z\partial_t \bar{z}}{1 + z\bar{z}} + \mathcal{J} \frac{(\partial_x \bar{z})\partial_x z}{(1 + z\bar{z})^2} + G(Q) \left(\frac{1 - z\bar{z}}{1 + z\bar{z}} \right)^2 + \text{terms independent of } z, \bar{z}, \quad (\text{F5})$$

with

$$G(Q) = \hat{\Gamma}_N - \frac{\mathcal{J}}{4N} \text{tr} \left((\partial_x Q^\dagger) \partial_x Q \right). \quad (\text{F6})$$

Extremizing the action w.r.t. \bar{z} and z we get respectively

$$\partial_t z = \frac{\mathcal{J}}{2} \left(\partial_x^2 z - 2 \frac{\bar{z} (\partial_x z)^2}{1 + z \bar{z}} \right) + 2G(Q) \bar{z} z^2 \frac{1 - z \bar{z}}{1 + z \bar{z}}, \quad (\text{F7})$$

$$\partial_t \bar{z} = -\frac{\mathcal{J}}{2} \left(\partial_x^2 \bar{z} - 2 \frac{z (\partial_x \bar{z})^2}{1 + z \bar{z}} \right) - 2G(Q) z \bar{z}^2 \frac{1 - z \bar{z}}{1 + z \bar{z}}. \quad (\text{F8})$$

When $N = 1$, the term $G(Q)$ vanishes and the equations simplify:

$$\partial_t z = \frac{\mathcal{J}}{2} \left(\partial_x^2 z - \frac{2\bar{z}(\partial_x z)^2}{1 + z\bar{z}} \right) \quad (\text{F9a})$$

$$\partial_t \bar{z} = -\frac{\mathcal{J}}{2} \left(\partial_x^2 \bar{z} - \frac{2z(\partial_x \bar{z})^2}{1 + z\bar{z}} \right). \quad (\text{F9b})$$

When searching for saddle points of the action, one must then treat z and its complex conjugate \bar{z} as independent variables satisfying the equations of motion.

We expect that, in order to study the $N \rightarrow 1$ limit for the von Neumann entropy, it is sufficient to study the charge sector only at $N = 1$ (instead of having to find the solution for any N). Therefore below we will focus on Eqs. F9a, together with the the boundary conditions on z, \bar{z} that arise at $N = 1$.

We give a non-rigorous self-consistent argument for the fact that it is sufficient to study the charge-sector equations only for $N = 1$. In order to obtain the von Neumann entropy, we need the free energy of the field theory up to order $N - 1$ (see e.g. Eq. 57 in [32], taking $k = 1$, or [36]). Note that the saddle-point solution for Q discussed above satisfies $\text{tr}(\partial_x Q^\dagger)(\partial_x Q) \propto N - 1$ at small $N - 1$. Therefore we expect that the term $G(Q)$ may be treated as formally of order $N - 1$, and that dropping this term also affects the saddle-point solutions only at relative order $N - 1$ compared to the leading order. Therefore it affects the saddle-point action by at most order $(N - 1)^2$. It would be worthwhile to make this argument more precise.

Using coherent states one can show that the boundary states impose non-trivial boundary conditions on z and \bar{z} . When the boundary states are coherent states themselves $|\text{ini}\rangle = |z_{\text{ini}}(x)\rangle$ and $|\text{fin}\rangle = |z_{\text{fin}}(x)\rangle$, then [56]

$$z(x, 0) = z_{\text{ini}}(x), \quad \bar{z}(x, t) = \bar{z}_{\text{fin}}(x). \quad (\text{F10})$$

When $N = 1$, the boundary states are coherent states of the form (F4). The final-time boundary conditions we consider reduce when $N = 1$ to the state “ $|\mathbb{I}\rangle$ ”, and give $\bar{z}(x, t_{\text{fin}}) = i$ (see App. G). It then follows from Eq. F9a that $\bar{z}(x, t) = i$ for all x and t , i.e. it is a constant.

