# Simple Linear Loops: Algebraic Invariants and Applications

RIDA AIT EL MANSSOUR, IRIF, CNRS, Université Paris Cité, France GEORGE KENISON, Liverpool John Moores University, UK MAHSA SHIRMOHAMMADI, IRIF, CNRS, Université Paris Cité, France ANTON VARONKA, TU Wien, Austria

Automatic generation of loop invariants is a fundamental challenge in software verification. While this task is undecidable in general, it is decidable for certain restricted classes of programs. This work focuses on invariant generation for (branching-free) loops with a single linear update.

Our primary contribution is a polynomial-space algorithm that computes the strongest algebraic invariant for simple linear loops, generating all polynomial equations that hold among program variables across all reachable states. The key to achieving our complexity bounds lies in mitigating the blowup associated with variable elimination and Gröbner basis computation, as seen in prior works (see [24, 36, 58] among others). Our procedure runs in polynomial time when the number of program variables is fixed.

We examine various applications of our results on invariant generation, focusing on invariant verification and loop synthesis. The invariant verification problem investigates whether a polynomial ideal defining an algebraic set serves as an invariant for a given linear loop. We show that this problem is coNP-complete and lies in PSPACE when the input ideal is given in dense or sparse representations, respectively. In the context of loop synthesis, we aim to construct a loop with an infinite set of reachable states that upholds a specified algebraic property as an invariant. The strong synthesis variant of this problem requires the construction of loops for which the given property is the strongest invariant. In terms of hardness, synthesising loops over integers (or rationals) is as hard as Hilbert's Tenth problem (or its analogue over the rationals). When loop constants are constrained to bit-bounded rational numbers, we demonstrate that loop synthesis and its strong variant are both decidable in PSPACE, and in NP when the number of program variables is fixed.

Additional Key Words and Phrases: Algebraic Invariant, Program Synthesis, Loop Invariant, Zariski Closure, Polynomial Space, Algebraic Reasoning.

#### 1 INTRODUCTION

Reasoning about loops is a foundational task in program analysis and verification. Nowadays, loop invariants play a crucial and indispensable role; for instance, they help establish both safety properties (being used in proofs of non-reachability) and liveness properties (being used, e.g., as supporting invariants in termination proofs). The paper [14] goes so far as to call the problem of automatic invariant generation as *the most important task in program verification*.

The focus of this paper is on the algorithmic generation of algebraic invariants for programs. The invariants we study are given by polynomial equations on program variables. Not only are these invariants expressive, but they are amenable to a rich collection of techniques from algebraic geometry. From a computational perspective, a key question is to determine when the invariant generation problem is decidable. For this the program model must be fairly abstract, as for instance, algebraic invariant generation is already undecidable for polynomial programs [36].

Müller-Olm and Seidl [56] considered the generation of polynomial invariants within the framework of affine programs, raising the question of whether it is possible to compute (a basis of) all

Authors' addresses: Rida Ait El Manssour, manssour@irif.fr, IRIF, CNRS, Université Paris Cité, Paris, France; George Kenison, g.j.kenison@ljmu.ac.uk, Liverpool John Moores University, Liverpool, UK; Mahsa Shirmohammadi, mahsa@irif.fr, IRIF, CNRS, Université Paris Cité, Paris, France; Anton Varonka, anton.varonka@tuwien.ac.at, TU Wien, Vienna, Austria.

polynomial invariants for any given affine program. This problem can be recast in purely algebraic terms as a question about matrix semigroups: namely, the objective is to compute a representation of the Zariski closure of a finitely generated semigroup of matrices. If the matrices involved are all invertible then this task is equivalent to that of computing the Zariski closure of a finitely generated matrix *group*.

The first algorithm to compute the polynomial ideal defining the Zariski closure  $\overline{\langle M_1,\ldots,M_k\rangle}$  of the group generated by a set of invertible matrices  $M_1,\ldots,M_k$  was introduced in [27]. This algorithm was recently employed in [36, 37] as a subroutine to address the above-mentioned question posed by Müller-Olm and Seidl regarding invariant generation for affine programs. Both of these decision procedures have significant shortcomings in terms of computational complexity; notably, the complexity bound for group-closure computation in [27] is not known to be elementary [58, Appendix C].

A recent advance in computing the group closure was obtained through a linearization technique from [43, 55] in combination with a novel upper bound on the degrees of the polynomials defining the closure [58]. The resulting complexity bounds, although elementary, are of the order of sevenfold exponential time for rational matrices; nevertheless there still remains a significant gap between the upper and lower complexity bounds. Surprisingly, the approaches in [27, 36, 37, 58], and other works such as [26, 30], fail to achieve reasonable complexity even in the simplest setting of cyclic matrix groups and semigroups. This complexity blow-up is a consequence of using variable elimination in the computational procedures, which generally has a worst-case exponential-space complexity. This paper aims to address and resolve the computational complexity for this simplest setting.

In the vocabulary of loop programs, the above simple setting translates to that of branch-free loops with a single linear update, unlike the commonly studied programs with multiple linear updates [37, 48]. Notwithstanding the radical simplicity of this model, the most natural verification problems (such as termination and reachability) are already very difficult in this setting [59]. We refer to this subclass as the *simple linear loops*, and focus on the invariant generation problem for such loops.

By treating all updates as simultaneous, such a loop is specified by a single square matrix M and a vector  $\boldsymbol{\alpha}$  of initial program values. The program state is given by a vector, and an iteration of the loop body is summarised by a matrix-vector product. The *orbit* of the loop is the reachable set of program states, defined by  $O := \{M^n \boldsymbol{\alpha} : n \in \mathbb{N}\}$ . Our main contribution in this setting is as follows.

THEOREM 1.1. Let  $\langle M, \alpha \rangle$  be a rational loop with orbit O. A set of defining polynomials of  $\overline{O}$  is computable in PSPACE. For all fixed  $d \in \mathbb{N}$ , the computation of  $\overline{O}$  for d-dimensional loops is in polynomial time.

Motivation for complexity results for prototypical classes of loops, as in Theorem 1.1, arises from bottom-up approaches to invariant generation, where one works to summarise larger and larger subprograms in order to analyse expressive program models (cf. [24]).

Applications in Invariant Verification and Loop Synthesis. The concept of orbit closure is fundamental to numerous subfields of computer science, including geometric complexity theory, quantum computation, non-convex optimisation problems, and graph isomorphism [15, 18, 19, 27, 29]. Our problem of invariant generation can be interpreted as an implicit orbit-closure problem under the action of a cyclic semigroup [1].

The first application of invariant generation that we consider is the *invariant verification* problem. In our setting this amounts to checking whether all reachable states of a given loop satisfy a given collection of polynomial equations. We do not assume that the property to be verified is inductive, and so our analysis involves a non-trivial examination of reachability in the loop. The fact that our invariants are equations plays a key role. For example, allowing inequalities in our invariants

Fig. 1. Summary of our main results, see Section 2 for a comprehensive overview.

would render the invariant verification problem more general than the positivity problem for linear recurrence sequences, whose decidability status has been open for many decades [60].

The second application of our algorithm for invariant generation is *loop synthesis*. An example of the kind of scenario we seek to model is as follows. Imagine that a loop has integer variables x, y, w, and z. If, in each iteration of the loop, both w and y are incremented by 1, how should we update variables x and z to maintain the invariant that  $x^2 - y^2z^2 + z^3 = 0$ ? In other words, we ask to synthesise variable updates that maintain a given relation among the loop variables. In the example at hand, one solution would be  $x := w(y^2 - w^2)$  and  $z := y^2 - w^2$ . We note that this task is related to the problem of computing a parameterisation of a variety given by polynomial equations, which is a classical problem in algebraic geometry.

We prove that the invariant verification problem is coNP-complete when the polynomials describing the invariant to be verified are given in dense representation. We also show that the problem lies in PSPACE when the polynomials are given in sparse representation. In the context of synthesizing loops over integers and rationals, building on our work in invariant generation, we synthesise bit-bounded loops within PSPACE. Additionally, when the loop dimension is fixed, we establish NP upper bounds and, in some cases, provide matching lower bounds.

A summary of our main results is provided in Fig. 1. A comprehensive discussion of these results, along with related previous works, is presented in Section 2.

## 2 OVERVIEW OF MAIN RESULTS

In this section, we give a high-level overview of our main results. We will also introduce the basic definitions required to follow the main techniques exhibited in the algorithms we introduce. See Appendix A for extended preliminaries.

We denote by  $\mathbb{Z}$  and  $\mathbb{Q}$  the set of all integer and rational numbers, respectively. We write  $\mathbb{Q}[x]$  for the ring of univariate polynomials with rational coefficients over x, and  $\mathbb{Q}[x]$  for the ring of multivariate polynomials over variables  $x = (x_1, \dots, x_d)$ . Recall that a complex number  $\alpha$  is algebraic if it is a root of a nonzero univariate polynomial in  $\mathbb{Q}[x]$ . The *minimal polynomial* of  $\alpha \in \overline{\mathbb{Q}}$  is uniquely defined as the monic polynomial in  $\mathbb{Q}[x]$  of smallest degree for which  $\alpha$  is a root. Denote by  $\overline{\mathbb{Q}}$  the algebraic-closure of  $\mathbb{Q}$ , that is, the set of all algebraic numbers. For algorithmic purposes we rely on a *representation* of algebraic numbers, which results in effective arithmetic, see [22, Section 4.2.1].

Given a polynomial  $P \in \mathbb{Q}[x]$ , its total degree is defined as the maximum total degree of its constituent monomials. Following [50], we define P(x) as being written in *dense representation* if it is given as an array of coefficients (both zero and nonzero) for all monomials up to its total degree. In contrast, it is in *sparse representation* if it is given as an explicit set of monomials with nonzero coefficients. The size of the polynomial P(x), in either representation, is the bit length of a reasonable encoding of the polynomial in the required representation, with all numbers written in binary. For instance, the size of  $x^{2^n}$  is  $2^n + 1$  when written in dense representation, whereas it is n when written in sparse representation. By the above, the degree of P(x) in dense representation is at most its size, whereas in sparse representation it could be exponential in its size. Given a set  $S \subseteq \mathbb{Q}[x]$ , its description size is defined as the combination of its cardinality, the size of its polynomials, and the number of variables.

Complexity Theory. We briefly summarise some relevant notions from complexity theory [6]. The Arthur-Merlin complexity class (AM) consists of all decision problems that admit a two-round interactive proof in which Arthur tosses some coins and sends the result to Merlin, who responds with a purported proof of membership in the language [8]. It is well-known that AM contains both BPP (that is, the class of randomised polynomial time with two-sided error) and NP. It is also contained in  $\Pi_2$ , the second level of the polynomial hierarchy (PH).

