We explore Bernal bilayer graphene in the presence of long-range Coulomb interactions, shortrange Hund's coupling, and proximity-induced Ising spin-orbit coupling using self-consistent Hartree-Fock simulations. We show that the interplay between these three ingredients produces an intricate phase diagram comprising a multitude of symmetry-broken metallic states tunable via doping and applied displacement field. In particular, we find intervalley coherent and spin-canted ground states that may hold the key to understanding spin-orbit-enabled superconductivity observed in this platform. We also investigate various phase transitions where a continuous U(1) symmetry is broken to ascertain the possible role of critical fluctuations on pairing.

#### I. INTRODUCTION

Rhombohedral graphene multilayers host an exceptionally rich and tunable set of quantum phases of matter [1–11]. Their exquisite tunability originates from the ability to electrically address, in a dual-gated device, both the doping level (by varying the chemical potential) and the effective interaction strength (through the band-flattening effect of a perpendicular displacement field D), as illustrated in Fig. 1. While the first member of the rhombohedral family, Bernal bilayer graphene (BLG), has a long history dating back to the early days of graphene research [12–16], its complex low-temperature phase diagram presents an enduring challenge to the quantum matter community.

Of particular interest is the recent observation of superconductivity when BLG is perturbed by an in-plane magnetic field [4] or by inducing spin-orbit coupling (SOC) via proximity to an adjacent  $WSe_2$  layer [17]. In the former case, the in-plane field nucleates a narrow sliver of superconductivity near the location of a Stoner-type phase transition in the normal state; this unconventional superconductor exhibits a low critical temperature  $T_{\rm c}\sim 30\,{\rm mK}$ and an extreme Pauli limit violation consistent with spintriplet pairing. The phenomenology of the latter case is very different: Up to four new superconducting regions appear with proximity-induced SOC [17-20]. The most prominent dome features a critical temperature  $T_{\rm c}$  enhanced up to  $\sim 500 \,\mathrm{mK}$  and spans a large density window within a symmetry-broken normal state. Furthermore, the Pauli limit violation evolves nontrivially across different superconducting regions, emphasizing the important role of SOC on superconductivity.

An important step towards understanding the origin and mechanism [21-31] of these spin-orbit-enabled superconductors consists of constraining the nature of their *normal state*. This endeavor is critical for two reasons: First, candidate metallic states differ by their fermiology and the symmetries they preserve, which can have an outsize influence on their potential superconducting

FIG. 1. Schematic of spin-orbit proximitized BLG. (a) A transition-metal dichalcogenide (such as WSe<sub>2</sub> or WS<sub>2</sub>) placed in proximity to BLG induces meV-scale spin-orbit coupling to the top graphene layer. Applying a perpendicular displacement field D generates an interlayer potential difference u through Eq. (2). (b) Bilayer graphene stacking configuration, with sublattices  $A_l$ ,  $B_l$  for layer  $l \in \{1, 2\}$ . (c) Lowenergy band structure in valley  $\mathbf{K}^+$  for  $k_y = 0$  (left panel) and density of states (right panel) for different u assuming Ising spin-orbit coupling of strength  $\lambda_I = 1.5$  meV. The Dfield opens a gap at charge neutrality and enhances van Hove singularities that drive strong interaction effects. Valley  $\mathbf{K}^$ exhibits a band structure related by time reversal symmetry.

instabilities. And second, the normal state can host collective modes (dependent on details of the underlying order) that potentially serve as a pairing glue [31, 32].

Our key objective in this work is to shed light on the interacting normal-state phase diagram of spin-orbit coupled BLG [17–20, 33] and to leverage these insights to further our understanding of superconductivity in this system. We use self-consistent numerical Hartree-Fock

simulations, following a recent implementation for rhombohedral trilayers [34], and contrast our results to other Hartree-Fock studies on proximitized BLG [17, 35–37]. In particular, Ref. 35 reported a thorough investigation of the role of Ising SOC on the phase diagram of BLG in the presence of long-range Coulomb repulsion. While we recover their results in the appropriate limit, our main contribution here is to explore the crucial role of additional short-range interactions, also known in the literature as Hund's coupling. As we show below the inclusion of this term produces ferromagnetic instabilities that can either coexist or compete with the effects of Ising SOC, leading to a rich landscape of symmetrybroken phases. Among the new metallic states we uncover, we note two instances of *spin-canting order*, within which spins in each valley tilt away from their respective Ising axes toward the graphene planes. The first instance is a spin-canted generalized half metal<sup>1</sup>, with a two-fold Fermi surface degeneracy, that occupies most of the experimentally relevant region for the strongest superconducting state in BLG/WSe<sub>2</sub>. The second instance possesses spin-canted intervalley coherent (IVC) order, hosts non-degenerate Fermi surfaces (generalized quarter metal), and may be relevant for one of the new superconductors (dubbed SC3) discovered in Ref. 20.

Comparing with recent experiments [20] that systematically vary the induced Ising SOC strength  $\lambda_{\rm I}$  by engineering the twist angle at the BLG/WSe<sub>2</sub> interface [22, 38-40], we identify two promising candidate normal states that can host the largest superconducting region. Namely, experiments reveal that while  $T_{\rm c}$  is enhanced with increasing  $\lambda_{\rm I}$ , its extent *shrinks* within the accessible displacement field and density regime. This observation suggests that the normal state that gives way to superconductivity (which exhibits two-fold Fermi surface degeneracy as per quantum oscillation measurements) is one of the symmetry-broken generalized half metals that *competes* against the symmetric spin-valleylocked state that is trivially favored by  $\lambda_{\rm I}$ . The spincanting order described above is one of the normal states we find that satisfies these properties; the other option is an IVC spin-triplet state that coexists with spin-valley locking (see Fig. 2a for an illustration). While both candidates are consistent with currently available data, we propose future experiments to distinguish between them. We also connect these observations with a recent proposal wherein spin-canting fluctuations provide a glue for superconductivity [31], and contrast with other pairing mechanisms including Kohn-Luttinger [24, 28, 30], acoustic phonons [41, 42] and IVC fluctuations [26, 43].

Finally, we hone in on U(1)-breaking transitions observed at mean-field level, of either IVC or spin-canting type. While we find IVC transitions to be generically first order, spin-canting transitions appear continuous (within the precision of our Hartree-Fock implementation). We speculate on the role of critical fluctuations associated with these putative continuous transitions.

The rest of this article is organized as follows. In Sec. II we introduce the model Hamiltonian describing spin-orbit-proximitized BLG, discuss different (longrange vs. short-range) interaction terms, and present the self-consistent Hartree-Fock technique used throughout this study. In Sec. III we investigate the phase diagram of the system. Section III A first sets the stage by considering the situation without SOC, emphasizing the crucial role of Hund's coupling. In Sec. III B we then introduce Ising SOC, explore its effect on the delicate phase competition between symmetry-broken phases, and connect with recent experimental studies of BLG/WSe<sub>2</sub>. We explore in more detail U(1)-breaking phase transitions, towards either IVC or spin-canting order, in Sec. IV. We highlight how different symmetry-broken ground states respond to changes in screening in Sec. V. Finally, Sec. VI offers insights into spin-orbit-enabled superconductivity in BLG and suggests future research directions.

#### **II. MODEL AND METHODS**

Figure 1a sketches a spin-orbit-proximitized BLG device featuring a displacement field D applied normal to the graphene planes; see Fig. 1b for the BLG atomic structure. Let us first discuss the physics of 'pure' BLG without the proximitizing transition-metal dichalcogenide (TMD) layer. Relevant symmetries here include three-fold rotations C<sub>3</sub>, translations, time reversal  $\mathcal{T}$ , and SU(2)<sub>s</sub> spin rotations (neglecting weak native spin-orbit coupling). The system also exhibits an approximate U(1)<sub>v</sub> valley conservation at low energies.

