A SIMPLE ALGORITHM FOR CHECKING EQUIVALENCE OF COUNTING FUNCTIONS ON FREE MONOIDS

PETR KIYASHKO AND ALEXEY TALAMBUTSA

ABSTRACT. In this note we propose a new algorithm for checking whether two counting functions on a free monoid M_r of rank r are equivalent modulo a bounded function. The previously known algorithm has time complexity O(n) for all ranks r > 2, however in case r = 2 it was estimated only as $O(n^2)$. Here we apply a new approach, based on explicit basis expansion and weighted rectangles summation, which allows us to construct a much simpler algorithm with time complexity O(n) for any $r \ge 2$.

1. INTRODUCTION

Let $S_r = \{a_1, a_2, \ldots a_r\}$ be the alphabet, $r \ge 2$. The free monoid M_r of rank r is defined as the set of all finite words over S_r including the empty word ϵ . For any fixed word wwe denote its length as |w|, and for any natural number i such that $1 \le i \le |w|$, we denote by w_i the *i*-th letter of w. If w is a non-empty word, we denote its last letter as w_{fin} .

An elementary counting function $\rho_v(w)$ for a fixed word $v \in M_r$ counts the number of (possibly intersecting) occurrences of v in the argument word $w \in M_r$. The function ρ_{ϵ} is defined as $\rho_{\epsilon}(w) = |w|$. A general counting function on M_r is a linear combination

(1)
$$f = \sum_{i=0}^{k} x_i \rho_{w_i}$$

with x_i being coefficients from \mathbb{Z} , \mathbb{Q} , \mathbb{R} or \mathbb{C} and $w_i \in M_r$. The ring of integers is the main target of our interest, and in this case we present the sum (1) in the input of the algorithm by enlisting the coefficients x_i in binary form and the words w_i in natural way (see the full formalization of integer and rational cases in [2]).

Two counting functions f and g are considered equivalent if their difference f - g is a bounded function on M_r . It is worth noting that two counting functions are equivalent if and only if they coincide on any cyclic word (see [1, Corollary A.5]).

From this point on, for brevity we will be using counting functions to denote their equivalence classes, and we will be using = to denote equivalence. Our goal is to devise an algorithm for checking whether two general counting functions having form (1) are equivalent. Here are some key insights into the structure of the equivalence relation obtained in previous works:

Theorem 1.1 (Theorem 1.3 in [1], Theorem 1.4 in [3]). The class of bounded functions (i. e. ones equivalent to 0) is spanned by left and right extension relations for all words $w \in M_r$ defined as

$$\begin{split} l_w &= \rho_w - \sum_{s \in S_r} \rho_{sw}, \\ r_w &= \rho_w - \sum_{s \in S_r} \rho_{ws}. \end{split}$$

Theorem 1.2 (Theorem 1.5 in [1], Theorem 1.5 in [3]). The basis of the space of classes of equivalent functions is represented by

$$\{\rho_w \mid w \in M_r, where w_1 \neq a_1 and w_{fin} \neq a_1\}.$$

We denote by \widehat{C} the space of classes of equivalent functions, and by B the basis identified in theorem 1.2.

The following result describes the time complexity of a useful formal procedure, which sums up the coefficients in a general counting function with repetitions.

Lemma 1.3 (Lemma 4.2 in [2]). Consider a function $f \in \widehat{C}(M_r)$ with integer coefficients, there exists a procedure N that takes f as input and produces a function g obtained from f by reducing the coefficients at terms with identical elementary counting functions. Furthermore, the time complexity of N is O(rn), where n is the size of f as input.

Now, we state the main result obtained here:

Theorem 1.4. There exists an algorithm that takes as input two counting functions f and g represented as arbitrary linear combinations of elementary counting functions and checks whether they are equivalent. Furthermore, for integer coefficients this algorithm has time complexity $O(r^3(|f| + |g|))$, where |f| + |g| denotes the input size.

Even though the relations for monoid M_2 have the shortest and easiest form, the equivalence problem for M_2 appeared to be most complicated. For integer coefficients and any monoid M_r , where $r \ge 3$ the previously known algorithm from [2] has time complexity O(r(|f| + |g|)), still for r = 2 its complexity could be estimated only as $O(r(|f| + |g|)^2)$.