Denote by  $\exists \mathbb{R}$  the class of problems that are polynomial-time reducible to the decision problem for the existential theory of the reals. Since the latter lies in PSPACE we have that  $\exists \mathbb{R} \subseteq PSPACE$ . We recall that PSPACE is closed under PSPACE-oracles, that is, PSPACE PSPACE = PSPACE.

**Simple Linear Loops.** A simple loop consists of a single-path loop with linear variable updates. For example, consider the loop in Fig. 2. It is easy to see that after n iterations of the while loop, the values of the variables x and y are given by the (n+1)th and nth Fibonacci numbers, respectively. After n iterations, the value of variable z is  $(-1)^n$ .

Input: 
$$(x, y, z) \leftarrow (1, 0, -1)$$
 while true do

$$\begin{pmatrix} x \\ y \\ z \end{pmatrix} \leftarrow \begin{pmatrix} 1 & 1 & 0 \\ 1 & 0 & 0 \\ 0 & 0 & -1 \end{pmatrix} \begin{pmatrix} x \\ y \\ z \end{pmatrix}$$

end while

Fig. 2. Fibonacci simple loop program

Recall that  $\operatorname{Mat}_d(\overline{\mathbb{Q}})$  is the set of all  $d \times d$  matrices with entries in  $\overline{\mathbb{Q}}$ . A *linear loop*  $\mathcal{L} = \langle M, \boldsymbol{\alpha} \rangle$  is formally defined as a loop program of the form

$$x \leftarrow \alpha$$
; while true do  $x \leftarrow Mx$ ,

where  $\alpha \in \overline{\mathbb{Q}}^d$  is an *initial vector* and  $M \in \operatorname{Mat}_d(\overline{\mathbb{Q}})$  is an *update matrix*. The main focus of the paper is on rational and integer loops, where all constants lie in  $\mathbb{Q}$  and in  $\mathbb{Z}$ , respectively. We define loops more generally to encompass intermediate steps in our procedures.

The *orbit* of  $\mathcal{L}$  is the reachable set of program states, that is defined by  $O := \{M^n \alpha : n \in \mathbb{N}\} \subseteq \overline{\mathbb{Q}}^d$ . The orbit of the program in Fig. 2 is

$$\left\{ \begin{pmatrix} 1\\0\\-1 \end{pmatrix}, \begin{pmatrix} 1\\1\\1 \end{pmatrix}, \begin{pmatrix} 2\\1\\-1 \end{pmatrix}, \begin{pmatrix} 3\\2\\1 \end{pmatrix}, \begin{pmatrix} 5\\3\\-1 \end{pmatrix}, \begin{pmatrix} 8\\5\\1 \end{pmatrix}, \dots \right\}.$$

A program with a finite orbit is called trivial, and non-trivial otherwise. The above program is non-trivial [47].<sup>1</sup>

**Algebraic Geometry.** A polynomial ideal I is an additive subgroup of  $\mathbb{Q}[x]$  that is closed under multiplication by polynomials in  $\mathbb{Q}[x]$ . Hilbert's Basis theorem states that every polynomial ideal  $I \in \mathbb{Q}[x]$  is *finitely generated*, equivalently, that every strictly ascending chain of ideals in  $\mathbb{Q}[x]$  is finite. Denote by  $I = \langle S \rangle$  if  $S \subseteq \mathbb{Q}[x]$  is a generating set for I.

We view program orbits as a subset of affine space  $\overline{\mathbb{Q}}^d$  for some dimension d. Following [36, 37], we consider over-approximations of program orbits by  $algebraic\ sets$ . An algebraic set (or variety) is the set of common zeros of a polynomial ideal I; thus, the set  $V(I) := \{v \in \overline{\mathbb{Q}}^d : f(v) = 0 \text{ for all } f \in I\}$ , is an algebraic set. By Hilbert's Basis theorem, every algebraic set can be represented as the set of common zeros of a finite set of polynomials. An algebraic set  $X \subseteq \overline{\mathbb{Q}}^d$  is irreducible if it cannot be written as  $X = X_1 \cup X_2$  such that  $X_1$  and  $X_2$  are both algebraic sets and both proper subsets of X. In this paper we use the terms algebraic set and variety interchangeably whereas certain authors reserve the term variety for irreducible algebraic sets.

The *strongest algebraic approximation* for a program is the smallest algebraic set containing the program orbit. In this context, *smallest* refers to the closure in the Zariski topology on  $\overline{\mathbb{Q}}^d$ , where closed sets are algebraic subsets of  $\overline{\mathbb{Q}}^d$ . For any set  $X \subseteq \overline{\mathbb{Q}}^d$ , its closure in the Zariski topology on  $\overline{\mathbb{Q}}^d$ , denoted by  $\overline{X}$ , is the smallest algebraic set that contains it. Subsequently, the strongest algebraic approximation of a program is  $\overline{O}$ .

**Algebraic Invariant.** Given a loop program  $\mathcal{L} = \langle M, \alpha \rangle$ , a set  $A \subseteq \overline{\mathbb{Q}}^d$  is an *invariant* if it overapproximates the orbit O of  $\mathcal{L}$ , that is,  $\{M^n\alpha : n \in \mathbb{N}\} \subseteq A$ . Moreover, if A is an algebraic set then we call A an *algebraic invariant*. We may refer to the polynomial ideal  $I \in \mathbb{Q}[x]$  such that V(I) = A as an invariant ideal for  $\mathcal{L}$ .

We say that a set  $A \subseteq \overline{\mathbb{Q}}^d$  is *inductive* with respect to  $\mathcal{L}$  if  $\alpha \in A$  and  $\{Mv : v \in A\} \subseteq A$ . It is immediate that an inductive set is an invariant. It is equally straightforward that the converse fails in general: not every invariant is inductive. However, the loop  $\mathcal{L}$  admits a smallest algebraic invariant, namely the Zariski closure  $\overline{O}$  of the orbit, and this set *is* inductive. Indeed  $M(\overline{O}) \subseteq \overline{M(O)} \subseteq \overline{O}$  holds by Zariski continuity of the selfmap  $v \mapsto Mv$  on  $\overline{\mathbb{Q}}^d$ . A non-trivial algebraic invariant for the program depicted in Fig. 2 is (the zero set of) the polynomial

$$(y^2 + xy - x^2)^2 - z^2 = 0; (1)$$

see, for example [46]. This set is an invariant by virtue of being inductive. Indeed, we have that the initial point (1,0,-1) satisfies (1). Further, by substitution of the update assignments in Fig. 2, we have that  $(x^2 + (x+y)x - (x+y)^2)^2 - (-z)^2 = (y^2 + xy - x^2)^2 - z^2 = 0$ . In other words, Equation (1) is stable under the update matrix of the loop.

## 2.1 Algebraic Invariant Generation

Our main contribution in Theorem 1.1 is a PSPACE algorithm to compute the strongest algebraic invariant of a given simple linear loop. This algorithm runs in polynomial time if the dimension of the loop is fixed.

The geometric properties of the algebraic closure of cyclic subsemigroups of  $\mathrm{Mat}_d(\mathbb{Q})$  are studied in [30]. Principally, it is shown that each irreducible component of the closure of a cyclic semigroup is either an isolated point or isomorphic to a toric variety. Recall that a *toric variety* is the closed image of a monomial map. Toric varieties form an important and rich class of varieties in algebraic geometry, particularly in view of their combinatorial and algorithmic properties. To obtain the result in Theorem 1.1, we rely on the observation that the closures of cyclic subsemigroups of matrices

<sup>&</sup>lt;sup>1</sup>The definition of a non-trivial loop aligns with that of a wandering point in the arithmetic dynamics literature [12, 64].

and orbit closures of linear loops, under some isomorphism of varieties, have the same geometric structure. A careful analysis of results in [30], which inspired our research, provides an exponential degree bound for the polynomials defining the closure of matrix semigroups. Such an exponential degree bound, combined with techniques in [43, 55], gives an inefficient EXPSPACE procedure for invariant generation.

In our construction, the main obstacle to improve the PSPACE bound is the basis computation for the lattice of multiplicity relations between the eigenvalues of the update matrix. The best known bound for this task is through a brute-force search in combination with Masser's bound, see [27, 30, 36, 58] and Appendix A.3. If the eigenvalues of the matrix updates are rational numbers, rational multiples of roots of unity, or rational multiples of unnested radicals, this task can be performed more efficiently through identity testing problems for the underlying fields [9, 10]. In those cases, this allows us to place the invariant generation problem in the second level of the polynomial hierarchy (PH).

**Related Work: Invariant Generation.** Automatically generating invariants for simple linear loop programs has garnered significant attention. This task remains highly challenging even for simple loop programs with multiple linear updates [37, 40, 48, 51].

There is also a line of work addressing more expressive computational models, such as programs with nested loops, conditional branching, probabilistic updates, and unstructured control flow. However, these procedures are often limited by the types of polynomial invariants they can generate, rendering them necessarily incomplete. Typically, they produce polynomials only up to a user-defined degree [4, 5, 11, 56]. Amongst recent works, a complete method for generating polynomial invariants for extended P-solvable loops is presented in [41]. Another recent work [24] generates polynomial invariants for programs with arbitrary control flow, building on an earlier heuristic framework in [48]. The approach is complete for solvable transition ideals, a generalisation of solvable polynomial maps [62]. However, the Gröbner basis calculations in Algorithm 3 dominate the running time, making the computation exponential [24, pg.21]. Recently, invariant generation for moment-computable probabilistic loops was shown to be decidable [57]; the proof employs a reduction to invariant generation in our setting (that of simple linear loops).

## 2.2 Invariant Verification

In this subsection, we consider two decision problems concerning invariants for a given loop. The first problem asks whether a set is an inductive invariant; the second problem asks whether a set is an invariant.

Determining whether an input ideal defines an *inductive set* for a given loop is in principal a simple task, reducible to *radical membership testing*. Recall that the radical of a polynomial ideal  $I \subseteq \mathbb{Q}[x]$ , denoted by  $\sqrt{I}$ , is obtained by taking all roots of its elements within  $\mathbb{Q}[x]$ . By Hilbert's Nullstellensatz, if a variety V is such that V = V(I), the only other polynomials which vanish on V are those in  $\sqrt{I}$ . The *radical membership test* asks to determine whether a polynomial  $P(x) \in \mathbb{Q}[x]$  belongs to the radical of a given ideal  $I \subseteq \mathbb{Q}[x]$  (see [23, Proposition 8, Chapter 4]). Radical membership testing reduces to the satisfiability problem of polynomial equations over  $\mathbb{Q}$ . This is a byproduct of the *Rabinowitsch trick*, see [23, Chapter 4. §2] for example, which shows that  $f \in \sqrt{I}$  if and only if  $V(\langle I \cup \{1 - yf\} \rangle) = \emptyset$  where  $I \subseteq \mathbb{Q}[x]$  and  $\langle I \cup \{1 - yf\} \rangle \in \mathbb{Q}[x, y]$ .

