## Abstract

We study the behavior of two-time correlation functions at late times for finite system sizes considering observables whose (one-point) average value does not depend on energy. In the long time limit, we show that such correlation functions display a ramp and a plateau determined by the correlations of energy levels, similar to what is already known for the spectral form factor. The plateau value is determined, in absence of degenerate energy levels, by the fluctuations of diagonal matrix elements, which highlights differences between different symmetry classes. We show this behavior analytically by employing results from Random Matrix Theory and the Eigenstate Thermalisation Hypothesis, and numerically by exact diagonalization in the toy example of a Hamiltonian drawn from a Random Matrix ensemble and in a more realistic example of disordered spin glasses at high temperature. Importantly, correlation functions in the ramp regime do not show self-averaging behaviour, and, at difference with the spectral form factor the time average does not coincide with the ensemble average.

## 1 Introduction

Universal properties derived from Random Matrix Theory (RMT) [1] have demonstrated exceptional robustness in describing quantum non-integrable systems [2]. Recently, there has been a growing interest in applying these concepts to systems with many interacting degrees of freedom, with developments from various fields, including the characterization of chaotic behavior in quantum many-body dynamics [3–5] and the emergence of gravity in high-energy physics [6–9].

RMT universality has long been observed in the correlations that govern close by *energy levels* in “non-integrable” Hamiltonians, at least at high enough energies. The paradigmatic observation generically made for non-integrable models is the phenomenon of level repulsion which forbids excessively small energy gaps and enforces some spectral rigidity. Correlations between energy levels are accurately diagnosed by their Fourier transform called the Spectral Form Factor (SFF). At short times, the SFF always decays during a phase called the *slope*. At late times, the behaviour of the SFF depends on the nature of the system considered. For chaotic or RMT systems, the SFF first shows a clear growth, usually dubbed the *ramp*, which is a fingerprint of level repulsion. At even larger times comparable with the Hilbert space dimension (the Heisenberg time), the SFF reaches a *plateau* and fluctuates around this constant value. For integrable models, the ramp is absent, and the slope instead directly transitions to a plateau. In RMT and chaotic quantum many-body systems, the averaged (over an ensemble or time) SFF can thus be decomposed in two terms

$$\overline{\text{SFF}}(t) = \text{SFF}_{\text{slope}}(t) + \text{SFF}_{\text{RMT}}(t), \quad (1)$$

where the first term describes the slope and the second part contains the universal late-time behaviour predicted by RMT.

RMT universality has also been discussed in the context of chaotic *eigenvectors*, extending the pioneering idea that eigenfunctions of the Hamiltonian can be modeled as random vectors [10]. While the eigenvectors of rotationally-invariant random matrix ensembles are structureless, and therefore too simple to account for some form of locality present in more realistic Hamiltonians, many of their properties can be generalised in order to take into account some energy dependence. This has been done within the Eigenstate Thermalisation Hypothesis (ETH), first in its original version [3, 11–13] and later in more general extensions [14, 15]. Although the ETH’s original scope was to describe the onset of thermal equilibrium [12, 13, 16], the objects of interest described within the ETH are dynamical correlation functions, typically seen in the thermodynamic limit. While the ETH remains formally unproven, a good working hypothesis is that it holds for systems exhibiting level repulsion (an exception being made for systems with quantum many-body scars, which display a few “athermal” eigenstates [17–19]).

In this work, we put together the universal properties of energy levels and those of the ETH eigenvectors to characterize the late-time behavior of two-time correlation functions (at

equilibrium) in large but finite systems. We show that, upon averaging and for well-chosen observables, correlation functions of some observables display a ramp and a plateau similar to that of the SFF. This leads to the decomposition

$$\bar{\mathcal{C}}(t) = \mathcal{C}_{\text{slope}}(t) + \mathcal{C}_{\text{RMT}}(t), \quad (2)$$

for a suitably-defined connected correlation function  $\mathcal{C}(t)$  which depends on the RMT universality class of the system. We show that the  $\mathcal{C}_{\text{slope}}(t)$  amounts for the non-universal physical dynamical correlations (is the Fourier transform of the smooth ETH off-diagonal function), while  $\mathcal{C}_{\text{RMT}}(t)$  can be written as the convolution of the latter with the spectral correlations, hence it represents the spectral correlations that generically dominate the long-time displaying the ramp-plateau behavior.