Finding an algorithm working in time O(|f| + |g|) for the case of monoid M_2 was the main motivation for this work. The main idea of the new construction is quite natural: to represent all elementary counting functions from the input by linear combinations of basis elements using the explicit formulas from [3], and then collapse the coefficients to see whether the result is a trivial combination (see formal details in [2, Lemma 4.2]). However, showing that this strategy can be implemented in linear time is not straightforward.

2. Algorithm for M_2

In this section, we describe an algorithm which works for the case M_2 and in the next section we will extend it to the general case. Actually, we will be checking whether a counting function having form (1) is bounded. Indeed, if we are given two counting functions f and g, then we can first form the difference function f - g and then we need to check whether the result is bounded. As this step is linear with respect to the input size, and the size of function f - g does not exceed |f| + |g|, it does not affect the overall complexity of the algorithm.

2.1. **Basis representation.** First we describe an explicit procedure which allows to represent elementary counting function as a linear combination of basis elements. This decomposition will be used extensively in our considerations later.

Here and further on we will say that applying the left or right extension relation to the elementary counting function ρ_v with $v = s_1 w s_2$ means a substitution of ρ_v by

$$\rho_{ws_2} - \sum_{s \in S \smallsetminus \{s_1\}} \rho_{sws_2} \quad \text{(left extension)},$$
$$\rho_{s_1w} - \sum_{s \in S \smallsetminus \{s_2\}} \rho_{s_1ws} \quad \text{(right extension)},$$

which is valid since the extension relation functions are bounded.

Now, we show how to decompose most of the elementary counting functions.

Lemma 2.1. Let $w = a_1^k v a_1^m \in M_2$ with $v_1 = v_{fin} = a_2$. Then

(2)
$$\rho_w = \rho_v - \sum_{i=0...k-1} \rho_{a_2 a_1^i v} - \sum_{j=0...m-1} \rho_{v a_1^j a_2} + \sum_{\substack{i=0...k-1, \\ j=0...m-1}} \rho_{a_2 a_1^i v a_1^j a_2}.$$

Proof. Applying the left extension relation to ρ_w for k iterations, we obtain

(3)
$$\rho_w = \rho_{va_1^m} - \sum_{i=0...k-1} \rho_{a_2a_1^i va_1^m}$$

Applying the right extension relation to $\rho_{va_1^m}$ for *m* iterations, we obtain

$$\rho_v - \sum_{j=0\dots m-1} \rho_{va_1^j a_2},$$

and after doing the same transformation to every term in the sum from (3), one has

$$\sum_{i=0...k-1} \rho_{a_2a_1^iv} - \sum_{\substack{i=0,...,k-1\\j=0,...,m-1}} \rho_{a_2a_1^iva_1^ja_2},$$

which yields the desired representation.

The direct application of the Lemma to any input may produce a list of weighted elementary functions from the basis, but its size can now be $O(n^3)$ for the input of size n. The subsequent summing of the coefficients can be estimated then as $O(n^3)$ for integers or as $O((n \log n)^3)$ for rationals. To make the algorithm linear we will bypass this elongation in Subsection 2.2, where a convenient compressed encoding for sums from (2) will be introduced. Then, we will show how to effectively work with the encoded sums.

Note that the words of M_2 , which were not considered in Lemma 2.1, have form a_1^k . In order to account for this case, let us introduce a few more definitions.

Definition 2.2. Let $B_U = \{\rho_{\epsilon}\} \cup \{\rho_{a_2}\} \cup \{\rho_{a_2a_1^ka_2} \mid k \ge 0\} \subset B$, and let U be the subspace spanned by B_U . Let $V = U^{\perp}$, and let $B_V = B \setminus B_U$.

Lemma 2.3. The counting function $\rho_{a_k^k}$ belongs to U for any $k \ge 0$.