The satisfiability problem for polynomial equations over  $\mathbb{Q}$ , also known as the *Hilbert's Null-stellensatz* problem (HN for short), takes as an input a set S of polynomial equations and asks to determine whether the system is satisfiable, i.e., whether the variety of the ideal  $\langle S \rangle$  is non-empty. It is known that the HN problem admits an AM protocol [49] under the generalised Riemann hypothesis. This result is independent of representation of input polynomials.

By the above, an algorithm to decide whether an input ideal  $\langle S \rangle \subseteq \mathbb{Q}[x]$  defines an inductive set for a given loop  $\langle M, \alpha \rangle$  must (1) determine whether  $\alpha$  satisfies all relations in S, and (2) test whether  $P(Mx) \in \sqrt{\langle S \rangle}$  for all polynomials  $P(x) \in S$ . Both of these tests algorithmically reduce to HN. An alternative approach is to write a query in the existential theory of reals; this leads to an unconditional  $\exists \mathbb{R}$  upper bound. We note in passing that for a fixed number of variables such queries can be decided in polynomial time.

In comparison to determining whether an ideal defines an inductive set for a linear loop, it is more demanding to determine whether it defines a mere invariant (not necessarily inductive). We call the latter the *invariant verification* problem. A conceptually simple algorithm for the invariant verification problem is a backward algorithm, used in similar settings in [11, 13, 44, 45], examining the ascending chain  $I_0 \subseteq I_1 \subseteq I_2 \subseteq \cdots$  of ideals where

$$I_0 = \langle S \rangle$$
 and  $I_i = \langle P(M^j x) : P \in S, j \le i \rangle$ , (2)

for all  $i \in \mathbb{N}$ . By virtue of  $\mathbb{Q}[x]$  being Noetherian, the ascending sequence of nested ideals in (2) stabilises. In our setting, by properties of linear transformations and the well-known fingerprinting procedure for solving Algebraic Circuit Identity Testing (ACIT) [2], we obtain the following.

PROPOSITION 2.1. Given  $S \subseteq \mathbb{Q}[x]$  in dense representation and a loop with the orbit O, verifying whether  $O \subseteq V(S)$  is coNP-complete.

The above naïve algorithm results in an inefficient EXPSPACE upper bound when the polynomials in S have sparse representation. One of our contributions shows that invariant verification is in PSPACE, even if the input polynomials are given in sparse representation. Our procedure also verifies whether  $\overline{O} = V(S)$ , a task that cannot be performed through the study of the ideal chain in (2).

PROPOSITION 2.2. Given  $S \subseteq \mathbb{Q}[x]$  and a loop with the orbit O, verifying whether  $O \subseteq V(S)$  holds is in PSPACE, and is coNP-hard. Similarly, the test  $\overline{O} = V(S)$  can be done in PSPACE. For all fixed  $d \in \mathbb{N}$ , both problems for d-dimensional loops are decidable in polynomial time.

**Related Work: Invariant Verification.** Invariant verification in the setting of matrix semigroups (a non-deterministic model of loop programs) was shown to be decidable by Dräger [28]. While the program model considered in [28] is more expressive than linear loops (which essentially correspond to matrix semigroups with a single generator), the latter work considers a more specialised class of invariants—namely disjunctions of linear equations. Dräger adopts an angelic model of non-determinism: the invariant is considered to hold if there is *some* resolution of the non-determination that guarantees that the property remains true indefinitely.

## 2.3 Weak and Strong Loop Synthesis

Another application of the computation of the strongest invariants, is the complementary view of synthesising linear loops from a given invariant. Most generally, the loop synthesis problem asks, given a polynomial ideal with a generating set  $S \subseteq \mathbb{Q}[x]$  of polynomials, whether there exists a linear loop with (an infinite) orbit O such that  $\overline{O} \subseteq V(S)$ . This problem and its variants have recently received much attention [34, 38, 39]; see the discussion in related works below.

A recently defined variant of the loop synthesis problem sharpens the inclusion of  $\overline{O}$  in V(S) by requiring equality of these two varieties. We call this variant the *strong synthesis* problem, whereas we may refer to the loop synthesis problem as the *weak synthesis problem*. As an instance, recall the ideal  $I := \langle (y^2 + xy - x^2)^2 - z^2 \rangle$  generated by the polynomial in (1). Given I as the input, the loop program in Fig. 2 is a witness for weak synthesis but not for strong synthesis. Indeed, the strongest polynomial invariant for the loop in Fig. 2 is the ideal generated by  $J = \langle y^2 + xy - x^2 + z, z^2 - 1 \rangle$  for which I is a strict subset (meaning that,  $V(J) \subset V(I)$ ).

We study both weak and strong synthesis for loops over  $\mathbb{Z}$  and  $\mathbb{Q}$ . An informal discussion in [34, Remark 2.8] connects loop synthesis and Diophantine equations. The immediate observation in Lemma 2.3 formalises this connection. The proof of Lemma 2.3 is given in Appendix B.

LEMMA 2.3. The weak synthesis problem over  $\{\mathbb{Z}, \mathbb{Q}\}$  is as hard as Hilbert's Tenth problem (HTP) over  $\{\mathbb{Z}, \mathbb{Q}\}$ , even in fixed dimension.

The HTP over  $\mathbb Z$  was shown undecidable by Matiyasevich in 1970 [54], even for polynomial equations with fixed number of variables (as small as 11 variables) [61]. The decidability of HTP over  $\mathbb Q$  is a long-standing open problem in the theory of Diophantine Equations [63] and in arithmetic geometry [61]. Lemma 2.3 implies undecidability of the weak synthesis of loops over  $\mathbb Z$ . In [25], it is shown that the problem of asking whether a variety has infinitely many integer points is as hard as HTP over  $\mathbb Z$ . The reduction in [25] can be extended naturally to show that the problem of asking whether a variety has infinitely many rational points is also as hard as HTP over  $\mathbb Q$ . The strong synthesis of loops over  $\mathbb Z$  and  $\mathbb Q$  has the flavour of this latter problem, and we leave the decidability open.

**Bit-bounded Loops.** The HTP-hardness of (weak) loop synthesis motivate us to define the notion of synthesis of bit-bounded loops. The bitsize of a rational number  $\frac{a}{b}$ , with a and b co-prime integers, is  $\log(|a|) + \log(|b|)$ . Given a linear loop  $\mathcal{L} = \langle M, \alpha \rangle$ , we say that it is *B-bounded rational*, if all entries of M and  $\alpha$  are rational numbers with bitsize at most B.

The strong synthesis problem for bit-bounded loops asks, given a set  $S \subseteq \mathbb{Q}[x]$  of polynomials and a bound  $B \in \mathbb{N}$ , whether there exists some B-bounded linear loop  $\mathcal{L} = \langle M, \alpha \rangle$  with orbit O such that  $\overline{O} = V(S)$ . Similarly, the weak synthesis problem for bit-bounded loops asks whether  $\overline{O} \subseteq V(S)$  holds.

We place the bit-bounded variants of the loop synthesis, for both strong and weak cases, in PSPACE, through the invariant verification problem. We also establish complexity lower bounds for these problems, through reductions from 3SAT and Unique SAT.

PROPOSITION 2.4. The strong and weak synthesis problems for bit-bounded loops over  $\{\mathbb{Q}, \mathbb{Z}\}$  lie in PSPACE. The weak variant is NP-hard; and the strong variant is NP-hard under randomised reductions.

When synthesising loops with a fixed dimension  $d \in \mathbb{N}$ , we obtain an NP upper bound. For weak synthesis over  $\mathbb{Z}$  we show that the problem is complete for the class NP.

PROPOSITION 2.5. For all fixed  $d \in \mathbb{N}$ , the strong and weak synthesis problems for bit-bounded d-dimensional loops over  $\{\mathbb{Q}, \mathbb{Z}\}$  is in NP. The weak variant for loops over  $\mathbb{Z}$  is NP-complete.

Related Work: Loop Synthesis. Program synthesis, conceived as the problem of generating constraints that relate unknowns and enforce correctness requirements, has received significant attention [3, 33]. Recent works focusing on polynomial invariants [34, 38, 39, 47] have leveraged algebraic techniques to recast the problem of loop synthesis as that of solving an algebraic system of recurrence sequences. The template-based procedure in the work by Humenberger et al. [38, 39] finds the solution to this system of recurrences by solving a polynomial constraint problem; however, we note their solutions result in loops defined over  $\overline{\mathbb{Q}}$ . A Diophantine approach to loop synthesis is employed in [34]; therein, those authors synthesise loops when given a single quadratic equation as input. Another recent work [47] give a procedure for synthesising loops for an input binomial ideal.

Matrix completion is the task of completing a partially defined matrix according to a given specification [42]. Perhaps the most notable variant is the *Netflix Problem* [21] (an application in collaborative filtering [32]). In this application the goal is to complete a matrix of movie recommendations so as to minimise the rank (or some proxy thereof, such as the nuclear norm). This

is reminiscent of the template-based approaches towards program synthesis [65]. In the language of loop synthesis, the partial matrix represents an incomplete program fragment and the task is to complete the program so as to guarantee certain desired polynomial invariants.

## 3 ALGEBRAIC CLOSURE OF LINEAR LOOPS

Our goal in this section is to construct the strongest algebraic invariant of an input loop. Fix a loop  $\mathcal{L}$  with update matrix  $M \in \mathbb{Q}^{d \times d}$  and initial vector  $\boldsymbol{\alpha} \in \mathbb{Q}^d$ . We define the size of  $\mathcal{L}$  as  $d + \ell$ , where  $\ell$  is the bitsize of the entries of M and  $\boldsymbol{\alpha}$ .

As in [27, 30, 36, 58], our first step is to compute the Jordan normal form of the update matrix M via a Jordan decomposition. A Jordan decomposition of M comprises a Jordan matrix J, and a change-of-basis matrix P which satisfy  $M = PJP^{-1}$ . Recall that the matrix J is such that the only nonzero entries of J are on its diagonal and its superdiagonal, and that the matrix P in the Jordan decomposition is not unique. In Section 3.1, roughly speaking, we show that P can be chosen such that  $P^{-1}\alpha$  is a binary vector. This simplifies the computation of the invariant equations, derived in Section 3.2, and our proposed algorithms. We analyse the computational complexity of the algorithm in Section 3.3.