The tight-binding Hamiltonian describing BLG can be expanded near the two graphene valleys  $\tau \in \{\pm 1\}$  as

$$\hat{H}_0 = \sum_{\mathbf{k}} \sum_{\tau s \sigma \sigma'} h(\mathbf{K}^{\tau} + \mathbf{k})_{\sigma \sigma'} c^{\dagger}_{\tau s \sigma \mathbf{k}} c_{\tau s \sigma' \mathbf{k}}, \qquad (1)$$

where  $c_{\tau s \sigma \mathbf{k}}$  annihilates an electron with momentum  $\mathbf{k}$ in valley  $\tau$ , with spin  $s \in \{\uparrow,\downarrow\}$  and sublattice  $\sigma \in \{A_1, B_1, A_2, B_2\}$ . The matrix h contains the leading intra- and inter-layer tunneling matrix elements as well as on-site potentials [44]; see Appendix A. The D field in particular generates an interlayer potential difference u that enters  $\hat{H}_0$  as

$$u = q_e d^{\perp} D / \epsilon_{\rm r}^{\perp}, \tag{2}$$

with  $q_{\rm e}$  the electron charge,  $d^{\perp} \approx 3.3$  Å the interlayer distance and  $\epsilon_{\rm r}^{\perp} = 4.4$  a dielectric constant describing the screening of perpendicular fields. The low-energy valence and conduction bands predicted by  $\hat{H}_0$  host van Hove singularities that are amplified by nonzero D (see Fig. 1c), in turn dramatically enhancing interaction effects.

<sup>&</sup>lt;sup>1</sup> Throughout this work, we refer to metallic states with a reduced Fermi surface degeneracy as *generalized half-metals* (two-fold degeneracy) or *generalized quarter-metals* (one-fold degeneracy), irrespective of the presence of minority Fermi surfaces.

TABLE I. Symmetry classification of Hartree-Fock ground states. A minimal set of spin-valley operators characterizing each class of ground states is listed along with their transformation properties under electronic time-reversal  $\mathcal{T} = \tau^x s^y \mathcal{K}$ ,  $U(1)_v$ valley conservation, and  $U(1)_s$  spin rotations around the z axis. Among states that break  $\mathcal{T}$ , we highlight cases that preserve an effective antiunitary symmetry  $\mathcal{T}_{\text{eff}}$  that enforces a nesting condition for zero-momentum pairing: either spinless time-reversal symmetry  $\mathcal{T}_0 = \tau^x \mathcal{K}$ , or a product of  $\mathcal{T}$  with a valley ( $\mathcal{T}_v$ ) or spin ( $\mathcal{T}_s$ ) rotation. The integer g denotes the spin-valley degeneracy of the Fermi surfaces, while the last column shows the color and hatching scheme used in phase diagrams throughout this work.

Coulomb repulsion between electrons is included using a convenient decomposition into long- and short-range components. The long-range component

$$\hat{H}_{\rm C} = \frac{1}{2A} \sum_{\mathbf{q}} V_{\rm C}(\mathbf{q}) : \rho(\mathbf{q})\rho(-\mathbf{q}):$$
(3)

involves the long-wavelength part of the electronic density,  $\rho(\mathbf{q}) = \sum_{\mathbf{k}\alpha} c^{\dagger}_{\alpha \mathbf{k}} c_{\alpha(\mathbf{k}+\mathbf{q})}$ , where  $\alpha = (\tau, s, \sigma)$  is a combined flavor index. The prefactor A is the sample area, and we consider the dual-gated Coulomb potential  $V_{\rm C}(\mathbf{q}) = (q_{\rm e}^2/2\epsilon_{\rm r}\epsilon_0 q) \tanh(qd)$ , with d the distance from BLG to the gates,  $\epsilon_{\rm r}$  the relative permittivity, and  $\epsilon_0$  the permittivity of free space. Electronic screening (beyond that provided by the gates and the h-BN spacer layers) is accounted for by treating  $\epsilon_{\rm r}$  as a tunable parameter fixed by comparing to experiments—see below.

The interacting model  $\hat{H}_0 + \hat{H}_C$  defined above preserves a non-generic SU(2) × SU(2) symmetry corresponding to independent spin rotations in each valley. This symmetry is reduced to global SU(2)<sub>s</sub> spin rotations by introducing the short-range component  $\hat{H}_V$  (see Appendix A for the explicit form), with coupling strength  $J_H$ , that captures exchange of electrons between valleys. Also known as the Hund's coupling, such a term (for  $J_H > 0$ ) favors aligning the electron spins in the two valleys, consistent with experimental observations of metallic ferromagnetism in rhombohedral graphene multilayers [2, 4–6].

Proximitizing BLG with an adjacent TMD as sketched in Fig. 1a breaks  $SU(2)_s$  spin rotation symmetry by inducing meV-scale SOC in the top graphene layer [45–52]. The two main contributions are Ising- and Rasbha-type SOC, whose strength can be tuned through the relative twist angle between the TMD and BLG [22, 38–40], as demonstrated experimentally [20]. The effective Rashba scale in the low-energy BLG bands is suppressed by the D-field-induced sublattice polarization of the corresponding wavefunctions [53]. In this work we therefore focus on Ising SOC, which takes the form

$$\hat{H}_{\rm I} = \frac{\lambda_{\rm I}}{2} \sum_{\mathbf{k}} \mathbf{c}_{\mathbf{k}}^{\dagger} \left( \tau^z s^z \mathbb{P}_2 \right) \mathbf{c}_{\mathbf{k}}.$$
(4)

Here  $\mathbf{c}_{\mathbf{k}}^{\mathsf{T}} = \begin{bmatrix} c_{+\uparrow A_1 \mathbf{k}} & \dots & c_{-\downarrow B_2 \mathbf{k}} \end{bmatrix}$  combines the relevant fermion operators,  $\lambda_{\mathrm{I}}$  denotes the Ising energy scale, and  $\mathbb{P}_2$  projects onto the top graphene layer. Throughout we respectively use  $\tau^{\mu}$ ,  $s^{\mu}$ , and  $\sigma^{\mu}$  to label valley, spin, and sublattice Pauli matrices. As shown in Fig. 1c, Ising SOC leads to a noticeable spin splitting in the valence band for D > 0 (and in the conduction band for D < 0), due to the induced layer polarization of the low-energy wavefunctions [54, 55].

To explore the system's phase diagram in the presence of long-range Coulomb interactions, short-range Hund's coupling, and proximity-induced Ising SOC, we implement a self-consistent Hartree-Fock procedure described in detail in Ref. 34 (see in particular Appendix B therein). We consider all symmetry-breaking orders in the fourdimensional spin and valley subspace spanned by  $\tau^{\mu}s^{\nu}$ with  $\mu, \nu \in \{0, x, y, z\}$ , and compare the lowest-energy instance of each class of ground states obtained using a symmetry-restricted algorithm. Throughout this work we assume that  $\mathbf{k}$  remains a good quantum number (*i.e.* we do not allow for translation symmetry breaking, except for commensurate  $\sqrt{3} \times \sqrt{3}$  charge density waves associated with intervalley coherence). We further impose orbital  $C_3$  symmetry (*i.e.* we do not attempt to capture nematic or momentum polarization instabilities [56–58], which are difficult to resolve numerically [34]).