Proof. It is possible to derive the exact basis representation of $\rho_{a_1^k}$, but it would not be useful. Instead, let us prove this by induction. For k = 0 it holds that $\rho_{a_1^k} = \rho_{\epsilon} \in B_U$, and for k = 1 it holds that $\rho_{a_1^k} = \rho_{a_1} = \rho_{\epsilon} - \rho_{a_2} \in U$. Now, presume that for some k > 1 it holds that $\rho_{a_1^{k-1}} \in U$. Let us apply the left extension relation to $\rho_{a_1^k}$:

$$\rho_{a_1^k} = \rho_{a_1^{k-1}} - \rho_{a_2 a_1^k}.$$

The first term on the right hand side of this equation lies in U by the induction hypothesis. Now we apply the right extension relation to the second term for k iterations:

$$\rho_{a_2 a_1^k} = \rho_{a_2} - \sum_{i=0...k-1} \rho_{a_2 a_1^i a_2}$$

All terms of the right hand side of this equation lie in B_U , thus $\rho_{a_1^k}$ lies in U.

Lemma 2.4. Out of the terms of (2) the first term (ρ_v) can either lie in U or in V, and all the other terms lie in V.

Proof. First, consider the term ρ_v . It is a basis element due to the fact that $v_1 = v_{fin} = a_2$, thus it either lies in U (when $v = a_2$ or $v = a_2 a_1^k a_2$), or lies in V.

Now, all the individual elementary counting functions in the other three terms from (2) are of form $\rho_{a_2a_1^iv}$, $\rho_{va_1^ja_2}$ or $\rho_{a_2a_1^iva_1^ja_2}$. Again, since $v_1 = v_{fin} = a_2$, each of the three corresponding words has at least one letter a_2 in the middle. Therefore none of these function lie in B_U , and thus the terms lie in V.

3

In the algorithm we check whether $(f-g)|_U \equiv 0$ and whether $(f-g)|_V \equiv 0$ separately. In order to do that, we choose alternative bases for U and V, and then represent f-g in terms of these bases. The description of the basis for U is quite simple.

Lemma 2.5. $B'_U := \{\rho_{a_1^k} \mid k \ge 0\}$ is the basis of U. Furthermore, for a word $w = a_2 a_1^k a_2 \in M_2$ with $k \ge 0$ it holds that

$$\rho_w = \rho_{a_1^k} - 2\rho_{a_1^{k+1}} + \rho_{a_1^{k+2}}$$

Proof. First, B'_U is a linearly independent set, because it is a subset of a basis of \widehat{C} (obtained by symmetrically substituting a_1 and a_2 in B).

Next, it holds that $\rho_{a_2} = \rho_{\epsilon} - \rho_{a_1}$, thus ρ_{a_2} lies in the span of B'_U .

Finally, for $w = a_2 a_1^k a_2$ we may apply the left extension relation as follows:

$$\rho_{a_2 a_1^k a_2} = \rho_{a_1^k a_2} - \rho_{a_1^{k+1} a_2},$$

and by two applications of right extension relations

$$\rho_{a_1^k a_2} - \rho_{a_1^{k+1} a_2} = \left(\rho_{a_1^k} - \rho_{a_1^{k+1}}\right) - \left(\rho_{a_1^{k+1}} - \rho_{a_1^{k+2}}\right) = \rho_{a_1^k} - 2\rho_{a_1^{k+1}} + \rho_{a_1^{k+2}}.$$

Therefore, all the elements of B_U lie in the span of B'_U , and thus B'_U is also a basis. \Box

The description of the basis we choose for V is more complicated. Here we will not provide the proof of its correctness, but rather prove it implicitly later.

Proposition 2.6. The set

$$B'_{V} \coloneqq \left\{ \sum_{\substack{i=0...k, \\ j=0...m}} \rho_{a_{2}a_{1}^{i}va_{2}^{j}a_{2}} \mid k, m \ge 0, v \in M_{r} \text{ where } v_{1} = v_{fin} = a_{2} \right\} \text{ is a basis of } V.$$

2.2. The algorithm. Now, let us describe the algorithm for M_2 . The outline of the algorithm is as follows. First, we replace all the terms with words of form $a_1^k v a_1^m$ with their basis decompositions of the form (2). Then, we divide all of the terms into two sets, one representing the projection onto U, and the other — onto V. Finally, we represent these projections in terms of the bases B'_U and B'_V , and verify whether these representations are trivial via the procedure N from Lemma 1.3. As it turns out, unlike B_U and B_V , the representations in terms of B'_U and B'_V have the size proportional to the initial input size multiplied by a constant factor, which allows for an efficient triviality check.