# 3.1 A Convenient Jordan Block Decomposition

The *Jordan normal form*  $J \in \overline{\mathbb{Q}}^{d \times d}$  of M is given by the direct sum of several so-called Jordan blocks  $J_1, \ldots, J_s$ . Each block  $J_i$  is a square matrix of dimension  $d_i$  as follows:

$$J_i := \begin{pmatrix} \lambda_i & 1 & & & \\ & \ddots & \ddots & & \\ & & \lambda_i & 1 & \\ & & & \lambda_i \end{pmatrix}.$$

The multiset  $\{\lambda_1, \dots, \lambda_s\}$  of algebraic numbers is equal to the multiset of eigenvalues of M. Indeed, for each eigenvalue  $\lambda_i$  the sum of the sizes of all Jordan blocks corresponding to  $\lambda_i$  is its algebraic multiplicity. Recall that J is unique up to the ordering of its Jordan blocks.

A *Jordan decomposition* of M, denoted by (P, J), consists of the associated Jordan normal form J and an invertible change-of-basis matrix  $P \in \overline{\mathbb{Q}}^{d \times d}$  for which  $M = PJP^{-1}$ . According to the s blocks of (P, J), we can partition d-dimensional vectors v into s block vectors  $v_i$  such that

$$v := (v_1, \dots, v_s) \tag{3}$$

where each  $v_i$  is a vector of size  $d_i$ . The *fingerprint* of  $\alpha$  with respect to (P, J) is defined as a binary vector  $\beta \in \{0, 1\}^d$  where, for each block  $\beta_i = (\beta_{i,1}, \dots, \beta_{i,d_i})$  with  $i \in \{1, \dots, s\}$ ,

• the entry  $\beta_{i,j}$  is 1 if and only if j is the largest index such that  $\alpha_{i,j}$  is nonzero.

We define a Jordan decomposition (P, J) as *convenient* for  $\langle M, \alpha \rangle$  if  $P^{-1}\alpha$  is the fingerprint of  $\alpha$  with respect to the decomposition.

LEMMA 3.1. For a loop  $\langle M, \alpha \rangle$  and any Jordan decomposition (P, J) of M, there exists a matrix  $U \in GL_d(\overline{\mathbb{Q}})$  such that  $(PU^{-1}, J)$  is a convenient Jordan decomposition for  $\langle M, \alpha \rangle$ . The computation of U is in polynomial time in the size of the loop.

PROOF. Let (P, J) be a Jordan decomposition of M. Write  $J = J_1 \oplus \cdots \oplus J_s$  as a direct sum of Jordan blocks. Consider the corresponding block decomposition of the vector  $P^{-1}\alpha = \alpha_1 \oplus \cdots \oplus \alpha_s$ . We construct a matrix  $U = U_1 \oplus \cdots \oplus U_s$  such that  $UP^{-1}\alpha \in \{0, 1\}^d$  and U commutes with J. To this

end, suppose that  $\alpha_i$  is given by  $\alpha_i = (\alpha_{1,i}, \dots, \alpha_{r,i}, 0 \dots, 0)^T$  such that  $\alpha_{r,i} \neq 0$ . We define

$$U_i := egin{pmatrix} b_r & \cdots & b_1 & \cdots & 0 \\ & \ddots & & \ddots & dots \\ & & \ddots & & b_1 \\ & & & \ddots & dots \\ & & & b_r \end{pmatrix},$$

such that each  $U_i$  is upper triangular and Toeplitz (meaning that along each diagonal the entries are constant). The entries  $b_1, \ldots, b_r$  are chosen such that  $U_i \alpha_i = e_r$ , where  $e_r$  is the standard unit vector with 1 in the rth position. Specifically,  $b_r = \frac{1}{\alpha_{r,i}}$ , and the other values of  $b_j$ 's are defined one-by-one for  $j = r - 1, \ldots, 1$  by back substitution.

By construction we have  $UP^{-1}v \in \{0,1\}^d$ . By a well-known property of upper triangular Toeplitz matrices, each  $U_i$  commutes with  $J_i$ , implying that JU = UJ. Define  $Q := PU^{-1}$ , and observe that  $M = PJP^{-1} = QJQ^{-1}$ . Moreover  $Q\alpha \in \{0,1\}^d$  holds, and  $Q\alpha$  is in addition the fingerprint of  $\alpha$ . Hence, the Jordan decomposition  $(PU^{-1}, J)$  is convenient for  $\langle M, \alpha \rangle$ .

# 3.2 Computing the Strongest Algebraic Invariant

Let (P, J) be an arbitrary Jordan decomposition of M such that all Jordan blocks with zero eigenvalue appear first. Consider the orbit  $O := \{M^n \alpha : n \in \mathbb{N}\}$  of the loop. We are interested in computing the polynomials that define the algebraic set  $\overline{O} = \overline{\{M^n \alpha : n \in \mathbb{N}\}}$ . Since  $M^n \alpha = PJ^nP^{-1}\alpha$  holds for all  $n \in \mathbb{N}$ , we compute the polynomials  $\overline{O}$  in two steps:

- first, we can compute the polynomials that define the algebraic set  $\overline{\{J^n\ (P^{-1}\alpha):n\in\mathbb{N}\}}$  and
- $\bullet$  second, we apply the invertible linear transformation P.

For the decomposition (P, J) of M, let N be the direct sum of all Jordan blocks associated with eigenvalue 0. Let  $d_0$  be the dimension of N; that is, the algebraic multiplicity of 0. Write  $J_1, \ldots, J_s$  for all Jordan blocks with associated nonzero eigenvalues  $\lambda_1, \ldots, \lambda_s$ , respectively. Denote by  $d_i$  the dimension of the Jordan blocks  $J_i$ . Thus  $J = N \oplus J_1 \oplus \cdots \oplus J_s$ .

The above-mentioned matrix N is *nilpotent*, i.e., there is an integer  $m \le d_0$  such that  $N^m = 0$ . Thus the set  $\{N^n : n \in \mathbb{N}\}$  is finite, which in turn implies that the algebraic set  $\overline{\{J^n \ (P^{-1}\alpha) : n \in \mathbb{N}\}}$  contains at most m isolated points:

$$\{P^{-1}\boldsymbol{\alpha}, JP^{-1}\boldsymbol{\alpha}, \dots, J^{n_0-1}P^{-1}\boldsymbol{\alpha}\}. \tag{4}$$

Write  $n_0$  for the number of distinct isolated points in the above set. Define  $\gamma := J^{n_0}(P^{-1}\alpha)$ . We obtain  $\tilde{J}$  from  $J = N \oplus J_1 \oplus \cdots \oplus J_s$  by replacing N with the zero matrix (of size  $d_0 \times d_0$ ). By (4) and the definitions of  $\gamma$  and  $\tilde{J}$ , the algebraic set  $\{J^n(P^{-1}\alpha) : n \in \mathbb{N}\}$  decomposes as

$$\{J^i P^{-1} \boldsymbol{\alpha} : 0 \leq i < n_0\} \cup \overline{\{\tilde{J}^n \boldsymbol{\gamma} : n \in \mathbb{N}\}}$$

This allows us to first focus on the Zariski closure of the loop with the invertible transition matrix  $J_1 \oplus \cdots \oplus J_s$ , and then recover  $\overline{O}$ .

Towards this goal, we apply Lemma 3.1 to  $\langle \tilde{J}, \gamma \rangle$  in order to compute the matrix U for which  $(PU^{-1}, \tilde{J})$  is a convenient Jordan decomposition for  $\langle \tilde{J}, \gamma \rangle$ , which by construction respects the ordering of the Jordan blocks in  $\tilde{J}$ . Define  $\beta := U\gamma$ . Consider the partition of  $\beta$  according to the decomposition (P, J), defined in (3). Denote by  $\beta_i$  the block of  $\beta$  that corresponds to the Jordan block  $J_i$ . Thanks to the convenient Jordan decomposition, each block  $\beta_i$  is either a zero vector, or a standard unit vector. For the block  $\beta_i$ , write  $k_i$  if the nonzero entry of  $\beta_i$  is  $\beta_{i,k_i}$  (We assume  $k_i = 0$  in case  $\beta_i$  is a zero vector.)

Consider  $i \in \{1, ..., s\}$  such that the block  $\beta_i$  is a standard unit vector. A close analysis of  $J_i^n \beta_i$ , we see that

$$J_{i}^{n}\boldsymbol{\beta}_{i} = \begin{pmatrix} \binom{n}{k_{i-1}} \lambda_{i}^{n-k_{i+1}} \\ \binom{n}{k_{i-2}} \lambda_{i}^{n-k_{i+2}} \\ \vdots \\ n\lambda_{i}^{n-1} \\ \lambda_{i}^{n} \\ 0 \\ \vdots \\ 0 \end{pmatrix}$$

$$(5)$$

holds for all  $n \in \mathbb{N}$ .

At the next step we introduce a linear transformation  $R := I_{d_0} \oplus R_1 \oplus \cdots \oplus R_s$  to simplify (5) such that

$$R_{i}J_{i}^{n}\boldsymbol{\beta}_{i} = \begin{pmatrix} n^{k_{i}-1}\lambda_{i}^{n} \\ n^{k_{i}-2}\lambda_{i}^{n} \\ \vdots \\ n\lambda_{i}^{n} \\ \lambda_{i}^{n} \\ 0 \\ \vdots \\ 0 \end{pmatrix}. \tag{6}$$

Recall the combinatorial identity

$$n^{k} = \sum_{i=1}^{k} i! \binom{k}{i} \cdot \binom{n}{k} = \sum_{i=1}^{k} c_{k,i} \binom{n}{k}, \tag{7}$$

where  $\binom{k}{i} = \frac{c_{k,i}}{i!}$  is the Stirling number of the second kind. Since the Stirling numbers are defined recursively by the relation  $c_{k+1,i} = i(c_{k,i} + c_{k,i-1})$ , we can compute the coefficients in  $R_i$ , starting with  $c_{1,1} = \cdots = c_{k_i-1,1} = 1$ , in polynomial time. The block matrix  $R_i$  is defined below.

One can see that (6) is a direct consequence of (5), (7) and (8). We note that, by construction, R is an invertible matrix.