The results presented in this work were computed on momentum grids comprising  $\sim 1700$  points (except for higher-resolution linecuts shown in Fig. 6), keeping all

FIG. 2. Momentum-resolved textures of intervalley-coherent ground states stabilized by Ising SOC. Rows (a)–(c) illustrate the three IVC ground states obtained in the presence of Ising SOC in Fig. 4, projected to the occupied (hole) bands. The first column shows the valley polarization, which follows the trigonal-warping-induced energy difference between the two valleys. The second column depicts in-plane components  $\tau^+ = \tau^x + i\tau^y$  of the valley pseudospin, accompanied by an appropriate spin operator. The third column shows the spin-valley-locked polarization, which couples directly to Ising SOC. The fourth and fifth columns depict the out-of-plane and in-plane spin polarization, respectively. (a) The doubly degenerate (g = 2) SVL+IVC<sub>z</sub> state exhibits a spin-valley-locked polarization  $(\tau^z s^z)$  that coexists with spin-triplet IVC order  $(\tau^x s^z)$ , whereby intervalley coherence develops with an opposite sign for the two spin projections. The (b) SVL-IVC and (c) C-IVC states exhibit a single Fermi surface that arises by developing intervalley coherence within their respective (spin-valley locked or spin-canted) generalized half-metal state. The C-IVC state thus possesses a non-zero in-plane spin polarization, which distinguishes it from its SVL-IVC counterpart.

four bands (per spin and valley) of  $\hat{H}_0$  and imposing a momentum cutoff  $\Lambda = 0.12a^{-1}$ , where a = 2.46 Å is the graphene lattice constant. In Table I we list all the obtained symmetry-broken ground states (along with abbreviations and color schemes used throughout), their transformation properties under various symmetries, and their Fermi surface degeneracies labeled by the integer q.

# III. HARTREE-FOCK PHASE DIAGRAMS

References 35–37 previously studied the phase diagram of BLG in the presence of long-range Coulomb interactions and induced Ising SOC. Here we consider a crucial experimentally motivated addition to their treatment: ferromagnetic Hund's coupling with  $J_{\rm H} > 0$ . As we show below, inclusion of this term qualitatively changes the nature of the stabilized orders and their fermiology, with potentially important implications for the nature of superconductivity arising in proximitized BLG devices. Throughout we mostly focus our attention on the hole-doped region, which yields richer physics both numerically and experimentally (although superconductivity was also recently observed on the electrondoped side at very high displacement fields [19]). The relevant regimes for interaction parameters  $\epsilon_{\rm r}$  and  $J_{\rm H}$ can be estimated by benchmarking to experimental results [2, 4, 17, 59]. In this work, following Ref. 34 we take  $\epsilon_{\rm r} = 20$  and  $J_{\rm H} = 4 - 8 \, {\rm eV} \cdot {\rm A}_{\rm uc} \approx 200 - 400 \, {\rm meV} \, {\rm nm}^2$ (where  ${\rm A}_{\rm uc} \approx 0.052 \, {\rm nm}^2$  denotes the unit cell area of graphene). Other values of  $\epsilon_{\rm r}$  are explored in Sec. V.

FIG. 3. Phase diagrams without SOC. Hole- and electron-doped phase diagrams of BLG as a function of charge density  $n_e$ and interlayer potential u, at moderate Coulomb strength  $\epsilon_r = 20$ . We consider cases (a) without Hund's coupling  $(J_H = 0)$ , and with ferromagnetic Hund's coupling (b)  $J_H = 4 \text{ eV} \cdot A_{uc}$  and (c)  $J_H = 8 \text{ eV} \cdot A_{uc}$ . Different phases are denoted by their color and hatching (see Table I for legends). In panel **a**, unphysical degeneracies between different ground states arise due to the enlarged SU(2) × SU(2) symmetry of our model in the  $J_H = 0$  limit (see Appendix B). In panels **b** and **c**, Hund's coupling breaks the degeneracy between the g = 2 Stoner ferromagnets in favor of the spin-polarized ( $\blacksquare$ ) phase, and similarly promotes IVC<sub>z</sub> ( $\blacksquare$ ) and SP-IVC ( $\blacksquare$ ) phases. (d) Fermi surface structure at numbered points in panel **a**. Colors denote the number of mean-field valence bands occupied by holes. Fermi surfaces in the electron-doped regime are similar.

# A. No spin-orbit coupling

To set the stage, we present in Fig. 3 the ground state phase diagram of BLG without SOC. Figure 3a showcases the situation without Hund's coupling, where only longrange Coulomb interactions are included. The structure of the phase diagram consists of a cascade of phase transitions as either electron or hole density is tuned across the van Hove singularity [60]; generically, doping away from charge neutrality induces a series of transitions from the symmetry-unbroken phase (with full spin/valley degeneracy, g = 4) to generalized quarter metals (g = 1), half metals (g = 2), three-quarter metals (g = 1), and back to the symmetric phase. The different symmetrybroken phases can be further classified according to their transformation properties under  $U(1)_v$  valley rotations (see Table I). States that preserve  $U(1)_v$  are generalized Stoner ferromagnets, in which a subset of the four spin/valley flavors is preferentially occupied, while states that break that symmetry exhibit IVC order that spontaneously hybridizes the two graphene valleys. We note that IVC phases are more prevalent in the phase diagram of bilayer graphene compared to its rhombohedral trilayer cousin [34]—this trend is particularly evident in

the sector of g = 2 states<sup>2</sup>. In addition to the spindegenerate, generalized half-metal (g = 2) IVC states, we find their spin-polarized, non-degenerate (g = 1) counterparts within the regions that host quarter-metal phases [61]. Overall, the results we obtain in this limit are qualitatively consistent with those of Ref. 35.

Importantly, this phase diagram possesses numerous artificial degeneracies between different ground state orders as a consequence of the enlarged  $SU(2) \times SU(2)$  symmetry in the  $J_{\rm H} = 0$  limit; see Appendix B for details. As discussed above, the Hund's interaction reduces the symmetry of the model down to physical global  $SU(2)_{\rm s}$  rotations, and its inclusion is thus critical in order to capture the full richness of the problem. This reduction qualitatively affects the phase competition, resulting in the phase diagrams of Figs. 3b and 3c. First,  $J_{\rm H} > 0$  breaks the degeneracy of the various g = 2 Stoner

<sup>&</sup>lt;sup>2</sup> This trend can be ascribed to two tendencies. First, the van Hove singularities are generally more pronounced in rhombohedral trilayer graphene than BLG; the correspondingly enhanced interaction effects favor Stoner ferromagnets over IVC states (see also Fig. 7). Second, the Fermi surfaces of BLG tend to be more trigonally warped than their rhombohedral trilayer counterparts (compare for example Fig. 3 in this work to Figs. 4 and 5 in Ref. 34), which favors the development of intervalley coherence.

FIG. 4. Phase diagrams with SOC. Hole- and electron-doped phase diagrams of BLG as a function of charge density  $n_e$  and interlayer potential u, at moderate Coulomb strength  $\epsilon_r = 20$ . In (a)–(f) we consider cases with ferromagnetic Hund's coupling  $J_H = 4,8 \text{ eV} \cdot A_{uc}$  and induced Ising SOC strengths  $\lambda_I = 0.5, 1, 1.5 \text{ meV}$ . Different phases are denoted by their color and hatching (see Table I for legends). The fully degenerate (g = 4) phases without SOC now acquire a small spin-valley-locked polarization ( $\square$ ) due to the explicit symmetry breaking by  $\lambda_I$ . Yellow dashed lines denote line-cuts further explored in Fig. 6. (g) Fermi surface structure at numbered points in panel **a**. Colors denote the number of mean-field valence bands and conduction bands occupied by carriers in the hole- and electron-doped regimes, respectively.

phases in favor of spin-polarized ferromagnets ( $\blacksquare$ ), consistent with experimental observations [4–6]. Ferromagnetic Hund's coupling additionally breaks the degeneracy between the different g = 2 IVC states in favor of the spin-triplet IVC<sub>z</sub> ( $\blacksquare$ ). Likewise, the spin-polarized SP-IVC phase ( $\boxtimes$ ) is selected from the various g = 1 IVC states. More quantitatively, phase boundaries move with increasing  $J_{\rm H}$  to prefer states that host a large magnetic moment (*e.g.* the fully spin-polarized half-metal phase), which enjoy a larger energy advantage from the Hund's coupling. Representative Fermi surfaces of the various metallic ground states are presented in Fig. 3d.