Similar observations have been drawn in the high-energy literature [6, 20–23], random circuits [24] or hydrodynamics [25]. While the mechanism by which such a ramp can appear is easy to grasp, a justification of when it can be actually observed is instead rather subtle. Here, we provide a careful analytical study using the ETH approach. Our main assumption is that the average over energy levels and eigenvectors decouples. This is a standard result for rotationally-invariant Hamiltonians, and we here assume it holds true for realistic many-body systems satisfying the ETH. We also show numerical evidence for our predictions in macroscopic many-body systems. While we chose to study numerically spin glass models, the same conclusions could have been drawn considering the SYK model, which however was not convenient for us as we need to treat separately different RMT universality classes. A key requirement to expect such a RMT behaviour is to consider observables whose expectation values (one-point functions) do not show any energy dependence. This allows, in absence of degenerate energy levels, the plateau to arise mainly from the fluctuations of the observable's diagonal matrix elements, making it exponentially small in the system size. This is to be put in contrast with the case considered in [26, 27], and recently in [28], where an explicit energy dependence leads to a plateau which scales polynomially with the system size.

Interestingly enough, at late times when dynamical correlation functions present a ramp, their fluctuations are so large that *their time-average does not reproduce their ensemble-average*, contrary to the SFF. This is at stark contrast with usual quantities that are generically computed within the ETH and have a smooth self-averaging behaviour. The lack of self-averaging means that working with a fictitious ensemble as is usually assumed in the ETH is tricky. In order to show our predictions we preferred to work with disordered systems where we unequivocally specify the ensemble of Hamiltonians as that generated by all instances of disorder.

We organize the manuscript by presenting first the results from RMT in Sec. 2, where the Hamiltonian is drawn from the GOE or the GUE. In order to see the ramp, it appears important to distinguish between these two ensembles. Section 3 then presents the results for the many-body problems, justifying our predictions with ETH and RMT arguments, and then studying numerically two examples of spin glasses at infinite temperature exhibiting GOE or GUE statistics.

## 2 Random Matrix Hamiltonians

### 2.1 Two-time correlations and SFF in RMT

In this section, we review the simpler instance in which the system's Hamiltonian  $H$  is drawn from a rotationally-invariant ensemble [1], where Eq.(2) acquires a particularly straightforward form. For simplicity, in the numerical simulation, we will specialize in a  $\mathcal{N} \times \mathcal{N}$  Gaussian ensemble. Specifically, we consider the Orthogonal and Unitary Gaussian ensembles (GOE and

GUE), defined over symmetric (and Hermitian) matrices, described by the probability distribution

$$P(H) \propto \exp\left(-\beta_{\text{RMT}} \frac{\mathcal{N}}{4} \text{Tr}(H^2)\right), \quad (3)$$

where  $\beta_{\text{RMT}} = 1$  for the GOE and  $\beta_{\text{RMT}} = 2$  for the GUE [1, 29]. The eigenvalues  $\{E_i\}$  density of states is denoted

$$\rho(E) = \sum_i \delta(E - E_i) \quad (4)$$

and, for large  $\mathcal{N}$ , the associated single-eigenvalue distribution  $\rho(E)/\mathcal{N}$  converges to the Wigner semicircle distribution  $p(E) = \frac{1}{2\pi} \sqrt{4 - E^2}$  [30]. Let us stress again that while here, for simplicity, we focus on the GOE or GUE ensemble, the results could be generalised to any rotationally-invariant ensemble [1], suitably changing the asymptotic spectral function. This will only change the slope part.