Let  $\mathbf{x} = (x_1, \dots, x_d)$  where d is the dimension of the matrix M. Consider the partition of  $\mathbf{x} = (x_0, \dots, x_s)$  according to the decomposition (P, J), defined in (3). Let  $\mathbf{x}_i = (x_{i,1}, \dots, x_{i,d_i})$  be the block vector corresponding to the Jordan block  $J_i$ , with  $i \in \{1, \dots, s\}$ , and  $\mathbf{x}_0 = (x_{0,1}, \dots, x_{0,d_0})$  the concatenation of the block vectors corresponding to Jordan blocks with zero eigenvalues.

In the following, we construct a set of polynomials in  $\mathbb{Q}[x]$  that define the variety

$$R \cdot \overline{\{\tilde{J}^n \, \boldsymbol{\beta} : n \in \mathbb{N}\}} \tag{9}$$

which in turn helps us define the set of polynomials for the algebraic closure of the orbit of  $\langle M, \alpha \rangle$ . Recall that  $k_i$  is the only nonzero entry of the block  $\beta_i$  if  $\beta_i$  is a standard unit vector, and  $k_i = 0$  otherwise. Define the set  $S_1$  of polynomials in  $\mathbb{Q}[x_{1,k_1}, \dots, x_{s,k_s}]$  such that

$$V(S_1) = \overline{\{(\lambda_1^n, \dots, \lambda_i^n, \dots, \lambda_s^n) : n \in \mathbb{N}; \boldsymbol{\beta}_i \neq 0\}}.$$
 (10)

The task of computing the defining polynomials is well-understood, see for example [27, 30, 36, 58] and Appendix A.3 for details. The underlying idea is to compute a basis for the lattice of multiplicity relations between the eigenvalues.

For each Jordan block  $J_i$ , with  $i \in \{1, ..., s\}$ , define the set  $S_{2,i}$  of polynomials in  $\mathbb{Q}[x_i]$  as follows.

$$S_{2,i} := \begin{cases} \left\{ x_{i,k_i-1}^j - x_{i,k_i-j} x_{i,k_i}^{j-1} : 2 \le j \le k_i - 1 \right\} & \text{if } k_i \ge 3, \\ \emptyset & \text{otherwise} . \end{cases}$$

This set captures the relations between the nonzero entries of the *i*th block, as in (6).

For each pair of distinct Jordan blocks  $J_i, J_j$ , with  $i, j \in \{1, ..., s\}$ , we define the set  $S_{3,i,j}$  of polynomials in  $\mathbb{Q}[x_{i,k_i-1}, x_{i,k_i}, x_{j,k_j-1}, x_{j,k_j}]$  as follows.

$$S_{3,i,j} := \begin{cases} \{x_{i,k_i-1}x_{j,k_j} - x_{j,k_j-1}x_{i,k_i}\} & \text{if } k_i \ge 2 \text{ and } k_j \ge 2, \\ \emptyset & \text{otherwise} . \end{cases}$$

This set defines the relations between the two blocks  $J_i$  and  $J_j$ . Such a relation only exists when in both blocks  $\beta_i$  and  $\beta_j$ , the corresponding nonzero entries  $k_i$  and  $k_j$  are both greater or equal 2.

Define the set  $S_4$  of polynomials in  $\mathbb{Q}[x]$  such that

$$S_4 := \{x_{0,j} : 1 \le j \le d_0\} \cup \{x_{i,j} : 1 \le i \le s, k_i < j \le d_i\}$$

captures the zero entries. Define  $I_R := \langle S_1, S_{2,i}, S_{3,i,j}, S_4 : i, j \in \{1, ..., s\} \rangle$ . We are now in the position to prove the following:

CLAIM 3.2. 
$$V(I_R) = R \cdot \overline{\{\tilde{J}^n \boldsymbol{\beta} : n \in \mathbb{N}\}}.$$

PROOF. Let  $v_n$  be the vector obtained from  $\tilde{J}^n \gamma$  under the transformation R, shown explicitly in (6). We consider the block decomposition of  $v_n$  according to (P, J).

We did not precisely define the set of polynomials in  $S_1$  as we borrow the technology developed in [27, Lemma 6] to construct  $S_1$  defining the variety in (10). The polynomials in  $S_1$  are defined over the variables  $x_{1,k_1}, \ldots, x_{s,k_s}$ . This choice is justified by the fact that in the block corresponding to the Jordan block  $J_i$  of  $v_n$  the  $k_i$ th entry is  $\lambda_i^n$ .

For each Jordan block  $J_i$ , the set  $S_{2,i}$  reflects the relations between corresponding entries in  $v_n$ . Inspecting (6) again for the entry values of  $v_n$ , the following identity

$$(n\lambda_i^n)^j - n^j \lambda_i^n (\lambda_i^n)^{j-1} = 0$$

is realised by  $x_{i,k_i-1}^j - x_{i,k_i-j} \cdot x_{i,k_i}^{j-1}$ , with  $j \in \{2, ..., k_i - 1\}$ .

Furthermore, for each pair of distinct Jordan blocks  $J_i$ ,  $J_j$ , with  $i, j \in \{1, ..., s\}$ , the set  $S_{3,i,j}$  encompasses the relations between the two blocks. As mentioned above, there is no relation between  $J_i$ ,  $J_j$  if either  $k_i < 2$  or  $k_j < 2$ . Otherwise, the identity

$$(n\lambda_i^n)(\lambda_i^n) - (n\lambda_i^n)(\lambda_i^n) = 0$$

is realised by  $x_{i,k_i-1}x_{j,k_i}-x_{j,k_i-1}x_{i,k_i}$ . The set  $S_4$  reflects the entries in  $v_n$  that always remain zero.  $\square$ 

In [30] it was shown that the irreducible components of the variety defined by a cyclic matrix semigroup is isomorphic to the Cartesian product of a toric variety and a normal rational curve (excluding few isolated points). Our contribution in this regard is to show an explicit construction of that isomorphism (in the case of loops) can be computed in polynomial time using the matrices R and U. In (6) we read-off the effect of the Cartesian product of a toric variety and a normal rational curve.

It remains to define a generating set of polynomials for O from the ideal  $I_R$ . From the steps detailed in the construction, we observe that

$$\overline{\{M^n \boldsymbol{\alpha} : n \in \mathbb{N}\}} = PU^{-1} R^{-1} R \cdot \overline{\{\tilde{J}^n \boldsymbol{\beta} : n \in \mathbb{N}\}} \cup \{M^i \boldsymbol{\alpha} : 0 \le i < n_0\}.$$
(11)

By this equality, to obtain the polynomials defining  $\overline{O}$ ,

- we first compute ideals  $I_0, \ldots, I_{n_0-1}$ , each defining one of the  $n_0 \le d$  isolated points in  $\{M^i \alpha : 0 \le i < n_0\}$ ,
- next we obtain an ideal  $\mathcal{J}$  by applying the transformation  $PU^{-1}R^{-1}$  to the vector of variables x for each polynomial in

$$(S_1 \cup S_4) \cup \bigcup_{\substack{i,j \in \{1,\dots,s\}\\i \neq i}} (S_{2,i} \cup S_{3,i,j}).$$
 (12)

This completes the construction of the strongest algebraic invariant of the loop  $\langle M, \alpha \rangle$  as it is simply  $V(I_0 \cap \cdots \cap I_{n_0-1} \cap \mathcal{J})$ . For complexity purposes, in particular to avoid an exponential blow-up, we choose to output the generators of the  $I_i$  and  $\mathcal{J}$  separately. (This choice is crucial for the obtained PSPACE bound in Proposition 2.2.)

The obtained polynomials are not in  $\mathbb{Q}[x]$  but in k[x] where  $k = \mathbb{Q}(\lambda_1, \dots, \lambda_s)$  is the number field obtained by adjoining the eigenvalues to  $\mathbb{Q}$ . As an extra step, not necessary to obtain the complexity bound, we convert the coefficient of polynomials to integers. We introduce the variables  $y_i$ , one for each eigenvalue  $\lambda_i$ . Recall that each  $\lambda_i$  appears with all its Galois conjugates, and its degree is bounded from above by d. For brevity, given a Galois automorphism  $\sigma$  of the field  $\mathbb{Q}(\lambda_i)$  we denote by  $\sigma(y_i)$  the variable among  $y_1, \dots, y_s$  corresponding to  $\sigma(\lambda_i)$ . For each  $\lambda_i$ , write  $m_i = \sum_{k=0}^n a_k x^k$  for the minimal polynomial. By basic algebra, we know that the set of equations

$$a_{n-1} = -\sum_{\sigma \in Gal(\mathbb{Q}(\lambda_i)/\mathbb{Q})} \sigma(y_i)$$

$$a_{n-2} = \sum_{\sigma, \sigma' \in Gal(\mathbb{Q}(\lambda_i)/\mathbb{Q})} \sigma(y_i) \sigma'(y_i)$$

$$\vdots$$

$$a_0 = (-1)^n \prod_{\sigma \in Gal(\mathbb{Q}(\lambda_i)/\mathbb{Q})} \sigma(y_i)$$
(13)

is such that the solutions to variables  $\sigma(y_i)$  define the set of all conjugates of  $\lambda_i$ . We can thus rewrite  $PU^{-1}R^{-1}$  by changing the constants  $\lambda_i$  to  $y_i$  before the computation of  $\mathcal{J}$ , and for each  $\lambda_i$  we add the set of polynomials given in (13) to the defining ideal.

## 3.3 Computational Complexity

We now proceed with the statement and proof of our main result.

THEOREM 1.1. Let  $\langle M, \alpha \rangle$  be a rational loop with orbit O. A set of defining polynomials of  $\overline{O}$  is computable in PSPACE. For all fixed  $d \in \mathbb{N}$ , the computation of  $\overline{O}$  for d-dimensional loops is in polynomial time.

PROOF. The construction detailed in Section 3.2 can be performed in polynomial time, modulo the computation of the set  $S_1$  of polynomials defining  $\{(\lambda_1^n, \dots, \lambda_i^n, \dots, \lambda_s^n) : n \in \mathbb{N}; \beta_i \neq 0\}$  in (10).

Indeed, every rational square matrix has a Jordan decomposition that can be computed in polynomial time [20], and in polynomial time we can shuffle the decomposition so that the Jordan blocks with zero eigenvalues appear first. Due to the representation in [22, Section 4.2.1] of eigenvalues, all constructions in the remaining steps are performed in polynomial time. This includes the computation of U obtained by applying Lemma 3.1 and the computation of its inverse.

It remains to discuss the computation of  $S_1$ . Here, we employ the architecture developed in [27, Lemma 6]. Therein, the problem of computing the polynomial ideal that defines the closure  $\{(\lambda_1^n, \ldots, \lambda_i^n, \ldots, \lambda_s^n) : n \in \mathbb{N}; \beta_i \neq 0\}$  reduces to finding a set of generators for the associated lattice L. To obtain the complexity bounds, we rely on a theorem of Masser [53] that gives an explicit upper bound on the magnitude of the components of a basis for L.