#### B. Effects of Ising SOC

The case with Ising SOC but without Hund's coupling—which also features a pathological symmetry group,  $U(1) \times U(1)$ —is described in Appendix B for completeness and comparison with the results of Ref. 35. In

what follows we focus on simulations that include both Hund's coupling and meV-scale Ising SOC; addition of the latter qualitatively changes the stabilized groundstate orders as shown in Fig. 4.

First, and most intuitively, for sufficiently large  $\lambda_{\rm I}$ or low D field (corresponding to regimes where singleparticle physics dominate over interaction effects), the preferred q = 2 Stoner ferromagnet becomes the spinvalley-locked (SVL) state (). Here, the electron spins minimize energy from Ising SOC by aligning in opposite out-of-plane directions in the two valleys, thus preserving all symmetries of the Hamiltonian. In contrast, for smaller  $\lambda_{\rm I}$  and/or at larger D fields, the system finds a compromise between the competing requirements of Hund's coupling and Ising SOC by tilting the electron spins in each valley by an angle  $\theta_0$  away from their respective Ising axes [31, 34, 59]. In-plane spin polarization is thus generated along a spontaneously chosen direction (parametrized e.g. by  $\tau^0 s^x$ ), which coexists with spinvalley locking (described by  $\tau^z s^z$ ). As these two order pa-

FIG. 5. Ferromagnetism and spin canting. Spin canting angle  $\theta_0$  extracted from our Hartree-Fock simulations using Eq. (5), as a function of charge density  $n_e$  and interlayer potential u. Here  $\theta_0 = 0$  corresponds to a purely spin-valley-locked state (with zero net spin magnetization) while the limiting case  $\theta_0 = 90^\circ$  denotes the ferromagnetic state expected without Ising SOC. We focus on g = 2 Stoner phases and g = 1, 2 IVC regions of the phase diagrams, which may exhibit spin-canting; remaining areas are masked in dark gray. Parameters used for the various panels follow those in Figs. 4a to 4f, respectively.

rameters anti-commute, the resulting phase ( $\square$ )—which we refer to in the following as the spin-canted Stoner ferromagnet (C)—remains doubly degenerate (g = 2). While time reversal  $\mathcal{T} = \tau^x s^y \mathcal{K}$  (where  $\mathcal{K}$  denotes complex conjugation) is broken by the net spin magnetization of the spin-canted state C, composing  $\mathcal{T}$  with a global spin rotation around the z axis yields an antiunitary symmetry  $\mathcal{T}_{\rm s} = e^{i\pi s^z/2}\mathcal{T}$  that remains unbroken.

Ising SOC also alters the IVC ground states of Figs. 3b and 3c. The IVC<sub>z</sub> phase ( $\blacksquare$ ) now accommodates an underlying SVL polarization; we denote this state by SVL+IVC<sub>z</sub> ( $\blacksquare$ ). Again, because spin-valley locking described by  $\tau^z s^z$  anticommutes with the IVC<sub>z</sub> order parameter  $\tau^x s^z$ , the resulting state remains two-fold degenerate (g = 2). Although this phase breaks microscopic time reversal  $\mathcal{T}$ , it preserves an antiunitary symmetry  $\mathcal{T}_v = \tau^y s^y \mathcal{K}$  that combines  $\mathcal{T}$  and a valley rotation [34].

For moderate to large values of  $\lambda_{\rm I}/J_{\rm H}$ , the g = 1 IVC states align their spin quantization axes with the out-of-plane Ising axes, leading to a spin-valley-locked IVC phase (SVL-IVC/ $\boxtimes$ ) whose valley and spin textures along the Fermi surfaces are intertwined [34, 62] (see Fig. 2b for an illustration). This state was recently evidenced in a closely related system, rhombohedral trilayer graphene proximitized by WSe<sub>2</sub> [63]. The SVL-IVC phase breaks time reversal  $\mathcal{T}$  but preserves both the valley- and spin-rotated antiunitaries  $\mathcal{T}_{\rm v}$  and  $\mathcal{T}_{\rm s}$ —a consequence of the underlying spin-valley locking.

Finally, at low  $\lambda_{\rm I}/J_{\rm H}$  (see Figs. 4a, 4d and 4e), the competing requirements of Hund's coupling and Ising SOC

generate a new type of intervalley coherent order: the spin-canted IVC phase (C-IVC/ $\boxtimes$ ), where intervalley coherence sets in between the two Fermi surfaces of the corresponding g = 2 spin-canted state. The momentum-resolved texture of this state is very similar to its SVL-IVC cousin, except for the finite in-plane spin moment generated by spin-canting (see Fig. 2c). Like the spin-canted C state, the C-IVC phase preserves the antiunitary symmetry  $\mathcal{T}_{s}$ . Representative Fermi surfaces of various ground states obtained in the presence of Hund's coupling and Ising SOC are shown in Fig. 4g.

Importantly, all of the IVC states we obtain possess an antiunitary symmetry that enforces Fermi surface degeneracies, making them well-nested for zero-momentum pairing instabilities. This symmetry protection is operative provided the relevant U(1) symmetry [either U(1)<sub>v</sub> or U(1)<sub>s</sub>] is preserved microscopically (*i.e.* broken spontaneously rather than explicitly). In particular, short-range disorder potentials will be detrimental to phases relying on  $\mathcal{T}_v$  by inducing intervalley scatterings, whereas Rashba SOC will counteract the protection offered by  $\mathcal{T}_s$ .

We note that the spin-canting transition between the two g = 1 IVC phases (SVL-IVC/ $\boxtimes$  and C-IVC/ $\boxtimes$ ) occurs at a much *smaller* value of  $\lambda_{\rm I}/J_{\rm H}$  as compared to the transition between their g = 2 valley-symmetric counterparts (SVL/ $\blacksquare$  and C/ $\blacksquare$ ); see *e.g.* the evolution in Fig. 4d through Fig. 4f. This trend occurs because the competition between Ising SOC (a single-particle effect) and Hund's coupling (an interaction effect) is density dependent [31, 34, 59]. For example, in a simple Ginzburg-Landau description of the spin-canting transition [31, 63], canting order disappears in favor of spinvalley locking when  $\lambda_{\rm I} \geq \lambda_{\rm I}^{\rm c}$ , with the critical SOC strength  $\lambda_{\rm I}^{\rm c} = 2J_{\rm H}n_0$ . Here  $n_0$  is the polarization density of the phase—*i.e.* the density difference between the majority and minority spin components, which equals the total carrier density for a fully polarized state. For low polarization densities (as in the g = 1 IVC phases mentioned above) Ising SOC can therefore more efficiently combat Hund's coupling tendencies, as compared to larger polarization densities in the corresponding g = 2states.

Figure 4 also reveals interesting trends with increasing  $\lambda_{\rm I}$  that can be compared to recent experiments systematically inducing Ising SOC through twist-angle engineering of the  $BLG/WSe_2$  interface [20]. In particular, the experimental data exhibit a counter-intuitive trend in the properties of the most prominent superconducting region of BLG/WSe<sub>2</sub> when  $\lambda_{I}$  increases: the area populated by superconductivity *shrinks* within the regime of accessible D field and density, while the optimal critical temperature is enhanced. The first property can be naturally tied to the competition between different phases evidenced by our calculations. Namely, the symmetric spin-valley-locked (SVL) phase ( $\square$ ) is preferred by Ising SOC, and correspondingly expands with increasing  $\lambda_{\rm I}$  at the expense of the two competing symmetry-broken g = 2states: the intervalley coherent  $SVL+IVC_z$  state ( $\blacksquare$ ) and the spin-canted C state ( $\square$ ). These two states are therefore natural candidates for the normal state hosting superconductivity in these devices, as their phase space also shrinks upon increasing  $\lambda_{\rm I}$  —see Sec. V and Sec. VI for more discussion on this important point.