We consider physical initial density matrices that are product states, where each site has a fixed chemical potential $2\mu_j$:

$$\rho = \prod_j \frac{e^{\mu_j n_j}}{e^{\mu_j} + 1} \quad (\text{F11})$$

(recall that $n_j = N_F^{-1} \sum_\mu c_{j,\mu}^\dagger c_{j,\mu}$). For these states we find (see App. G) the initial condition (switching to continuum notation)

$$z(x, 0) = -if(x), \quad (\text{F12})$$

where

$$f(x) = e^{-\mu(x)} \quad (\text{F13})$$

Writing (F7) in terms of $f(x, t) = iz(x, t)$ [and using $\bar{z}(x, t) = i$] we see that $f(x, t)$ remains real at all times. While the equation of motion for $f(x, t)$ does not have a simple form, this reduces to a standard diffusion equation for the physical density of fermions by writing

$$d = \frac{1}{2} \frac{1 - f}{1 + f}. \quad (\text{F14})$$

which gives

$$\partial_t d = \frac{\mathcal{J}}{2} \partial_x^2 d. \quad (\text{F15})$$

Recall that $d = n - 1/2$, where n is the charge density.

Appendix G: Further properties of boundary states

The simplest final state we will consider is $|\mathbb{I}\rangle$, which is used to compute traces, i.e. $\langle \mathbb{I} | \rho^{\otimes N} \rangle = \text{Tr}(\rho)^N$. This satisfies $\langle \mathbb{I} | V^{(+a)} = \langle \mathbb{I} | (V^{(-a)})^T$ for any Pauli operator V in the bosonic representation obtained by Jordan-Wigner (see App. B). From this we have

$$\langle \mathbb{I} | c_{j,\mu}^{(-a)} = -i \langle \mathbb{I} | c_{j,\mu}^{(+a)} \quad \langle \mathbb{I} | (c_{j,\mu}^{(-a)})^\dagger = -i \langle \mathbb{I} | (c_{j,\mu}^{(+a)})^\dagger, \quad (\text{G1})$$

and thus

$$\langle \mathbb{I} | S_j = \langle \mathbb{I} | \begin{pmatrix} \tilde{L}_j & i(\frac{1}{2} - \tilde{L}_j) \\ -i(\frac{1}{2} + \tilde{L}_j) & -\tilde{L}_j \end{pmatrix}. \quad (\text{G2})$$

From this, one can verify the condition stated in the main text that $\langle \mathbb{I} | S_j^2 = \langle \mathbb{I} | \mathbb{1}/4 + O(1/N_F)$. Taking the expectation value we have (for any value of N_F)

$$\langle \mathbb{I} | S_j | \mathbb{I} \rangle = \langle \mathbb{I} | \begin{pmatrix} 0 & i\frac{1}{2} \\ -i\frac{1}{2} & 0 \end{pmatrix} | \mathbb{I} \rangle. \quad (\text{G3})$$

When $N = 1$, this gives the expectation value of the $\text{SU}(2)$ spin operators as $(n_x, n_y, n_z) = (0, 1, 0)$ so that at $N = 1$ this is an $\text{SU}(2)$ coherent state with $z = -i$ (by Eq. F2).

From Eq. G3 we also we read off the final-time boundary condition

$$Q(x, t_{\text{fin}}) = \mathbb{1} \quad (\text{G4})$$

corresponding to the boundary state $|\mathbb{I}\rangle$.

To compute the average Von Neumann entropy of a state, we further need to consider the final state $\langle \text{vN} |$ defined by $\langle \text{vN} | \rho^{\otimes N} = \text{Tr}(\rho^N)$. The state must then satisfy $\langle \text{vN} | V^{(-a)} = \langle \text{vN} | (V^{+(a+1)})^T$ for $a < N$ and $\langle \text{vN} | V^{(-N)} = \langle \text{vN} | (V^{(+1)})^T$. While the expectation values of \tilde{L}_j and \tilde{R}_j are zero,

$$\langle \text{vN} | \tilde{Q}_j | \text{vN} \rangle = \frac{i}{2} Q_{\text{vN}}, \quad (\text{G5})$$

with

$$Q_{\text{vN}} \equiv \begin{pmatrix} 0 & 0 & \cdots & 0 & +1 \\ -1 & 0 & \cdots & 0 & 0 \\ 0 & -1 & \cdots & 0 & 0 \\ & & \cdots & & \\ 0 & 0 & \cdots & -1 & 0 \end{pmatrix}. \quad (\text{G6})$$