Following [35], membership of a tuple  $v \in L$  is in  $\exists \mathbb{R}$ , using a decision procedure for the existential theory of the reals. In combination with Masser's bound, it follows that we can compute a basis for L in PSPACE by brute-force search if the dimension is not fixed, and in polynomial time when the dimension is fixed. See Appendix A.3 for further details.

## 4 INVARIANT VERIFICATION

As discussed in Section 2, a standard backward algorithm, used in similar settings in [11, 13, 44, 45], provides a conceptually simple procedure for invariant verification.

Let  $\langle M, \alpha \rangle$  be a simple linear loop. Let  $S \subseteq \mathbb{Q}[x]$  be a set of polynomials, written in the dense representation, with the description size s. Define the sequence of nested ideals  $(I_i)_{i \in \mathbb{N}}$  by  $I_0 = \langle S \rangle$  and  $I_i = \langle P(M^jx) : P \in S, j \leq i \rangle$ , as defined in (2). Since  $\mathbb{Q}[x]$  is Noetherian, this ascending sequence  $I_0 \subseteq I_1 \subseteq I_2 \subseteq \cdots$  of ideals stabilises: there exists k such that  $I_k = I_{k+j}$  for all  $j \in \mathbb{N}$ . Denote by  $I_\infty$  the stabilising value of the sequence. The algorithm tests whether  $\alpha \in V(I_\infty)$ . If yes, then V(S) is an algebraic invariant for  $\langle M, \alpha \rangle$ ; otherwise, it is not.

Since Mx is a linear transformation, the degree of  $P(M^ix)$  is at most the degree of P(x). From this observation we prove that if  $\alpha \notin V(I_{\infty})$  holds then there exists  $k = O(2^s)$  such that  $\alpha \notin V(I_k)$ . Below, we use this bound to obtain a coNP upper bound for invariant verification with the input ideal given in dense representation.

PROPOSITION 2.1. Given  $S \subseteq \mathbb{Q}[x]$  in dense representation and a loop with the orbit O, verifying whether  $O \subseteq V(S)$  is coNP-complete.

PROOF. Recall that s denote the description size of S, and recall the chain of nested ideals  $(I_i)_{i \in \mathbb{N}}$ , defined above (and in (2)). To show the coNP membership, it suffices to provide a polynomial-time verifiable certificate showing that  $\alpha \notin V(I_{\infty})$  for negative instances of the problem. We first prove that

CLAIM 4.1. Suppose that  $\alpha \notin V(I_{\infty})$ . There exists  $k = O(2^s)$  such that  $\alpha \notin V(I_k)$ .

PROOF. By definition, the maximal degree D of polynomials in S and the number d of variables are both bounded by s. For all  $n \in \mathbb{N}$  and all polynomials  $P \in S$ , the degree of  $P(M^n x)$  is at most D, meaning that the ideal  $I_n$  is generated by polynomials of degree at most D.

Let  $N \in \mathbb{N}$  be such that  $I_N = I_{N+1}$ . This implies that  $Q(M^{N+1}x) \in \langle P(M^jx) : P \in S, j \leq N \rangle$  for all  $Q \in S$ . But then  $Q(M^{N+2}x) \in \langle P(M^jx) : P \in S, j \leq N + 1 \rangle = I_{N+1} = I_N$  for all  $Q \in S$ . Hence, using an inductive argument we can show  $I_{N+j} = I_N$  for all  $j \in \mathbb{N}$ . Let k be the smallest integer such that  $I_k = I_{k+1}$ , which implies  $I_k = I_{\infty}$ . Since  $I_0 \subsetneq I_1 \subsetneq \cdots \subsetneq I_k$ , at each step i we introduce at least one generator of  $I_i$  that can not be expressed as linear combination of the generators of  $I_{i-1}$ . The

generators of  $I_i$  lie in the vector space of polynomials of degree at most D with dimension  $\binom{D+d}{d}$ . Therefore,  $k \leq \binom{D+d}{d}$  which completes the proof of the claim.

This claim implies that there exists  $P \in S$  such that  $P(M^k \mathbf{x})(\alpha) \neq 0$ . A conP algorithm guesses  $P(\mathbf{x}) \in S$ , an index  $k = O(2^s)$  and a prime p with bitsize s such that  $P(M^k \mathbf{x})(\alpha) \neq 0$ . Taking the binary representation of k into account and, by standard doubling techniques, the algorithms constructs a small circuit for  $P(M^k \mathbf{x})$  and checks whether  $P(M^k \mathbf{x}) \not\equiv 0 \pmod{p}$  in polynomial time. We borrow the correctness of the latter test from the well-known fingerprinting procedure for the ACIT problem [2].

The proof of coNP-hardness is by a reduction from 3SAT to the complement of the invariant verification problem. Given a 3SAT formula  $\Phi$ , we construct a loop  $\langle M, \alpha \rangle$  with orbit O and a polynomial Q(x) such that  $\Phi$  is satisfiable if and only if  $O \nsubseteq V(\langle Q \rangle)$ .

Let  $\Phi = \bigwedge_{i=1}^m C_m$  be in CNF over variables  $\{y_1, \dots, y_k\}$ . Let  $p_1 < \dots < p_k$  be the first k primes. Define  $D(i) := 1 + \sum_{j=1}^{i-1} p_j$  for  $i \in \{1, \dots, k\}$  and  $d := \sum_{j=1}^k p_j$ . Constrct  $M \in \{0, 1\}^{d \times d}$  and  $\alpha \in \{0, 1\}^d$  as follows: the entry  $\alpha_\ell$  of  $\alpha$  is 1 if, and only if,  $\ell = D(i)$  for some  $i \in \{1, \dots, k\}$ . The matrix M is a block-diagonal matrix  $M_1 \oplus \dots \oplus M_k$ , where  $M_j$  is a permutation matrix of size  $p_j$ . Intuitively speaking, for any  $n \in \mathbb{N}$ , the vector  $M^n \alpha$  splits into k blocks of prime size, and exactly one entry in each block is set to 1. By the Chinese remainder theorem, for every  $\beta \in \{0, 1\}^d$  with exactly one 1 entry in each block, there exists  $n \in \mathbb{N}$  such that  $\beta = M^n \alpha$ .

We construct the polynomial Q over the vector  $\mathbf{x} = (x_1, \dots, x_d)$  of variables. For each  $1 \le i \le k$ , we interpret the variables  $x_{D(i)}, x_{D(i)+1}$  as literals  $y_i$  and  $\neg y_i$ . The other variables of are called *non-literal*. Define  $Q \in \mathbb{Q}[\mathbf{x}]$  as follows

$$Q(\mathbf{x}) := \left(\prod_{x_i \text{ non-literal}} (1 - x_i)\right) \cdot \prod_{i=1}^m Q_i(\mathbf{x}),$$

where  $Q_i := \sum_{j=1}^k t_{ij}^2$  with

$$t_{ij} = \begin{cases} x_{D(j)+1} & \text{if } y_j \text{ appears in } C_i, \\ x_{D(j)+2} & \text{if } \neg y_j \text{ appears in } C_i, \\ 0 & \text{otherwise.} \end{cases}$$

The correctness of reduction follows from two simple observations: Q(x) vanishes on  $\beta \in \{0, 1\}^d$  if  $\beta_i = 1$  for some non-literal entry *i*. Furthermore, provided that all non-literal entries are zero, the point  $\beta$  is a zero of Q(x) if and only if it corresponds to an unsatisfying assignment of  $\Phi$ .

The backward algorithm employed in Proposition 2.1 results in an inefficient EXPSPACE upper bound when the input polynomials have sparse representation. Our route in obtaining the better complexity bound in this case is through invariant generation. By Theorem 1.1, we can construct a set  $\{I_1, \ldots, I_k\}$  of ideals such that  $\overline{O} = V(I_1 \cap \ldots, \cap I_k)$ . The generating set of each ideal  $I_i$  has a small cardinality, and comprises of polynomials in  $\mathbb{Q}[x]$  written in sparse representation with size polynomial in the input loop description. We perform several radical membership tests to determine the relation of  $\overline{O}$  with V(S).

PROPOSITION 2.2. Given  $S \subseteq \mathbb{Q}[x]$  and a loop with the orbit O, verifying whether  $O \subseteq V(S)$  holds is in PSPACE, and is coNP-hard. Similarly, the test  $\overline{O} = V(S)$  can be done in PSPACE. For all fixed  $d \in \mathbb{N}$ , both problems for d-dimensional loops are decidable in polynomial time.

PROOF. Let  $\langle M, \alpha \rangle$  be the input loop with orbit O. With Theorem 1.1 at our disposal, we construct the list of generators for the ideals  $I_0, \ldots, I_{n_0-1}$  and  $\mathcal{J}$ . Recall that when converting the coefficients of polynomials generating  $\mathcal{J}$  to integers, we have introduced new variables  $y_1, \ldots, y_s$  for nonzero

eigenvalues  $\lambda_1, \ldots, \lambda_s$ . Hence,  $\mathcal{J} \subseteq \mathbb{Z}[x_1, \ldots, x_d, y_1, \ldots, y_s]$ . Our construction is such that, for all  $i \in \{0, \ldots, n_0 - 1\}$ , we have  $\{M^i \boldsymbol{\alpha}\} = V(\mathcal{I}_i)$ . Moreover,  $(\boldsymbol{x}, \lambda_1, \ldots, \lambda_s) \in V(\mathcal{J})$  if and only if  $\boldsymbol{x} \in \overline{\{M^n \boldsymbol{\alpha} : n \geq n_0\}}$ .

We now demonstrate how to check in PSPACE whether

$$V(\mathcal{I}_0 \cap \cdots \cap \mathcal{I}_{n_0-1} \cap \mathcal{J}) \sim V(S)$$

holds for  $\sim \in \{=, \subseteq\}$ . Since  $\mathcal J$  is defined with extra variables  $y_i$ 's we add the relations between these extra variables to S. More precisely, for each  $\lambda_i$  we add the set of polynomials defined in (13) with  $1 \le i \le s$ . We first explain how to check  $\overline{O} \subseteq V(S)$  in PSPACE. Towards this, we first check if the rational points  $M^i \alpha$  with  $i \in \{0, \ldots, n_0 - 1\}$  lie in V(S), this reduces to the ACIT and can be tested in randomised polynomial time [2]. It remains to check whether  $V(\mathcal J) \subseteq V(S)$ ; we verify this through testing whether  $P \in \sqrt{\mathcal J}$  for each polynomial  $P \in S$ , which reduces to radical membership testing. As explained in Section 2, the latter task is in AM under GRH and in PSPACE unconditionally.