The main idea for M_r with $r \ge 3$ will be the same, but the proof is clearer for M_2 since the $S_r \setminus \{a_1\} = \{a_2\}$, and thus the proposed compressed encodings are simpler. Furthermore, the representations in terms of B'_U and B'_V in the case of $r \ge 3$ (which will be defined for the general case later) increase the input size by a factor of r^2 .

First, assume that we have replaced all the terms of form $\rho_{a_1^k v a_1^m}$ with the four terms from (2). Having done that, let us propose and alternative encoding for the terms that we are left with.

We will define an *encoding function* \mathbf{e} for a non-empty word $w \in M_r$ such that $w_1 = w_{fin} = a_2$. We will encode such word as a sequence of non-negative integer numbers, which are the lengths of a_1 -powers in w delimited by letters a_2 . We note that two consecutive letters a_2 in the word w actually mean a 0-length sequence of a_1 -s in between. For the word a_2 , its encoding is an empty sequence, i.e. $\mathbf{e}(a_2) = ()$. For any other word starting and ending with a_2 , one has

$$\mathbf{e}(a_2a_1^{k_1}a_2a_1^{k_2}\ldots a_2a_1^{k_m}a_2) = (k_1,k_2,\ldots,k_m).$$

When the encoding sequence is considered as a word for algorithm processing, the integers k_1, \ldots, k_m are written in binary notation, separated by commas and enclosed in

parenthesis. For example $e(a_2^2 a_1^3 a_2 a_1 a_2) = (0,11,1)$. We emphasize the meaning of the encoding sequence as a word by calling it *list*.

To make the decomposition algorithm fast, we also introduce slightly more general encoding, which is suitable for short writing of sums from (2). This generalization additionally uses two symbols [and]. Having these symbols and two integers $a \leq b$ we encode the interval set $\{a, a + 1, \ldots, b\}$ as a word [a, b], where a and b are written in binary notation (however, we will be using such intervals only when a = 0).

Now, an encoding list (k_1, k_2, \ldots, k_m) is generalized in such a way, that k_1 and k_m can be not just integers, but also the intervals having form [a, b]. Having this in mind, we are ready to encode all terms from (2). The encoding of a single word $\mathbf{e}(v)$ is already defined, and let $\mathbf{e}'(v)$ be the word $\mathbf{e}(v)$ without the enclosing parethesis, then

$$\mathbf{e}\left(\sum_{i=0...k-1}^{k} \rho_{a_{2}a_{1}^{i}v}\right) = ([0, k-1], \mathbf{e}'(v)),$$
$$\mathbf{e}\left(\sum_{\substack{j=0...m-1\\j=0...m-1}}^{k} \rho_{va_{1}^{i}a_{2}}\right) = (\mathbf{e}'(v), [0, m-1]),$$
$$\mathbf{e}\left(\sum_{\substack{i=0...k-1,\\j=0...m-1}}^{k} \rho_{va_{1}^{i}a_{2}}\right) = ([0, k-1], \mathbf{e}'(v), [0, m-1])$$

Thus, using (2) we can equivalently replace every term $x_i \rho_{w_i}$ of the input (where $w_i \neq a_1^k$) as four words in generalized encoding and keep the same coefficient x_i in front of them. This enlarges the length of the input only by a multiplicative constant.

Now, let us separate the obtained encoded terms into those that lie in U and in V. For an encoding list $e = (k_1, \ldots, k_m)$ we define its length |e| = m.

Lemma 2.7. Consider a term t from the function f - g after the substitutions via Lemma 2.1. If t can not be encoded with \mathbf{e} , or $|\mathbf{e}(t)| \leq 1$, then $t \in U$. Otherwise, $t \in V$.

Proof. If t can not be encoded, then $t = x \rho_{a_1^k}$ for some $k \ge 0$. Therefore from Lemma 2.5 it follows that $t \in U$.

Now, if $|\mathbf{e}(t)| \leq 1$, then $t = \rho_{a_2}$ or $t = \rho_{a_2 a_1^k a_2}$ for some $k \geq 0$, therefore $t \in B_U$.