The eigenvalues of the matrix q_n are studied in App. I of Ref. 32. From that we find that $q = i/2$ and $Q = q_n$. In the $N = 1$ limit, this again reduces to a state polarized along y , fixing $\bar{z}(x, t) = i$. Summarizing: to compute the bipartite entanglement entropy, it is sufficient to impose the boundary condition $Q = \mathbb{1}$ on one subsystem and $Q = Q_{\text{vN}}$ on the other.

Finally, the most generic initial states we will consider are product states where each site has a fixed chemical potential μ_j , as in Eq. F11. Taking replicas of this physical state gives the initial state

$$|\text{ini}\rangle = \left[\prod_j \frac{\exp\left(\mu_j N_F^{-1} \sum_\mu \sum_{a=1}^N c_{j\mu}^{(+a)\dagger} c_{j\mu}^{(+a)}\right)}{(e^{2\mu_j} + 1)^{N/2}} \right] |\mathbb{I}\rangle, \quad (\text{G7})$$

where the normalization is fixed by $\langle \text{ini} | \text{ini} \rangle = 1$. Taking the expectation value of the spin operator S on $|\text{ini}\rangle$ gives

$$\langle \text{ini} | \tilde{Q}_j | \text{ini} \rangle = \frac{i}{2 \cosh \mu_j} \mathbb{1}, \quad \langle \text{ini} | d_j | \text{ini} \rangle = \frac{1}{2} \tanh \mu_j, \quad (\text{G8})$$

while the expectation value of L and R are zero. One can check that this corresponds to a fully polarized state for \mathbf{n} . This implies that when $N = 1$ it is a coherent state (F4) with $z = -ie^{-\mu_j}$, fixing the initial condition for z as in (F12) and (F13).

Appendix H: Proof of the validity of the QR decomposition in simulating the stochastic Schrodinger equation

Simulating the stochastic Schrodinger equation associated to the time evolution we consider requires discretizing time into intervals of size δt . For each time step, the Kraus operator is of the form

$$K(\delta t) = \exp \left[\sum_j n_j \left(\delta B_j + (2\langle n_j \rangle - 1) \Gamma \delta t \right) \right] e^{-iH(t)\delta t} \quad (\text{H1})$$

where $\mathbb{E}[\delta B_j^2] = \Gamma \delta t$.

Since we are interested in pure initial states, we represent the state of the system as

$$|\psi(t)\rangle = \mathcal{U}(t) c_1^\dagger \cdots c_N^\dagger |0\rangle = \prod_{k=1}^N \left[\sum_{j=1}^L u_{jk} c_j^\dagger \right] |0\rangle, \quad (\text{H2})$$

where $\mathcal{U} = \exp[-ih_{a,b}(t)c_a^\dagger c_b]$ and $h_{a,b}(t)$ is an Hermitian matrix. [Here and in the following we use the convention that calligraphic operators act in the many-body space, while lower-case letter operators are the corresponding single-particle-sector $L \times L$ matrices.]

Updating the matrix $U(t)$ after the application of the first time-evolution step $e^{-iH(t)\delta t}$ is trivial. In contrast, efficiently computing how the non-unitary transformation in the second step affects the covariance matrix is non-trivial and was first discussed in Ref. [3]. In this section we summarize the technique and explicitly prove its validity for pure states.