Figure 5 shows how the spin canting angle  $\theta_0$  evolves throughout the phase diagram, with different parameters  $J_{\rm H}$  and  $\lambda_{\rm I}$ . We extract  $\theta_0$  from our simulations as

$$\theta_0 = \arctan \left| \frac{\langle \tau^0 s^x \rangle}{\langle \tau^z s^z \rangle} \right|,\tag{5}$$

where  $\langle \ldots \rangle$  denotes an expectation value taken in the Hartree-Fock ground state. Throughout the spin-canted region of the phase diagram  $\theta_0$  evolves continuously as shown in Fig. 5, with larger canting angles (*i.e.* closer to the ferromagnetic limit  $\theta_0 = 90^\circ$ ) for larger D fields and doping. Both of these trends can be understood from the free-energy picture described above [31]: stronger D fields and increased doping level generally lead to a larger polarization density  $n_0$ , which favors Hund's coupling's effectiveness over Ising SOC. Increasing  $J_{\rm H}$  leads to an expansion of the spin-canting phase and canting angles closer to  $\theta_0 = 90^\circ$ . In contrast, enhancing  $\lambda_{\rm I}$  leads to a reduction of the phase space occupied by canting order, as well as smaller canting angles. In the pairing scenario of Ref. 31, which relies on the magnon modes associated with the development of canting order, small canting angles (closer to the spin-valley-locked limit  $\theta_0 = 0$ ) yield stronger pairing interaction. Hence, together with our Hartree-Fock analysis this scenario provides a plausible

Nature of U(1)-breaking phase transitions. FIG. 6. Energy difference between relevant ground states, normalized by the total hole density (top panels), and expectation value of order parameters  $\tau^{\mu}s^{\nu}$  of interest (bottom panels), along three different cuts shown by yellow dashed lines in Figs. 4 and 5 for  $\lambda_{\rm I} = 1 \,{\rm meV}$ . U(1)-breaking phase transitions of interest are identified by vertical black dashed lines. (a) Focusing on  $J_{\rm H} = 4 \, {\rm eV} \cdot {\rm A}_{\rm uc}$  and  $u = 50 \, {\rm meV}$ , we characterize the  $U(1)_v$ -breaking transition between the symmetric SVL state  $(\square)$  and the SVL+IVC<sub>z</sub> state  $(\square)$ . The transition appears weakly first order, as evidenced by the level crossing between the respective ground state energies and the small jump in the  $\tau^x s^z$  order parameter. (b) Taking a higher u = 65 meV, we see the appearance of the spin-canting (C) solution  $(\square)$ . While the C to SVL+IVC<sub>z</sub> transition is first order due to symmetry considerations, the onset of spin canting (*i.e.* the SVL to C transition) appears continuous within the numerical accuracy of our simulations. (c) A similar scenario plays out for both spin-canting transitions between SVL-IVC (🔯) and C-IVC ( $\boxtimes$ ) states, shown here for  $u = 95 \,\mathrm{meV}$  and larger  $J_{\rm H} = 8 \, {\rm eV} \cdot A_{\rm uc}$ . These results were computed on a finer momentum grid with  $\sim 3300$  points.

explanation for the experimentally observed tunable enhancement of  $T_c$  with  $\lambda_I$  accompanied by a phase space reduction for superconductivity [20].

# IV. INTERVALLEY COHERENT AND SPIN-CANTING PHASE TRANSITIONS

As shown above, the mean-field phase diagram of spin-orbit-coupled BLG hosts multiple phase transitions where a U(1) symmetry is spontaneously broken. These come in two broad categories: transitions associated with the onset of IVC order, where U(1)<sub>v</sub> is broken, and those where spin canting sets in, which break U(1)<sub>s</sub> spin rotations about the z axis.

Such transitions can occur between states with different Fermi surface degeneracies—*e.g.* from a SVL-IVC  $(\boxtimes)$  to a SVL  $(\square)$  state (Figs. 6a and 6b)—or that break different symmetries of the underlying Hamiltoniane.q. from a C ( $\blacksquare$ ) state to a SVL+IVC<sub>z</sub> ( $\blacksquare$ ) state (Fig. 6b). In these cases one expects first-order transitions, as confirmed in our Hartree-Fock numerics. On the other hand, continuous transitions would be of interest to exotic proposals for pairing in BLG<sup>3</sup>. At meanfield level, a promising setting to look for continuous transitions arises when only the relevant U(1) symmetry is spontaneously broken at a transition between states with the same g. This situation occurs for 'pure' IVC or spin-canting transitions detailed below. Here, symmetry considerations alone are insufficient to predict the order of the transition, which is ultimately determined by Stoner [65] or IVC energetics.

Figure 6 hones in on three representative examples of U(1)-breaking phase transitions, following line cuts identified by yellow dashed lines in Figs. 4 and 5. Figure 6a explores the  $U(1)_{v}$  breaking transition where the symmetric SVL state  $(\square)$  develops intervalley coherence and turns into the  $SVL+IVC_z$  state ( $\blacksquare$ ) with increased holedoping. Even though both states are generalized half metals with q = 2, the transition appears first order, with a visible level crossing of the two (symmetry-broken and symmetric) ground state energies and a jump in the  $\tau^x s^z$  order parameter. In Fig. 6b we show the spincanting transition, where in-plane magnetization is spontaneously generated starting from the symmetric SVL phase ( $\square$ ), leading to the C phase ( $\square$ ). This transition appears continuous within the precision of our Hartree-Fock algorithm: the  $\tau^0 s^x$  order parameter smoothly vanishes, and the energy of the symmetry-breaking solution merges with the symmetry-preserving one. A similar situation occurs for spin-canting transitions<sup>4</sup> between the two g = 1 IVC states, SVL-IVC ( $\boxtimes$ ) and C-IVC ( $\boxtimes$ ), as shown in Fig. 6c. The presence of these two putative continuous phase transitions calls for an examination of pairing mechanisms based on critical spin canting fluctuations.

#### V. DISTINGUISHING NORMAL-STATE ORDERS THROUGH SCREENING

Based on their trends with increasing  $\lambda_{\rm I}$  and the presence of an antiunitary symmetry ( $\mathcal{T}_{\rm s}$  or  $\mathcal{T}_{\rm v}$ ), we identified in Sec. III B two natural candidates for the normal state of the dominant superconducting region in BLG/WSe<sub>2</sub>: either the spin-canted C ( $\blacksquare$ ) or intervalley coherent SVL+IVC<sub>z</sub> ( $\blacksquare$ ) generalized half metals (g = 2). Experimentally distinguishing these orders—or ruling them out—poses an important challenge. Direct probes that search for the in-plane magnetic moment emerging in the spin-canted phase or lattice-scale symmetry-breaking order stemming from intervalley coherence provide one possible detection avenue (see next section for further discussion). Here, we propose an alternative approach that exploits the different response these orders exhibit to changes in screening.