To conclude, we explain how to test  $V(S) \subseteq \overline{O}$  in PSPACE. We require to test whether every polynomial  $P \in I_0 \cap \cdots \cap I_{n_0-1} \cap \mathcal{J}$  is a member of  $\sqrt{S}$ . This test could be algorithmically expensive due to the intersection, as a generating set for the intersection of these ideals can face an exponential blow-up in size. We instead test the complement of this question, by guessing one generator from each  $I_i$  and one from  $\mathcal{J}$  and checking whether the product is not a member of  $\sqrt{S}$ . We again here rely on the AM protocol of radical membership testing.

The hardness follows from the construction given in Proposition 2.1.

#### 5 BIT-BOUNDED LOOP SYNTHESIS

The results in this section are motivated by the HTP-hardness results in Lemma 2.3. Herein we consider complexity bounds for variants of the loop synthesis problem where one bounds the bitsizes of the loop components (Propositions 2.4 and 2.5). In Proposition 2.5, we obtain tighter bounds by placing an additional dimension specification on the loop.

PROPOSITION 2.4. The strong and weak synthesis problems for bit-bounded loops over  $\{\mathbb{Q}, \mathbb{Z}\}$  lie in PSPACE. The weak variant is NP-hard; and the strong variant is NP-hard under randomised reductions.

PROOF. The PSPACE bound follows by guessing M and  $\alpha$  with entries respecting the required bit bounds, and using the invariant verification subroutine in Proposition 2.2 applied to  $\langle M, \alpha \rangle$  and the input ideal. Thus all that remains is to prove the claimed lower bounds.

Our lower bounds are obtained by reductions from 3SAT, and Unique 3SAT, following the folklore encoding of 3SAT in HN [50]. The following encoding is the main building block for both reductions. Let  $\Phi := \bigwedge_{i=1}^m C_m$  be in CNF over variables  $\{y_1, \ldots, y_d\}$ . From  $\Phi$  we construct a set of polynomials  $S \subseteq \mathbb{Q}[x]$  with vector  $\mathbf{x} = (x_1, \ldots, x_{d+2})$  of variables. We initialise S with polynomial  $x_{d+1} - x_{d+2}$ . For each boolean variable  $y_i$ , with  $i \in \{1, \ldots, d\}$ , we add the polynomial  $x_i(1-x_i)$  to S. For each clause  $C_j$ , with  $j \in \{1, \ldots, m\}$ , we add  $P_i := \prod_{j=1}^d t_{ij}$  to S, where

$$t_{ij} = \begin{cases} 1 - x_j & \text{if } y_j \text{ appears in } C_i, \\ x_j & \text{if } \neg y_j \text{ appears in } C_i, \\ 1 & \text{otherwise.} \end{cases}$$
 (14)

Weak synthesis for bit-bounded loops over  $\{\mathbb{Q}, \mathbb{Z}\}$  is NP-hard: The proof is by a reduction from 3SAT. Given an instance  $\Phi$  of 3SAT, construct the set S of polynomials, as described above.

Assume that  $\Phi$  is satisfiable. Given a satisfying assignment, define  $\alpha$  such that  $\alpha_i = 1$  if and only if  $y_i$  is true in the assignment, and set  $\alpha_{d+1} = \alpha_{d+2} = 1$ . Clearly, the infinite orbit of the point  $\alpha$  under the matrix  $M := \operatorname{diag}(1, \ldots, 1, 2, 2)$  lies in  $V(\langle S \rangle)$ . Conversely, if  $\Phi$  is unsatisfiable, the set  $V(\langle S \rangle)$  is empty and, a fortiori, no loop exists for  $\langle S \rangle$ .

We note in passing that that the entries of such M and  $\alpha$  have constant bitsize.

**Strong synthesis for bit-bounded loops is** NP-hard under randomised reductions: Recall that the Unique 3SAT problem is NP-hard under randomised polynomial-time reductions [66]. It is a promised version of 3SAT, where the input formula is *promised* to have *at most one* satisfying assignment.

Given an instance  $\Phi$  of Unique 3SAT, construct again the set S of polynomials, as described above. By the promise on  $\Phi$ , the projection of  $V(\langle S \rangle)$  into the first d coordinates is either empty or a singleton. The proof is immediate from the previous case, and by the observation that if  $\Phi$  is satisfiable, the projection of  $\overline{\{M^n\alpha:n\in\mathbb{N}\}}$  into the last two coordinates is exactly  $V(\langle x_{d+1}-x_{d+2}\rangle)$ .

We now improve the complexity lower bounds under an additional dimensionality assumption.

PROPOSITION 2.5. For all fixed  $d \in \mathbb{N}$ , the strong and weak synthesis problems for bit-bounded d-dimensional loops over  $\{\mathbb{Q}, \mathbb{Z}\}$  is in NP. The weak variant for loops over  $\mathbb{Z}$  is NP-complete.

PROOF. The NP bound follows by guessing M and  $\alpha$  with entries respecting the required bit bounds, and using the invariant verification subroutine in Proposition 2.2 applied to  $\langle M, \alpha \rangle$  and the input ideal.

The NP lower bound is by reduction from the quadratic Diophantine equations problem, known to be NP-complete [31, 52]: it asks, given natural numbers a,b,c, whether there a solution  $(x,y) \in \mathbb{N}^2$  to the equation  $ax^2 + by = c$ . Given an instance (a,b,c) of the quadratic Diophantine equations problem (a,b,c), we construct polynomials  $L,P,Q \in \mathbb{Z}[x]$  with vector  $\mathbf{x} = (x,y,y_1,y_2,y_3,y_4,z_1,z_2)$  of variables such that there is an integer point in the variety  $V(\langle L,P\rangle) \subseteq \overline{\mathbb{Q}}^6$  if and only if the original equation  $ax^2 + by = c$  has a solution  $(x,y) \in \mathbb{N}^2$ . Define

$$L(\mathbf{x}) := y - y_1^2 - y_2^2 - y_3^2 - y_4^2,$$
  

$$P(\mathbf{x}) := ax^2 + by - c,$$
  

$$Q(\mathbf{x}) := z_1 - z_2.$$

By Lagrange's four-squares theorem, every positive integer y can be expressed as a sum of four integer squares; thus polynomial L ensures that variable y can attain only non-negative integer values. Suppose the intersection  $V(\langle L, P, Q \rangle) \cap \mathbb{Z}^8$  is non-empty. Observe that for  $\alpha \in V(\langle L, P, Q \rangle) \cap \mathbb{Z}^8$ , the orbit under  $M := \text{diag}(1, \ldots, 1, 2, 2)$  is infinite, and thus  $\langle M, \alpha \rangle$  is a non-trivial loop. The converse direction is immediate.

#### 6 FURTHER DISCUSSION

We suggest several directions for further research inspired by our contributions to invariant generation for simple linear loops and loop synthesis presented herein.

**Invariant Generation for affine programs.** A program is considered affine if it exclusively features nondeterministic branching (as opposed to conditional branching) and all its assignments are defined by affine expressions. The invariant generation problem for affine programs is addressed by the algorithm in [36] through the group-closure problem. This problem entails computing a generating set of polynomials for the Zariski closure  $\overline{\langle M_1, \ldots, M_k \rangle}$  for a given set  $\{M_1, \ldots, M_k\}$  of invertible rational matrices. The tightest complexity bound for solving the group-closure problem is sevenfold exponential time [58].

The main result in this paper, Theorem 1.1, presents a PSPACE algorithm for generating the invariants of a simple linear loop (the class corresponding to branch-free loops with a single linear update). To extend our technique to the general case of affine programs, we may first consider the setting with multiple linear updates  $M_1, \ldots, M_k$  where the matrices are commutative and invertible. Since the  $M_i$  commute, the orbit of the loop is defined by  $O = \{M_1^{n_1} \cdots M_k^{n_k} \boldsymbol{\alpha} : n_1, \ldots, n_k \in \mathbb{N}\}$  where  $\boldsymbol{\alpha}$  is the initial vector.

Recall that a matrix  $M \in \overline{\mathbb{Q}}^{d \times d}$  is *unipotent* if there exists  $n \in \mathbb{N}$  such that  $(M - \mathrm{Id}_d)^n = 0_d$  (here  $\mathrm{Id}_d$  and  $0_d$  are the  $d \times d$  identity and zero matrices, respectively) and M is *semisimple* if it is diagonalisable over  $\overline{\mathbb{Q}}$ . Define  $G := \overline{\langle M_1, \ldots, M_k \rangle}$  so that  $\overline{O} = \overline{G}\alpha$ . It is known that the subset of semisimple matrices in G, denoted by  $G_s$ , forms an algebraic subgroup; likewise the set of unipotent matrices in G, denoted by  $G_u$ , forms an algebraic subgroup. By the Jordan–Chevalley decomposition, we have  $\overline{O} = \overline{G_u G_s \alpha}$ .

In the case that  $G = G_s$  we have the following.

LEMMA 6.1. Let G be a semisimple commutative group. A set of defining polynomials for  $\overline{G}\alpha$  is computable in PSPACE.

PROOF. Since G is a semisimple commutative group, there exists  $P \in GL_d(\overline{\mathbb{Q}})$  such that for all  $i \in \{1, \ldots, k\}$ , the matrix  $D_i := P^{-1}M_iP$  is diagonal. Following Lemma 3.1, we can choose P in such a way that  $P^{-1}\alpha \in \{0, 1\}^d$ . Writing  $\overline{O} = P(\overline{D_1}, \ldots, \overline{D_k})P^{-1}\alpha$ , we observe that  $(\overline{D_1}, \ldots, \overline{D_k})P^{-1}\alpha$  is the closure of a group of diagonal matrices of dimension at most d. To obtain a PSPACE procedure it suffices to closely follow our construction in Theorem 1.1. The sole difference from that construction lies in the set  $S_1$  of polynomial equations, which is now defined by the intersection of lattices  $L_i$  of multiplicity relations between the entries of  $D_i P^{-1}\alpha$  [16, Chapter 3].

A natural direction for future research involves extending our PSPACE procedure to apply to commutative matrices more broadly. This requires a better understanding of the following polynomial map:

$$G_u \times \overline{G_s \alpha} \to \overline{G \alpha},$$
  
 $(g, v) \mapsto gv.$ 

Subsequently, an ambitious objective is to develop a procedure with improved complexity bounds for the invariant generation problem in affine programs.