Finally, if t has is encoded by a list of length at least 2, then either $t = \rho_v$ with $v_1 = v_{fin} = a_2$ and $\rho_{a_2}(v) > 2$, or t is a summation term from (2). In both cases $t \in V$. \Box

. Now it is clear which terms we have to process to verify $(f - g)|_U \equiv 0$, and which terms we have to process for the verification of $(f - g)|_V \equiv 0$.

2.3. Case $|e| \leq 1$ and $\rho_{a_1^k}(U)$. First, we substitute the terms of ρ_{a_2} (encoding of length 0) and of $\rho_{a_2a_1^ka_2}$ (encodings of length 1) with their B'_U decompositions as per Lemma 2.5. Each term is replaced by no more than 4 terms of form $\rho_{a_1^k}$ with words of similar length and with same coefficients, thus the input size grows by a constant multiplicative factor. Having done that, we use the procedure N from Lemma 1.3 to reduce the coefficients and check whether $(f-g)|_U$ is trivial. The running time of N is O(n), since we have increased the input size by a constant, and r = 2 is also a constant in the case of M_2 .

2.4. Case $|e| \ge 2$ (V). Now, we say that two elementary counting functions (or their encodings) from V are *interacting* if they if they have some common elements in their B_V basis representations, i. e. that they do not lie in orthogonal subspaces of V with respect to B_V . This means that if we replace the elementary counting functions with encodings of linear combinations of basis elements, we will only have to collapse coefficients in classes of mutually interacting functions.

For an encoding list e with $|e| \ge 2$, we define the *core* of e as a sublist $\mathbf{c}(e) = (k_2, \ldots, k_{m-1})$.

Lemma 2.8. Let e_1 and e_2 be two encoding lists with $|e_1|, |e_2| \ge 2$. If they interact, then

(1) $|e_1| = |e_2|$. (2) $\mathbf{c}(e_1) = \mathbf{c}(e_2)$.

Proof. Note that in every term from Lemma 2.1 all basis elements have the same core (if encoded). Thus, if two terms interact, i. e. have elements with equal words, they both must share a common core. \Box

We see that classes of interacting encoding lists share the same length and core, thus it is sufficient to efficiently collapse terms having fixed length and core. Furthermore, classes of interacting functions represent separate subspaces of V with respect to the basis B_V , thus we can further decompose the task of estimating $(f - g)|_V \equiv 0$ to similar tasks for these subspaces.

Let us now consider a single class of interacting functions representing a subspace V_i . Further we will refer to both the class and the subspace as V_i for brevity.

Since the only varying part of the encodings in V_i are the first and last elements, we may omit the fixed core and write the encoding singular counting functions, left-sum terms, right-sum terms and two-sided sum terms as

(4)

$$(k,m), \\
([0,k], m), \\
(k, [0,m]), \\
([0,k], [0,m])$$

respectively, with coefficients inherited from the initial counting function. Now, for the fixed core we need to check whether the sum of such terms equates to 0.

The four types of integer sets described in (4) can be depicted graphically as follows. Let us consider a 2-dimensional weighted multiset of rectangles parallel to the coordinates, which we call a *histogram*. Here, for a coefficient x the pair $\langle (k,m), x \rangle$ denotes a square at coordinates (k,m) with weight x, the pair $\langle ([0,k],m), x \rangle$ denotes a horizontal bar with its base on the y axis at coordinate m and length k, with its weight being x again, the pair $\langle (k,[0,m]), x \rangle$ denotes a similar vertical bar, and $\langle ([0,k],[0,m]), x \rangle$ denotes a rectangle starting in (0,0) with width of k and weight of m, again, with a weight of x.

FIGURE 1. Histogram example, without weights depicted.

Now, the shortened encodings defined above with respective coefficients define such histogram, and their summation equates to 0 if and only if this histogram has total weight of 0 at every grid square 1×1 . It turns out, that we can further simplify the task with the following observation.

Observation 2.9. Instead of considering singular squares, vertical and horizontal bars and rectangles from (4), we can consider only rectangles by applying the following subsitutions:

$$([0,k],m) = ([0,k], [0,m]) - ([0,k], [0,m-1]), (k,[0,m]) = ([0,k], [0,m]) - ([0,k-1], [0,m]) (k,m) = ([0,k], [0,m]) - ([0,k-1], [0,m]) - ([0,k], [0,m-1]) + ([0,k-1], [0,m-1]).$$
Note that these (0,0)-based rectangles exactly represent the elements of B'_{V} .