To this end, Fig. 7 investigates the role of long-range Coulomb interaction strength, controlled by the screening parameter  $\epsilon_{\rm r}$ , on the phase diagram of spin-orbitcoupled BLG. For concreteness we fix  $\lambda_{\rm I} = 1 \,{\rm meV}$  and  $J_{\rm H} = 4 \, {\rm eV} \cdot {\rm A}_{\rm uc}$  and present results for  $\epsilon_{\rm r} = 10, 15$ and 25; compare to  $\epsilon_r = 20$  shown in Fig. 4b. When interaction strength is increased ( $\epsilon_r$  is decreased), the symmetry-breaking regions of the phase diagram expand, as expected. The spin-canted phase in particular grows at the expense of the neighboring symmetry-preserving spin-valley-locked phase. The competition between IVC phases and their Stoner ferromagnet counterparts is also influenced by  $\epsilon_r$ —but crucially with an opposite trend. Generalized Stoner ferromagnets, which exhibit roughly uniform polarization across their Fermi sea, are favored at large interaction strength. By contrast, IVC phases are more prominent at weaker interaction strength, as they minimize their energy from a combination of polarization energy and their ability to rotate the valley pseudospin as a function of momentum  $\mathbf{k}$  to adjust to the trigonally warped band structure of BLG (see Fig. 2). In particular, the hole-doped  $\mathrm{SVL}{+}\mathrm{IVC}_{\mathrm{z}}$  half-metal state shrinks as the interaction strength increases.

These opposing, screening-dependent trends are expected to be mirrored in superconducting phases whose emergence is controlled by either candidate normal state, e.g. via Goldstone [31] or critical fluctuations [25, 26, 43]. In this case, superconductivity descending from the spin-canted C (intervalley coherent SVL+IVC<sub>z</sub>) phase is expected to occupy a smaller (larger) phase space upon an increase in screening. Conversely, other pairing mechanisms that are less reliant on the underlying normal state—such as acoustic phonons [41, 42] or Kohn-Luttinger [24, 28, 30]—are also sensitive to increased screening: respectively, an enhancement and a reduction of  $T_c$  is then predicted. A superconducting region's re-

<sup>&</sup>lt;sup>3</sup> First-order phase transitions could also be relevant for critical pairing scenarios if they are associated with a (nearly) divergent susceptibility [59, 64].

<sup>&</sup>lt;sup>4</sup> Note that the energy advantage from developing spin canting is much lower than for other symmetry-breaking phases. This occurs because only Ising SOC and Hund's coupling are involved in the canting transitions—both long-range Coulomb repulsion and kinetic energy are agnostic to the presence of canting order.

FIG. 7. Effects of screening on the phase competition. Hole- and electron-doped phase diagrams of BLG as a function of charge density  $n_e$  and interlayer potential u, at Coulomb strengths (a)  $\epsilon_r = 10$ , (b)  $\epsilon_r = 15$ , and (c)  $\epsilon_r = 25$ . All panels correspond to Hund's coupling  $J_{\rm H} = 4 \,\mathrm{eV} \cdot A_{\rm uc}$  and Ising SOC strength  $\lambda_{\rm I} = 1 \,\mathrm{meV}$ . The  $\epsilon_r = 20$  case is presented in Fig. 4b.

sponse to screening strength could therefore be used to help infer the pairing mechanism when considered in conjunction with normal-state evolution.

Experimentally, screening can be controlled in a variety of ways. For example, the gate distance could be varied by encapsulating with different thicknesses of h-BN [66, 67]; the h-BN substrate could also be supplemented by a stronger dielectric [68, 69] or another 2D material with tunable charge density [70, 71].

# VI. OUTLOOK AND DISCUSSION

We have provided a detailed Hartree-Fock investigation of the delicate phase competition in BLG with proximity-induced spin-orbit interaction. In particular, inclusion of Hund's coupling leads to qualitative differences as compared to previous studies [35–37]. The most striking addition comes in the form of *spin-canting* order, in which the system spontaneously generates an inplane spin magnetization on top of the spin-valley locking mandated by Ising SOC. Such an order can exist both on its own (giving the generalized half-metal, g = 2state, C/ ence (leading to a generalized quarter-metal, g = 1 state,  $C-IVC/\boxtimes$ ). Moreover, we showed that spin-triplet intervalley coherent order and spin-valley locking coexist in the preferred g = 2 IVC state (SVL+IVC<sub>z</sub>/ $\blacksquare$ ) while maintaining a two-fold Fermi surface degeneracy.

These results may prove crucial to understanding the phenomenology of SOC-proximitized BLG devices. First, the area occupied by both symmetry-broken generalized half metals (SVL+IVC<sub>z</sub> and the spin-canted phase C) is reduced by increasing  $\lambda_{\rm I}$ —with a more pronounced effect in the spin-canted case. These two states are thus promising candidates to host the strongest superconducting dome observed in BLG/WSe<sub>2</sub>, whose area is also markedly reduced with increasing  $\lambda_{\rm I}$ , and furnish a promising starting point to investigate superconducting instabilities. In particular, both of these states spontaneously break a continuous U(1) symmetry and therefore host low-energy collective (Goldstone) modes. A recent work [31] focusing on the spin-canted phase described a pairing mechanism that crucially relies on its soft magnon modes; a similar analysis for low-lying fluctuations around the IVC orders identified here would be an interesting direction to pursue [26, 43, 72]. Furthermore, the onset of canting order appears continuous within our Hartree-Fock treatment, which motivates further study of critical spin-canting fluctuations.

One of the new superconducting regions reported in Ref. 20 arises out of a singly degenerate, q = 1 normal state. Because valley polarization is highly detrimental to zero-momentum Cooper pairing (see however Ref. 73 for a possible finite-momentum pairing state arising from a valley-polarized quarter metal in tetralayer graphene), the corresponding normal state likely exhibits intervalley coherence. Whether this putative IVC state is spin-valley locked (SVL-IVC/🔯) or also possesses spin-canting order  $(C-IVC/\boxtimes)$ , and whether the (almost) continuous transition between the two, explored in Fig. 6c, can be tied to superconductivity in this system, constitute interesting directions for future research. Moreover, superconductivity was recently reported on the *electron-doped* side of proximitized BLG/WSe<sub>2</sub> devices. This superconductor exhibits a fairly large  $T_{\rm c}\,\sim\,200\,{\rm mK}$  and arises from a generalized half-metal (g = 2) state at markedly higher displacement fields compared to the hole-doped superconductors [19]. Interestingly, spin-canting instabilities in our Hartree-Fock simulations (see Figs. 4 and 5) also appear at higher D fields on the electron-doped side, due to the particle-hole asymmetry in the low-energy band structure of BLG (see also Fig. 1). Intervalley coherence with q = 2, in contrast, is not observed on the electrondoped side in our calculations.

Future experiments will be necessary to distinguish between the candidate normal states we propose (or different competing states outside the scope of the present study), and to determine whether superconductivity on the hole and electron-doped side of BLG/WSe<sub>2</sub> has a common origin. Nano-SQUID measurements [74] could image fringe magnetic fields associated with magnetic ordering and thus track the onset of spin canting [59, 63]. The behavior of phase boundaries with applied (in-plane and out-of-plane) magnetic fields, as extracted from compressibility and/or transport, can help constrain the spin and orbital moment of the phase of interest [4–6, 59, 63]. Scanning tunneling probes can directly image the atomicscale charge-density wave characteristic of an IVC state. In rhombohedral graphene devices, the need for dual gating presents a challenge to conventional STM measurements (as compared to *e.g.* studies of intervalley coherence in monolayer graphene [69, 75] or moiré systems [76, 77]). This challenge could perhaps be alleviated in a gate-defined junction geometry, with the characteristic  $\sqrt{3} \times \sqrt{3}$  modulation accessible in the exposed junction area [78, 79]. Magnetoresistance measurements were also recently proposed as a transport signature of intervalley coherence in rhombohedral graphene [80].

A complementary approach to resolve the nature of superconductivity in spin-orbit-proximitized BLG consists of transport experiments with variable screening. In Sec. V we showed that our two candidate normal states with g = 2 have opposing behaviors as screening is enhanced (recall Fig. 7): the SVL+IVC<sub>z</sub> state expands, while the spin-canted solution shrinks by moving towards higher D fields and (electron or hole) doping levels. Combining different experimental probes may prove crucial to constrain the nature of the normal states hosting spinorbit-enabled superconductivity in BLG and other rhombohedral graphene systems and ultimately shed light on their pairing mechanism.