Eigenvalues correlations are encoded in the Spectral Form Factor, which, for a fixed Hamiltonian, is defined as

$$\text{SFF}(t) = |\langle e^{-iHt} \rangle|^2,$$

where  $\langle \bullet \rangle = \text{Tr}(\bullet)/\mathcal{N}$  is the infinite temperature canonical average. In the case of random matrix models, the SFF displays well-known features and leads to the so-called *slope-dip-ramp-plateau* picture [6, 30, 31]. Let us recall here its basic properties. We will denote ensemble averages by  $\overline{\bullet}$ . In continuous energy variables, the ensemble average of SFF reads

$$\overline{\text{SFF}}(t) = \frac{1}{\mathcal{N}^2} \int dE_1 dE_2 \overline{\rho(E_1)\rho(E_2)} e^{i(E_1 - E_2)t}. \quad (5)$$

and can be split into two parts  $\overline{\text{SFF}}(t) = \text{SFF}_{\text{slope}}(t) + \text{SFF}_{\text{RMT}}(t)$ , as in Eq.(1). The disconnected part, denoted  $\text{SFF}_{\text{slope}}$ , is defined as

$$\text{SFF}_{\text{slope}}(t) = \frac{1}{\mathcal{N}^2} \int dE_1 dE_2 \overline{\rho(E_1)\rho(E_2)} e^{i(E_1 - E_2)t} = \frac{1}{\mathcal{N}^2} \left| \int dE e^{iEt} \overline{\rho(E)} \right|^2 \quad (6)$$

which encodes for the average  $\rho(E)$  and hence accounts for the non-universal early time decay. The connected part, here denoted  $\text{SFF}_{\text{RMT}}$ , encodes the level density correlations, and it accounts for the universal RMT level repulsion as

$$\text{SFF}_{\text{RMT}}(t) = \overline{\text{SFF}}(t) - \text{SFF}_{\text{slope}}(t) = \frac{1}{\mathcal{N}^2} \int dE_1 dE_2 \left( \overline{\rho(E_1)\rho(E_2)} - \overline{\rho(E_1)}\overline{\rho(E_2)} \right) e^{i(E_1 - E_2)t}, \quad (7)$$

At early times, the SFF is dominated by the decay (this is the *slope*) of  $\text{SFF}_{\text{slope}}$ . In the case of Gaussian ensembles, the slope is given by

$$\text{SFF}_{\text{slope}}(t) = \left( \frac{J_1(2t)}{t} \right)^2 \sim \frac{1}{t^3}. \quad (8)$$

Around the time  $t_{\text{dip}} \sim \sqrt{\mathcal{N}}$ , the SFF stops decreasing (*dip*) and the contribution  $\text{SFF}_{\text{RMT}}$  becomes dominant. It grows (*ramp*) before saturating at a constant value (*plateau*). In RMT, the connected two-point correlations of the density of states can be expressed as

$$\overline{\rho(E_1)\rho(E_2)} - \overline{\rho(E_1)}\overline{\rho(E_2)} = \mathcal{N}^2 \mathcal{R}[\mathcal{N}(E_1 - E_2)] \quad (9)$$

where the exact expressions of  $\mathcal{R}$  for the different ensembles can be found in Ref. [30]. For the GUE, taking the Fourier transform of  $\mathcal{R}$  yields a strictly linear ramp

$$\text{SFF}_{\text{RMT}}(t) = \begin{cases} \frac{t}{2\mathcal{N}^2} & \text{for } t < 2\mathcal{N} \\ \frac{1}{\mathcal{N}} & \text{for } t > 2\mathcal{N} \end{cases}, \quad (10)$$

while for the GOE, logarithmic corrections appear

$$\text{SFF}_{\text{RMT}}(t) = \begin{cases} \frac{t}{\mathcal{N}^2} - \frac{t}{2\mathcal{N}^2} \ln\left(1 + \frac{t}{\mathcal{N}}\right) & \text{for } t < 2\mathcal{N} \\ \frac{2}{\mathcal{N}} - \frac{t}{2\mathcal{N}^2} \ln\left(\frac{t+\mathcal{N}}{t-\mathcal{N}}\right) & \text{for } t > 2\mathcal{N} \end{cases}. \quad (11)$$

It is worth noting that the plateau value is always  $\mathcal{N}^{-1}$ , while the dip value is  $t_{\text{dip}}/\mathcal{N}^2 = \mathcal{N}^{-3/2}$ .