The covariance matrix of (H2) is

$$\langle \psi | c_j^\dagger c_k | \psi \rangle = u \begin{pmatrix} \mathbb{1}_N & 0 \\ 0 & 0 \end{pmatrix} u^\dagger. \quad (\text{H3})$$

Our goal is to find the exact covariance matrix corresponding to the normalized state

$$|\psi'\rangle = \frac{1}{\sqrt{\langle \psi | \mathcal{V}^\dagger \mathcal{V} | \psi \rangle}} \mathcal{V} |\psi\rangle, \quad (\text{H4})$$

where $\mathcal{V} = e^{\varepsilon c_j^\dagger c_j}$. Here, $\varepsilon \in \mathbb{R}$ does not need to be small. This can be done using the general method of Ref. [77]. However, since the state is pure and particle number is conserved, we can use an even more efficient method, which is the QR decomposition put forward in Ref. [3]. We explain it explicitly in the following.

First, noticing

$$\mathcal{V} |0\rangle = |0\rangle, \quad (\text{H5})$$

we can rewrite

$$\begin{aligned} |\psi'\rangle &= \frac{1}{\sqrt{\langle \psi | \mathcal{V}^\dagger \mathcal{V} | \psi \rangle}} \mathcal{V} \mathcal{U} c_1^\dagger \cdots c_N^\dagger |0\rangle \\ &= \frac{1}{\sqrt{\langle \psi | \mathcal{V}^\dagger \mathcal{V} | \psi \rangle}} \prod_{k=1}^N (\mathcal{W} c_k^\dagger \mathcal{W}^{-1}) |0\rangle \\ &= \frac{1}{\sqrt{\langle \psi | \mathcal{V}^\dagger \mathcal{V} | \psi \rangle}} \prod_{k=1}^N \left[\sum_{j=1}^L w_{jk} c_j^\dagger \right] |0\rangle, \end{aligned} \quad (\text{H6})$$

where $\mathcal{W} = \mathcal{V} \mathcal{U}$. Next, using the QR-decomposition

$$w = qr, \quad (\text{H7})$$

[r is an upper triangular matrix] we have

$$\begin{aligned} |\psi'\rangle &= \frac{1}{\sqrt{\langle \psi | \mathcal{V}^\dagger \mathcal{V} | \psi \rangle}} \mathcal{Q} \prod_{k=1}^N \left[\sum_{j=1}^L r_{jk} c_j^\dagger \right] |0\rangle \\ &= \frac{(\prod_{k=1}^N r_{kk})}{\sqrt{\langle \psi | \mathcal{V}^\dagger \mathcal{V} | \psi \rangle}} \mathcal{Q} c_1^\dagger \cdots c_N^\dagger |0\rangle, \end{aligned} \quad (\text{H8})$$

where we used $c_k^\dagger c_k^\dagger = 0$, and the fact that R is upper triangular.

Now, because \mathcal{Q} is unitary by construction, $\mathcal{Q}c_1^\dagger \dots c_N^\dagger |0\rangle$ is normalized. Thus

$$\prod_{k=1}^N r_{kk} = \sqrt{\langle \psi | \mathcal{V}^\dagger \mathcal{V} | \psi \rangle}, \quad (\text{H9})$$

and so

$$|\psi'\rangle = \prod_{k=1}^N \left[\sum_{j=1}^L q_{jk} c_j^\dagger \right] |0\rangle, \quad (\text{H10})$$

with covariance matrix

$$\langle \psi' | c_j^\dagger c_k | \psi' \rangle = q \begin{pmatrix} \mathbb{1}_N & 0 \\ 0 & 0 \end{pmatrix} q^\dagger. \quad (\text{H11})$$

This proves the validity of the QR decomposition used in Ref. [3]. Importantly, just like the method developed in Ref. [77], the QR decomposition is exact, and provides a physical covariance matrix not just at the first order in the Trotterization step, making it suitable for numerical implementation.

Appendix I: Further numerical data

In this Appendix we report more details concerning the numerical data reported in Fig. 1 and 2. The average values as a function of time are reported in Fig. 3. To compute the plateau value, we averaged $S_{\text{vN}}(t)$ starting from time $t_{\text{plateau}} = 130, 90, 50, 50$ for $\Gamma/\mathcal{J} = 0.25, 0.5, 1, 2$ respectively. We checked that significantly increasing t_{plateau} changes the average value of S_{vN} by an amount compatible with the associated statistical error.