#### Appendix A: Model Hamiltonian and Hartree-Fock procedure

The minimal tight-binding Hamiltonian describing Bernal bilayer graphene, expanded near the two valleys labeled by  $\tau \in \{\pm 1\}$ , reads [16, 44]

$$\hat{H}_0 = \sum_{\mathbf{k}} \sum_{\tau s \sigma \sigma'} h(\mathbf{K}^{\tau} + \mathbf{k})_{\sigma \sigma'} c^{\dagger}_{\tau s \sigma \mathbf{k}} c_{\tau s \sigma' \mathbf{k}}.$$
(A1)

Here the operator  $c_{\tau s \sigma \mathbf{k}}$  annihilates an electron at momentum  $\mathbf{k}$  measured from the Brillouin zone corner  $\mathbf{K}^{\tau} = \tau(4\pi/3a, 0)$  with lattice constant a = 2.46 Å, spin index  $s \in \{\uparrow, \downarrow\}$  and sublattice index  $\sigma \in (A_1, B_1, A_2, B_2)$ . In this basis the Hamiltonian matrix reads

$$h(\mathbf{q})_{\sigma\sigma'} = \begin{bmatrix} u/2 & -\gamma_0 f_{\mathbf{q}} & \gamma_4 f_{\mathbf{q}} & \gamma_3 f_{\mathbf{q}}^{\dagger} \\ -\gamma_0 f_{\mathbf{q}}^{\dagger} & \Delta + u/2 & \gamma_1 & \gamma_4 f_{\mathbf{q}} \\ \gamma_4 f_{\mathbf{q}}^{\dagger} & \gamma_1 & \Delta - u/2 & -\gamma_0 f_{\mathbf{q}} \\ \gamma_3 f_{\mathbf{q}} & \gamma_4 f_{\mathbf{q}}^{\dagger} & -\gamma_0 f_{\mathbf{q}}^{\dagger} & -u/2 \end{bmatrix}_{\sigma\sigma'},$$
(A2)

where the function  $f_{\mathbf{q}} = e^{iq_y a/\sqrt{3}} + 2e^{-iq_y a/2\sqrt{3}} \cos(q_x a/2)$  describes in-plane, nearest-neighbor hopping in the sublattice-centered convention [16, 81] and u denotes the interlayer potential difference induced by the perpendicular displacement field D through Eq. (2). Experimentally accessible values of this potential difference range up to  $u \sim 120 \text{ meV}$  for applied  $D \leq 1.6 \text{ V nm}^{-1}$  [17–20]. The other parameters appearing in Eq. (A2), *i.e.* the on-site potential  $\Delta$  and the hopping terms  $\gamma_0$ ,  $\gamma_1$ ,  $\gamma_3$  and  $\gamma_4$ , are fixed by fitting against ab-initio calculations [44] and are listed in Table II.

Proximity to a TMD, such as a  $WSe_2$  monolayer, induces both Ising- and Rashba-type SOC terms to the closest graphene layer (we consider the top layer for concreteness),

$$\hat{H}_{\mathrm{I}} = \frac{\lambda_{\mathrm{I}}}{2} \sum_{\mathbf{k}} \mathbf{c}_{\mathbf{k}}^{\dagger} \left( \tau^{z} s^{z} \mathbb{P}_{2} \right) \mathbf{c}_{\mathbf{k}}, \qquad \hat{H}_{\mathrm{R}} = \frac{\lambda_{\mathrm{R}}}{2} \sum_{\mathbf{k}} \mathbf{c}_{\mathbf{k}}^{\dagger} \left( \tau^{z} s^{y} \sigma^{x} - s^{x} \sigma^{y} \right) \mathbb{P}_{2} \mathbf{c}_{\mathbf{k}}, \tag{A3}$$

where  $\mathbf{c}_{\mathbf{k}}^{\mathsf{T}} = [c_{+\uparrow A_1 \mathbf{k}} \dots c_{-\downarrow B_2 \mathbf{k}}]$  and  $\lambda_{\mathrm{I}}$  and  $\lambda_{\mathrm{R}}$  respectively denote the strength of Ising and Rashba SOC. The operator  $\mathbb{P}_2$  projects onto the top layer of BLG and the Pauli matrices  $\tau^{\mu}$ ,  $s^{\mu}$  and  $\sigma^{\mu}$  act on the valley, spin and sublattice degrees of freedom respectively. As explained in the main text, due to the suppression of Rashba SOC effects at large D fields [53] we focus on Ising-type SOC throughout this work.

We then consider Coulomb repulsion between electrons, which can be conveniently separated into its long-range  $\hat{H}_{\rm C}$  and short-range  $\hat{H}_{\rm V}$  parts as

$$\hat{H}_{\rm C} = \frac{1}{2A} \sum_{\mathbf{q}} V_{\rm C}(\mathbf{q}) : \rho(\mathbf{q})\rho(-\mathbf{q}):,$$

$$\hat{H}_{\rm V} = \frac{J_{\rm H}}{2A} \sum_{\mathbf{k}\mathbf{k}'\mathbf{q}} \sum_{\tau s s' \sigma \sigma'} \eta(\mathbf{q})_{\tau \sigma \sigma'} : c^{\dagger}_{(-\tau)s\sigma\mathbf{k}} c_{\tau s\sigma(\mathbf{k}+\mathbf{q})} c^{\dagger}_{\tau s'\sigma'\mathbf{k}'} c_{(-\tau)s'\sigma'(\mathbf{k}'-\mathbf{q})}:,$$
(A4)

where A is the sample area,  $J_{\rm H}$  controls the strength of short-range interactions, and :: denotes normal ordering. The short-range Hamiltonian  $\hat{H}_{\rm V}$  is also referred to in the literature as the Hund's coupling, as it can be approximately recast in terms of a coupling between spin operators in the two valleys [43]. The long-range part  $\hat{H}_{\rm C}$  couples to the long-wavelength component of the electron density,  $\rho(\mathbf{q}) = \sum_{\mathbf{k}\alpha} c^{\dagger}_{\alpha \mathbf{k}} c_{\alpha(\mathbf{k}+\mathbf{q})}$ , which involves only intravalley scattering, where  $\alpha = (\tau, s, \sigma)$  encompasses valley, spin and sublattice indices. We consider an interaction potential  $V_{\rm C}(\mathbf{q})$  that incorporates screening from the two gates situated at a distance d on both sides of the BLG device,

$$V_{\rm C}(\mathbf{q}) = \frac{q_{\rm e}^2}{2\epsilon_{\rm r}\epsilon_0 q} \tanh\left(qd\right),\tag{A5}$$

with  $q_e$  the electron charge,  $\epsilon_r$  the relative permittivity, and  $\epsilon_0$  the vacuum permittivity. In this work we set  $d \approx 30$  nm and model additional screening arising from electrons in BLG by treating  $\epsilon_r$  as a free parameter. Generically, short-range components of Coulomb repulsion yield a *ferromagnetic* Hund's coupling with  $J_H > 0$ , which favors aligning spins across valleys. In principle, other lattice-scale effects, including electron-phonon interactions, may generate additional contributions. In this work we nevertheless fix the sign to be ferromagnetic,  $J_H > 0$ , in order to reproduce experimental observations.

TABLE II. Parameters used in the non-interacting Hamiltonian matrix, Eq. (A2), and their numerical values obtained from fitting to *ab initio* calculations in Ref. 44.