This approach allows us to reduce the histogram only to rectangles while increasing the size of the input by a multiplicative constant of no more than 4. Note, that after this substitution there may be multiple rectangles with the same coordinates, but different coefficients. Let us denote by h(x, y) the sum of coefficients in the rectangle with coordinates (x, y), and by H(x, y) the total weight of the histogram at (x, y)

. Now, a histogram containing only (0,0) based rectangles has some convenient properties. First of all, the histogram is constant 0 if and only if the weight of the histogram at every top-right corner of such rectangle is 0. Let us consider the top right corner of a rectangle (x, y). Its weight is affected only by rectangles with the same coordinates, or rectangles that include (x, y). This means that

$$H(x,y) = \sum_{x' \ge x, y' \ge y} h(x',y').$$

Lemma 2.10. $H \equiv 0$ if and only if $h \equiv 0$.

Proof. If $h \equiv 0$, then clearly so is H. Now presume that $H \equiv 0$. Then we prove that $h \equiv 0$ by descending induction over x and then y.

. As the base case we take the maximum value of x_0 over all rectangles, and the maximum y_{00} value for $x = x_0$. The only rectangles that contain (x_0, y_{00}) are those which have exactly those coordinates, thus $h(x_0, y_{00}) = H(x_0, y_{00}) = 0$, and the base is proven.

. Now let us consider some (x, y) and let us presume that by induction hypothesis for all (x', y') such that x' > x or x' = x and y' > y it holds that h(x', y') = 0. Then,

$$0 = H(x,y) = \sum_{x' \ge x, y' \ge y} h(x',y') = h(x,y) + 0 = h(x,y),$$

thus h(x, y) = 0 and the induction step is proven.

This means that the projection of f - g onto V_i is trivial if and only if its decomposition via functions represented by (0,0)-based rectangles is trivial. Therefore these functions form a basis of V_i , and the union such functions for all cores, which is B'_V by definition, is a basis of V, which coincidentally proves Proposition 2.6.

It now follows that in order to verify $(f-g)|_V \equiv 0$ it suffices to substitute each singular function, left-sum term-and right sum term with two-sided sum terms as per Observation 2.9, which are exactly elements of the basis B'_V , and then apply the procedure N from Lemma 1.3 to the result. Since this substitution also increases the input size by a multiplicative constant, the time complexity of the invokation of N is also linear.

Having performed the check for the projection of f-g onto U and then for the projection onto V, we conclude that $f \equiv g$ if and only if both checks concluded that the projections are trivial. Otherwise, f and g are not equivalent. Furthermore, the time complexity of both steps is O(|f| + |g|), thus this algorithm satisfies Theorem 1.4 for the case of M_2 .

3. EXTENSION TO $M_r, r \ge 3$

In the general monoid case, we consider words in alphabet S_r . Again, for any word w we distinguish the powers of letter a_1 in it, and consider any other letter $s \in S_r \setminus \{a_1\}$ as a delimiter. The powers of a_1 will be encoded by non-negative integer numbers written in binary form, and the separators are written as from the set $\{a_1, a_2, \ldots, a_r\}$. To adapt the previous proof to this generalized case we do three things.

First, let us update the basis decomposition lemmas to suite the general case.

Lemma 3.1. Let $w = a_1^k v a_1^m \in M_r$ with |v| > 0 and $v_1 \neq a_1$, $v_{fin} \neq a_1$. Then

$$\rho_w = \rho_v - \sum_{\substack{s \in S_r \smallsetminus \{a_1\}, \\ i = 0...k - 1}} \rho_{sa_1^i v} - \sum_{\substack{s \in S_r \smallsetminus \{a_1\}, \\ j = 0...m - 1}} \rho_{va_1^j s} + \sum_{\substack{s_1, s_2 \in S_r \smallsetminus \{a_1\}, \\ i = 0...k - 1, \\ j = 0...m - 1}} \rho_{s_1 a_1^i v a_1^j s_2}.$$

Proof. The proof is identical to the proof of Lemma 2.1.