Let us now discuss the dynamical correlations of a diagonal matrix  $A$  (the equivalent of local observable) and consider the connected two-point correlation function:

$$C_c(t) = \frac{1}{2} \langle \{A(t), A(0)\} \rangle - \langle A \rangle^2, \quad (12)$$

where  $\{\bullet, \bullet\}$  is the anticommutator. We consider the ensemble average  $\overline{C}_c(t)$  that, in the Hamiltonian's basis  $\{|E_i\rangle, E_i\}_i$ , can be rewritten as

$$\overline{C}_c(t) = \frac{1}{\mathcal{N}} \sum_{i,j} \overline{|A_{ij}|^2 e^{i(E_i - E_j)t}} - \langle A \rangle^2 = \frac{1}{\mathcal{N}} \sum_{i \neq j} \overline{|A_{ij}|^2 e^{i(E_i - E_j)t}} + \frac{1}{\mathcal{N}} \sum_i \overline{A_{ii}^2} - \langle A \rangle^2, \quad (13)$$

with  $A_{ij} = \langle E_i | A | E_j \rangle$  and where in the last equality, we have removed the ensemble average over  $\langle A \rangle$  since the trace of a matrix does not depend on the basis it is computed in. In rotationally-invariant ensembles as the GOE or the GUE, the probability distribution of eigenvectors and eigenvalues factorise, so that we can take their averages separately. For  $\mathcal{N} \gg 1$ , the averages over the matrix elements can be computed by using (see Ref. [32] for a proof of high-order expectations)

$$\overline{|A_{ij}|^2} = \begin{cases} \langle A \rangle^2 + \frac{1}{\mathcal{N}} \frac{2\kappa_2}{\beta_{\text{RMT}}} & \text{if } i = j \\ \frac{1}{\mathcal{N}} \kappa_2 & \text{if } i \neq j \end{cases}, \quad (14)$$

where we have introduced the second free cumulant  $\kappa_2 = \langle |A|^2 \rangle - \langle A \rangle^2$ . This leads to

$$\overline{C}_c(t) \stackrel{\mathcal{N} \gg 1}{\simeq} \frac{\kappa_2}{\mathcal{N}^2} \sum_{i \neq j} \overline{e^{i(E_i - E_j)t}} + \frac{2\kappa_2}{\mathcal{N} \beta_{\text{RMT}}} = \kappa_2 \overline{\text{SFF}}(t) + \left( \frac{2}{\beta_{\text{RMT}}} - 1 \right) \frac{\kappa_2}{\mathcal{N}}, \quad (15)$$

with the spectral form factor (SFF) defined as  $\text{SFF}(t) = \frac{1}{\mathcal{N}^2} \sum_{i,j} e^{i(E_i - E_j)t}$ . It is natural to introduce the shifted connected correlation function  $\mathcal{C}$  such that

$$\mathcal{C}(t) = C_c(t) - \left( 1 - \frac{\beta_{\text{RMT}}}{2} \right) \lim_{t \rightarrow \infty} \overline{C}_c(t), \quad (16)$$

where in the above, the infinite time limit of  $\overline{C}_c(t)$  is well defined, i.e.  $\lim_{t \rightarrow \infty} \overline{C}_c(t) = \frac{2}{\beta_{\text{RMT}}} \frac{\kappa_2}{\mathcal{N}}$ . With this notation, one has

$$\overline{\mathcal{C}}(t) = \kappa_2 \overline{\text{SFF}}(t). \quad (17)$$

This identity shows that, for a Hamiltonian drawn from random ensembles, the behavior of a two-point function can be extracted from that of the SFF [6, 30]. The present analysis emphasizes the importance of the symmetry classes for extracting the eigenvalue correlations from dynamical correlators, which is encoded in the re-scaled Eq.(16) and not in the bare connected correlator. Following from Eq.(17), it follows that random matrices the decomposition of dynamical correlations in Eq.(2) holds upon identifying  $\mathcal{C}_{\text{slope}}(t) = \kappa_2 \text{SFF}_{\text{slope}}(t)$  and  $\mathcal{C}_{\text{RMT}}(t) = \kappa_2 \text{SFF}_{\text{RMT}}(t)$ .