**Loop Synthesis.** Our results for the synthesis of bit-bounded loops over the rationals (Propositions 2.4 and 2.5) demonstrate an inherent source of hardness (Hilbert's Tenth Problem). A first direction for future research might consider circumventing such obstacles by focusing on classes of ideals with an abundance of rational solutions. A small initial step in this direction, the synthesis of loops for pure-difference binomials, was shown in [47]. An ultimate goal is the synthesis of loops for the larger class of binomial ideals.

## A EXTENDED BACKGROUND

# A.1 Complexity Theory

An *Arthur–Merlin protocol* is a two-message interactive proof system between two participants, respectively called Arthur and Merlin. Arthur can be considered as a probabilistic polynomial time verifier, while Merlin is an oracle with infinite computational power. Given an instance of the problem at hand, Arthur generates some random bits and sends the bits (together with the instance) to Merlin. Merlin then replies to Arthur with a message of length polynomial in the instance. Arthur decides to accept or reject based on the random bits and Merlin's message.

The complexity class AM of problems that admit Arthur–Merlin protocols was introduced by Babai [7, 8], motivated by decision problems about matrix groups. A problem is solved by such a protocol if, for a "yes" instance, the probability over Arthur's bits that there exists a response by Merlin that causes Arthur to accept is  $\geq 2/3$ , while for a "no" instance, the probability is  $\leq 1/3$ .

The complexity class BPP is the class of decision problems solvable by an NP machine such that

- a "yes" instance is accepted with probability at least 2/3,
- a "no" instance is accepted with probability at most 1/3,

Roughly speaking, an AM protocol can be viewed as a BPP machine that makes one call to an NP oracle accepting its answer.

Important to us is the following chain of inclusions: BPP  $\subseteq$  AM  $\subseteq$  PH  $\subseteq$  PSPACE. (Here, PH denotes the union of all classes in the *polynomial hierarchy*.)

## A.2 Ideals and Varieties

Let R be a ring. A *polynomial ideal* is a subset  $I \subseteq R[x]$  that satisfies the following properties:  $0 \in I$ ; I is closed under addition; and for each  $p \in R[x]$  and  $q \in I$ , necessarily  $pq \in I$ . For a set  $S \subseteq R[x]$  of polynomials, the *ideal generated by* S is given by  $I = \langle S \rangle := \{s_1q_1 + \dots + s_\ell q_\ell : s_j \in S, q_j \in R[x], \ell \in \mathbb{N}\}$ . A polynomial ideal I is *proper* if I is not equal to R[x] and I is *radical* if  $p^n \in I$  implies that  $p \in I$ . The *radical*  $\sqrt{I}$  of an ideal I is defined by  $\sqrt{I} = \{p \in R[x] : p^n \in I \text{ for some } n \in \mathbb{N}\}$ . The radical  $\sqrt{I}$  is an ideal of R[x] itself.

A *Noetherian* ring is a ring R that satisfies an *ascending chain condition* for ideals. That is, every chain of inclusions  $I_1 \subseteq I_2 \subseteq \cdots$  where each  $I_j$  is an ideal of R[x] *stabilises*, i.e., there exists an ideal  $I_n$  such that  $I_n = I_{n+1} = \cdots$ . We recall that  $R \in \{\mathbb{Z}, \mathbb{Q}, \overline{\mathbb{Q}}\}$  are Noetherian. Henceforth, the rings we discuss will always be assumed to be Noetherian.

Hilbert's Basis Theorem states that every ideal in R[x] has a finite basis. Seminal work by Buchberger introduced Gröbner bases for polynomial ideals, which permit the algorithmic computation of key properties of polynomial ideals [17, 23], including ideal membership, ideal union/intersection, elimination ideals, and many more.

Hilbert's Nullstellensatz is a celebrated theorem that identifies that radical ideals are exactly those ideals that correspond to varieties. Formally, let I be an ideal in  $\overline{\mathbb{Q}}[x]$ . A *variety* is the set of common zeros of a polynomial ideal I so that  $V(I) := \{v \in \overline{\mathbb{Q}}^d : f(v) = 0 \text{ for all } f \in I\}$ . Hilbert's Nullstellensatz states that the ideal of all polynomials in  $\overline{\mathbb{Q}}[x]$  that vanish on V(I) is  $\sqrt{I}$ .

A variety  $V \subseteq \overline{\mathbb{Q}}^d$  is *irreducible* if it cannot be written as  $V = V_1 \cup V_2$  such that  $V_1$  and  $V_2$  are both varieties properly contained in V. The dimension of a variety V is defined to be the maximum number  $n \in \mathbb{N}$  such that there is a strictly increasing chain  $V_0 \subset V_1 \subset \cdots \subset V_n$  of non-empty irreducible subvarieties of V. A variety  $V \subseteq \overline{\mathbb{Q}}^d$  has dimension at most d.

The Zariski topology on  $\overline{\mathbb{Q}}^d$  is the topology whose closed sets are varieties. The Zariski closure  $\overline{X}$  of a set  $X \subseteq \overline{\mathbb{Q}}^d$  is the smallest variety that contains X.

# A.3 Multiplicative Relations Between Algebraic Numbers

Let us first recall some standard terminology. Let M be a  $d \times d$  square matrix with entries in  $\mathbb{Q}$  (or  $\overline{\mathbb{Q}}$ ). Then the distinct characteristic roots  $\lambda_1, \ldots, \lambda_s$  of M are algebraic numbers. To every vector  $v \in \mathbb{Z}^s$  we associate a unique *canonical binomial*,  $P(y_1, \ldots, y_s) := y^{v_+} - y^{v_-}$ , where  $v_+ = (\max\{v_1, 0\}, \ldots, \max\{v_s, 0\}) \in \mathbb{N}^s$  and  $v_- = v_+ - v \in \mathbb{N}^s$ . Here,  $y = (y_1, \ldots, y_s)$  and  $y^{\alpha}$  denotes  $y_1^{\alpha_1} \ldots y_s^{\alpha_s}$  for a vector  $\boldsymbol{\alpha} = (\alpha_1, \ldots, \alpha_s) \in \mathbb{N}^s$ .

In the course of our work, we need to compute the relations between the geometric sequences  $(\lambda_1^n)_n, \ldots, (\lambda_s^n)_n$ . These relations are, in turn, rooted in the set of multiplicative relations of nonzero algebraic numbers  $\lambda_1, \ldots, \lambda_s$ . Recall that  $(n_1, \ldots, n_s) \in \mathbb{Z}^s$  is a *multiplicative relation* of  $(\lambda_1, \ldots, \lambda_s) \in \mathbb{Q}^s$  if  $\lambda_1^{n_1} \cdots \lambda_s^{n_s} = 1$ . For the aforementioned set of multiplicative relations, the *exponent lattice* of  $\lambda_1, \ldots, \lambda_s \in \mathbb{Q}$ , is thus defined as follows:

$$L_{\exp}(\lambda_1,\ldots,\lambda_s):=\left\{(n_1,\ldots,n_s)\in\mathbb{Z}^s:\prod_{i=1}^s\lambda_i^{n_i}=1\right\}.$$

We note the set of all multiplicative relations forms an additive free abelian group (lattice).

The *height* of  $\lambda \in \overline{\mathbb{Q}}$  is the maximum absolute value of the coefficients of its minimal polynomial.

THEOREM A.1 (MASSER). Let  $\lambda_1, \ldots, \lambda_s \in \overline{\mathbb{Q}}$ . The exponent lattice  $L_{\exp}(\lambda_1, \ldots, \lambda_s)$  has a basis  $v_1, \ldots, v_r$  for which

$$\max_{i,j} |v_{i,j}| \le (D \log H)^{O(s^2)},$$

where H and D are upper bounds for heights and degrees of  $\lambda_i$ 's, respectively.

In order to determine the dependencies between the geometric sequences  $\langle \lambda_1^n \rangle_n, \ldots, \langle \lambda_s^n \rangle_n$ , we first compute a basis  $v_1, \ldots, v_r$  such that  $L_{\exp}(\lambda_1, \ldots, \lambda_s) = \mathbb{Z}v_1 + \cdots + \mathbb{Z}v_r$ , employing Masser's bound. As a second step, we introduce variables  $y_1, \ldots, y_s$  to represent the geometric sequences. We further read a set of canonical binomials  $P_1, \ldots, P_r \in \mathbb{Z}[y_1, \ldots, y_s]$  from vectors  $v_1, \ldots, v_r$ .

Under the assumption  $\lambda_i \neq 0$  for all  $1 \leq i \leq s$ , we have that

$$\overline{V(P_1,\ldots,P_r)\setminus V\left(\prod_{i=1}^s y_i\right)} = \overline{\{(\lambda_1^n,\ldots,\lambda_s^n): n\in\mathbb{N}\}}.$$

The proof can be found in [27, Lemma 6]. The following is corollary is then immediate.

COROLLARY A.2. Let  $\lambda_1, \ldots, \lambda_s$  be nonzero eigenvalues of a rational matrix. The Zariski closure of the set  $\{(\lambda_1^n, \ldots, \lambda_s^n) : n \in \mathbb{N}\}$  is computable in PSPACE.

#### **B HARDNESS RESULT IN SECTION 2**

LEMMA 2.3. The weak synthesis problem over  $\{\mathbb{Z}, \mathbb{Q}\}$  is as hard as Hilbert's Tenth problem (HTP) over  $\{\mathbb{Z}, \mathbb{Q}\}$ , even in fixed dimension.

PROOF. Let  $P_1, \ldots, P_k \in \mathbb{Z}[x_1, \ldots, x_d]$  define an instance of HTP over  $R \in \{\mathbb{Q}, \mathbb{Z}\}$ . We construct an instance of the weak synthesis problem in d + 2 variables as follows. Define the input ideal  $S = \langle P_1, \ldots, P_k, x_{d+1} - x_{d+2} \rangle$  in  $\mathbb{Z}[x_1, \ldots, x_d, x_{d+1}, x_{d+2}]$ .

Clearly, negative instances (no solutions in  $R^d$  for the system of equalities  $P_i = 0$ ) remain negative, because polynomials  $P_1, \ldots, P_k$  still have to vanish on every valuation of the loop. Now assume that the original instance is positive, and so there exists a solution to the system of equations. Let  $(\xi_1, \ldots, \xi_d) \in R^d$  be a solution. Then there exists a non-trivial linear loop for the produced instance of the Weak Synthesis Problem for loops over R, namely one with an initial vector  $\alpha = (\xi_1, \ldots, \xi_d, 1, 1)$ , and an update matrix diag $(1, \ldots, 1, 2, 2)$ . The constructed loop is non-trivial, concluding the proof of the reduction correctness.