The simulations are performed using respectively $\delta t = 0.05, 0.01, 0.01, 0.005$ for the different values of Γ listed above. We checked that increasing δt by a factor of 2 did not significantly affect the plateau value of S_{vN} .

Appendix J: Extended symmetries for fixed-phase hopping

The presence of the extended symmetry is most easily shown in the case of imaginary hopping amplitudes $J_j \in i\mathbb{R}$. (It does not matter whether these depend on time.) Redefining the fermionic operators via a particle-hole transformation on the $\sigma = -$ replicas,

$$b_j^{(\sigma a)} = \begin{cases} c_j^{(\sigma a)} & \text{if } \sigma = +, \\ c_j^{(\sigma a)\dagger} & \text{if } \sigma = -. \end{cases} \quad (\text{J1})$$

and expressing the replicated Hamiltonian (C1) in terms of these, it is immediate to verify that the Hamiltonian

is invariant under

$$b_j^\alpha \mapsto U^{\alpha\beta} b_j^\beta \quad (\text{J2})$$

for any $U(2N)$ unitary matrix U .

This consideration applies to any lattice (bipartite or not bipartite) with imaginary hoppings, including regular lattices in any number of dimensions, as the replicated Hamiltonian (C1) has a similar form on an arbitrary lattice.

Having established the extended symmetry for imaginary hoppings, the more general case discussed in the main text follows by making a simple change of gauge for the *physical* fermion operators, $c_j^\dagger \rightarrow e^{i\chi_j} c_j^\dagger$. If it is possible to find a gauge where all the hoppings are imaginary then the extended symmetry holds. For example, this is always possible in a nearest-neighbor chain (with $N_F = 1$), if the phases of the hoppings are time-independent.

Finally, we give a heuristic argument for the manifold of the NL σ Mfor models which obey the constraint discussed in this appendix.

For a concrete example, consider the model of the main text with $N_F = 1$ but with imaginary random $J_i(t)$. We assume that the semiclassical ground states may be characterized by expectation values of fermion bilinears (as in the case described in the main text) and that there is a semiclassical ground state that breaks replica symmetry in the same way as the state $|\mathbb{I}\rangle$ defined in App. G. Recall that this state appears in the computation of traces and entropies and defines a choice of pairing of forward and backward replicas.

After averaging, and the particle-hole transformation described above, the effective Hamiltonian may be written in terms of the $4N \times 4N$ matrix of fermion bilinears

$$A = \begin{pmatrix} b^{(+)} \\ b^{(-)} \\ b^{(+)\dagger} \\ b^{(-)\dagger} \end{pmatrix} (b^{(+)\dagger}, b^{(-)\dagger}, b^{(+)}, b^{(-)}) - \frac{1}{2} \mathbb{1}_{4N}, \quad (\text{J3})$$

where e.g. $b^{(+)}$ is an N -component vector indexed by a replica label $a = 1, \dots, N$. The expectation value in the state $|\mathbb{I}\rangle$ is

$$A = \begin{pmatrix} 0_{2N} & \frac{i}{2} B \\ -\frac{i}{2} B^* & 0_{2N} \end{pmatrix}, \quad (\text{J4})$$

with

$$B = \begin{pmatrix} 0_N & -\mathbb{1}_N \\ \mathbb{1}_N & 0_N \end{pmatrix}. \quad (\text{J5})$$

$SU(2N)$ rotations of the vector $(b^{(+)}, b^{(-)})$ preserve the form in (J4), but rotate B into

$$B \mapsto U_{2N} \begin{pmatrix} 0_N & -\mathbb{1}_N \\ \mathbb{1}_N & 0_N \end{pmatrix} U_{2N}^\top. \quad (\text{J6})$$

The subgroup of $SU(2N)$ that leaves B invariant is therefore by definition $\text{Sp}(2N)$, sometimes denoted $\text{USp}(2N)$. Therefore the orbit of B is the manifold $SU(2N)/\text{Sp}(2N)$.

Figure 3. Average von Neumann entanglement entropy of half the system S_{vN} as a function of time t and for various system sizes L . The number of samples used for averaging depends on the plot but is at least 80 for all plots.