Finally, the phase factors  $\eta(\mathbf{q})_{\tau\sigma\sigma'}$  in the Hund's coupling Hamiltonian  $\hat{H}_{\rm V}$  must be chosen to preserve C<sub>3</sub> rotation symmetry. As explained in Appendix B of Ref. 34, we can choose a gauge and adopt the following form:

$$\eta(\mathbf{q})_{\tau\sigma\sigma'} = \begin{cases} e^{2i\tau(\lambda_{\sigma} - \lambda_{\sigma'})\theta_{\mathbf{q}}} & \mathbf{q} \neq \mathbf{0} \\ \delta_{\sigma\sigma'} & \mathbf{q} = \mathbf{0}, \end{cases}$$
(A6)

where we introduced the sublattice-valued index  $\lambda_{\sigma} = 0, +1, -1$  for the sublattices  $B_2$ ,  $A_1$  and  $A_2/B_1$ , respectively, and  $\theta_{\mathbf{q}} = \arg(q_x + iq_y)$ .

Our starting point for the Hartree-Fock algorithm is the spin-orbit proximitized, non-interacting Hamiltonian  $\hat{H}_0 + \hat{H}_I$  at a fixed electronic density  $n_e$  and displacement field D. We then decouple the interaction terms  $\hat{H}_C$  and  $\hat{H}_V$  by introducing mean-field order parameters with different broken symmetries. In each symmetry sector, the best Slater-determinant ground state is obtained self-consistently through a symmetry-restricted Hartree-Fock algorithm. Finally, the optimal instance of each symmetry sector are compared; the mean-field ground state is taken as the state with the lowest energy. Details of the numerical implementation can be found in Appendix B of Ref. 34.

#### Appendix B: Analysis in the Hund's coupling free limit

In this Appendix we consider the case where Hund's coupling is neglected  $(J_{\rm H} = 0)$ . First let us consider  $\lambda_{\rm I} = 0$ and discuss the enlarged symmetry group that characterizes this limit. Here SU(2)<sub>s</sub> spin rotations can be enacted separately in each valley due to the lack of intervalley exchange processes. In what follows it will be useful to consider, in addition to global SU(2) rotations parameterized by  $e^{i\theta \mathbf{s}\cdot\mathbf{n}/2}$  with  $\theta$  a rotation angle about the **n** unit vector and  $\mathbf{s} = (s^x, s^y, s^z)$  a vector of spin Pauli matrices, the corresponding valley-contrasting spin rotations  $e^{i\phi\tau^z\mathbf{s}\cdot\mathbf{n}/2}$ .

#### 1. Ground state degeneracies

Using this extra symmetry we can show that various ground states listed in Table I become degenerate in the special case of  $J_{\rm H} = 0$ . For example, SP and SVL states (with order parameters  $\tau^0 s^z$  and  $\tau^z s^z$  respectively) can be connected by a  $\pi$  spin rotation along (say) the x-axis, which applies only to electrons in valley  $\mathbf{K}^-$ . The operator enacting this transformation is  $\mathcal{U} = e^{i\pi(\tau^0 - \tau^z)s^x/4}$ . Similarly, the two g = 2 IVC states (IVC<sub>0</sub> and IVC<sub>z</sub> with order parameters  $\tau^x s^0$  and  $\tau^x s^z$  respectively) are related by a  $\pi$  spin rotation around the z axis for one valley only, implemented by the operator  $\mathcal{U}' = e^{i\pi(\tau^0 - \tau^z)s^z/4}$ . Note that the operator  $\mathcal{U}'$  is also contained in the U(1) × U(1) symmetry group that characterizes the situation with Ising SOC but without Hund's coupling, which we explore numerically below to connect with the results of Ref. 35. The degeneracy between the IVC<sub>0</sub> and IVC<sub>z</sub> states (and their spin-orbit-proximitized cousins SVL+IVC<sub>0</sub> and SVL+IVC<sub>z</sub>) therefore survives in this case.

Two of the g = 1 IVC states discussed in this work (SP-IVC and SVL-IVC, where intervalley coherence respectively sets in within spin-polarized and spin-valley-locked Fermi surfaces) are also degenerate in the  $J_{\rm H} = 0$  and  $\lambda_{\rm I} = 0$  limit. To see this, note that their order parameters are given by a combination of  $\tau^x s^0$  and  $\tau^0 s^z$  (SP-IVC); or a combination of  $\tau^x s^x$  and  $\tau^z s^z$  (SVL-IVC). We have seen above that their respective valley-diagonal components  $\tau^0 s^z$  and  $\tau^z s^z$  are related by the operator  $\mathcal{U}$ . One can similarly show that (up to a global U(1) valley rotation) their intervalley coherent order parameters  $\tau^x s^0$  and  $\tau^x s^x$  are mapped to each other under the action of  $\mathcal{U}$ .

Finally, the valley-polarized (VP) solution discussed in the main text is a peculiar case that needs to be treated separately. Indeed, because of its vanishing spin polarization this state cannot be mapped to other Stoner half metals, such as SP and SVL states, using independent spin rotations in the two valleys. To understand why it is nevertheless degenerate with SP and SVL states, we return to the long-range part of Coulomb interactions, in the first line of Eq. (A4). Such a term has a larger SU(4) symmetry group that acts within the spin and valley subspace; thus its contribution to the ground state energy is identical for VP, SP and SVL states—which all host 2 out of 4 spin-valley flavors predominantly occupied. The kinetic energy part in Eq. (A2) breaks SU(4), but nevertheless time-reversal symmetry enforces that the non-interacting band structures in the two valleys are mirror copies of each other: the

FIG. 8. Phase diagrams without Hund's coupling. Hole- and electron-doped phase diagrams of BLG as a function of charge density  $n_e$  and interlayer potential u in the absence of Hund's coupling  $(J_H = 0)$ . We consider Ising SOC strengths (a)  $\lambda_I = 0.5 \text{ meV}$ , (b)  $\lambda_I = 1 \text{ meV}$ , and (c)  $\lambda_I = 1.5 \text{ meV}$ . The case without Ising SOC  $(\lambda_I = 0)$  is presented in Fig. 3a.

kinetic energy (for a particular filling) is thus identical regardless of whether two valley flavors (VP), two spin flavors (SP), or the two flavors preferred by Ising SOC (SVL) are occupied.

#### 2. Hartree-Fock phase diagrams

In Fig. 8 we consider the effects of Ising SOC on the phase diagram of BLG when Hund's coupling is neglected—this corresponds to the situation investigated in Ref. 35. Apart from quantitative differences arising from our choice of a weaker interaction strength, we reproduce the main features observed in this work. In particular, the location of Stoner ferromagnets (the SVL half metal and the SVP quarter and three-quarter metals) roughly coincide. The g = 1 and g = 2 IVC states are also reproduced, although Ref. 35 does not see the leftmost, generalized three-quarter-metal g = 1 IVC state obtained in our Fig. 8—presumably because of their larger interaction strength ( $\epsilon_r = 10$ ) that favors Stoner ferromagnets over IVC states (see also Fig. 7). Similarly to the conclusions reached in Ref. 35, increasing Ising SOC leads to the expansion of the SVL phase at the expense of the neighboring symmetry-broken g = 2 order: the SVL+IVC<sub>0</sub> state (which is degenerate with SVL+IVC<sub>z</sub> as explained above).

Two key differences arise between results without Hund's coupling, presented here and in Ref. 35, and those in the main text. First, setting  $J_{\rm H} = 0$  removes the energetic preference towards developing spin polarization, which drives the formation of the spin-canted (C) and the spin-canted IVC (C-IVC) states. Second, the non-generic U(1) × U(1) symmetry in this limit makes the g = 2 IVC region degenerate, while introducing  $J_{\rm H} > 0$  stabilizes the SVL+IVC<sub>z</sub> order in Fig. 4, at the expense of the SVL+IVC<sub>0</sub> state. These two orders are similar but nevertheless differ by the symmetries they preserve: whereas the spin-singlet variant SVL+IVC<sub>0</sub> preserves microscopic time reversal  $\mathcal{T}$ , its spin-triplet cousin SVL+IVC<sub>z</sub> preserves the effective antiunitary  $\mathcal{T}_{\rm v}$ .