Now, let us update the definitions of U and V. B_U is defined as

$$\left\{\rho_{\epsilon}\right\}\cup\left\{\rho_{s}\mid s\in S_{r}\smallsetminus\left\{a_{1}\right\}\right\}\cup\left\{\rho_{s_{1}a_{1}^{k}s_{2}}\mid s_{1},s_{2}\in S_{r}\smallsetminus\left\{a_{1}\right\},k\geq0\right\}.$$

The definitions of U, V and B_V are derived from B_U similarly to the case of M_2 .

Remark 3.2. All definitions for the case of M_r are the same as for the case of M_2 , but wherever there was the letter a_2 there is now a summation over all letters $s \in S_r \setminus \{a_1\}$.

Lemma 3.3. The set

$$B'_{U} \coloneqq \{\rho_{\epsilon}\} \cup \{\rho_{s} \mid s \in S_{r} \smallsetminus \{a_{2}\}\} \cup \{\rho_{s_{1}a_{1}^{k}s_{2}} \mid s_{1}, s_{2} \in S_{r} \smallsetminus \{a_{2}\}, k \ge 0\}$$

is another basis of U. Furthermore, for $w = a_2 a_1^k a_2 \in M_n$ with $k \ge 0$ it holds that

$$\rho_w = \rho_{a_1^k} - \sum_{s \in S \smallsetminus \{a_2\}} a_1^k s - \sum_{s \in S \smallsetminus \{a_2\}} s a_1^k - \sum_{s_1, s_2 \in S \smallsetminus \{a_2\}} s_1 a_1^k s_2 d_1^k s_2 d_2^k d$$

Proof. The proof of the first fact is similar to the proof of Lemma 2.5, and the proof of the second fact is similar to the proof of Lemma 2.1. \Box

Proposition 3.4. The set

$$B'_{V} \coloneqq \left\{ \sum_{\substack{i=0...k, \\ j=0...m \\ s_{1}, s_{2} \in S_{r} \smallsetminus \{a_{1}\}}} \rho_{s_{1}a_{1}^{i}va_{1}^{j}s_{2}} \mid k, m \ge 0, v \in M_{r} \text{ where } v_{1} \neq a_{1} \text{ and } v_{fin} \neq a_{2} \right\}$$

is a basis of V.

. Next, in the encoding of a single word $w = s_1 a_1^{k_1} s_2 a_1^{k_2} \dots a_1^{k_m} s_{m+1}$ we start to specify, which letters go in between the powers of letter a_1 :

$$\mathbf{e}(s_1a_1^{k_1}s_2a_1^{k_2}\ldots a_1^{k_m}s_{m+1}) = (s_1,k_1,s_2,k_2,\ldots,k_m,s_{m+1}).$$

. Second, using Lemma 3.1, we replace each term $\rho_{a_1^k v a_1^m}$ by $1 + 2(r-1) + (r-1)^2 = r^2$ terms, which are respectively

$$\mathbf{e}(v),
 (a_i, [0, k-1], \mathbf{e}'(v)), \text{ where } i \neq 1,
 (\mathbf{e}'(v), [0, m-1], a_i), \text{ where } i \neq 1,
 (a_i, [0, k-1], \mathbf{e}'(v), [0, m-1], a_j), \text{ where } i, j \neq 1.$$

(We remind that $\mathbf{e}'(v)$ is again the word $\mathbf{e}(v)$ without the enclosing parethesis.)

With all the definitions inplace, the proof is totally identical. We use Lemma 3.1 to decompose most elements of f - g by replacing terms with their encodings. Then, we separate terms that lie in U from terms that lie in V based on encodability and encoding length. For the subspace U, we use the representation from Lemma 3.3 to decompose the projection onto U in terms of B'_U , and then use the procedure N to check the triviality. In the case of V, two encoded terms also interact if they have the same cores, and in the case of $r \ge 3$ the same list of delimiters. Therefore, here the histogram method also applies to subspaces of interacting functions, and it is possible to similarly re-represent the projection of f - g onto V in terms of B'_V and then use the procedure N to collapse the coefficients. A more formal listing of the algorithm may be found in Appendix A.

Here, in both cases the size of the input is increased by a factor of r^2 , and the running time of N is O(rn), which yields the time complexity of $O(r^3(|f| + |g|))$, which satisfies Theorem 1.4.