## 2.2 Lack of self-averaging

While the previous calculation characterized the ensemble-averaged quantity  $\bar{\mathcal{C}}(t)$ , this section aims at estimating the single instance fluctuations  $\delta\mathcal{C}(t) = \mathcal{C}(t) - \bar{\mathcal{C}}(t)$ . In random matrices, because  $\overline{|A_{ij}|^4} \propto \overline{|A_{ij}|^2}^2$  with a proportionality constant dependent on the ensemble, we expect that matrix elements behave as:

$$|A_{ij}|^2 = \frac{1}{\mathcal{N}}\kappa_2 + \frac{c}{\mathcal{N}}\xi_{ij} \quad \text{for } i \neq j, \quad (18)$$

with  $\{\xi_{ij}\}_{ij}$  a set of weakly correlated random variables with mean zero, variance one, and whose exact distributions depend on the observable considered. In a single instance  $\mathcal{C}(t)$ , summing the  $\mathcal{N}^2$  noise contributions gives rise to a noisy component of strength  $\mathcal{N}^{-1}$ , i.e.

$$\mathcal{C}(t) = \bar{\mathcal{C}}(t) + \mathcal{O}(\mathcal{N}^{-1}). \quad (19)$$

While this does not significantly obstruct the recovery of  $\bar{\mathcal{C}}(t)$  in the slope of order  $\mathcal{O}(1)$  and the plateau of order  $\mathcal{O}(\mathcal{N}^{-1})$ , fluctuations completely hide the signal close to the dip which scales as  $\mathcal{N}^{-3/2}$  (see Sec. 2.1).

This is confirmed by the numerical in the Gaussian ensemble case (see the right panels of Figs. 1-2 below) where we plot the single-sample dynamical correlate  $\mathcal{C}(t)$ . Contrary to the Spectral Form Factor, where the small-window time average reproduces the dip-ramp behavior, for the dynamical correlator, the dip and ramp are nowhere to be seen even after averaging over a small time window. The fact that, in the RMT toy models, the noise  $\delta\mathcal{C}(t)$  can become larger than the average signal  $\bar{\mathcal{C}}(t)$  thus results in correlation functions not being self-averaging, and in the small-window time-average not reproducing the ensemble-average in contrast to what is usually expected in ETH in the decaying part.

## 2.3 Numerical analysis for RMT ensembles

We here check numerically the previous findings in the case of the gaussian ensembles sampled with Eq. (3).

### 2.3.1 The Gaussian Orthogonal Ensemble

We consider here a Hamiltonian from the GOE, i.e. drawn from Eq. (3) with  $\beta_{\text{RMT}} = 1$ , and take the observable  $A = S_j^z$ , with  $j$  an arbitrary site index. Fig. 1 (right) shows the behaviour of  $\mathcal{C}(t) = C_c(t) - \kappa_2/\mathcal{N}$  and of the SFF for a single realisation of the GOE Hamiltonian. Upon averaging over some small time window, one can not resolve the ramp in  $\mathcal{C}(t)$ . However, if one considers the average  $\bar{\mathcal{C}}(t)$  over many realisations of the GOE Hamiltonian, the slope-dip-ramp-plateau becomes clear as shown in Fig. 1 (left). This is in contrast with the SFF where, despite the fluctuations, the ramp is visible also in a single instance, and the time average of one single instance coincides with the ensemble average.

### 2.3.2 The Gaussian Unitary ensemble

We now consider a Hamiltonian from the GUE (Eq. (3) with  $\beta_{\text{RMT}} = 2$ ). Fig. 2 (right) shows the behaviour of  $\mathcal{C} = C_c(t)$  and of the SFF for a single realisation of the GUE Hamiltonian. Upon averaging over some small time window, the slope-dip-ramp-plateau feature becomes visible in the SFF, while the ramp can not be resolved in  $\mathcal{C}$ . If one averages  $\mathcal{C}$  and the SFF over many realisations of the GUE Hamiltonian, the ramp-plateau becomes much more clear as shown in Fig. 2 (left).

Figure 1: Left: (a) Shifted correlation function  $\bar{\mathcal{C}}(t)$  and (b) spectral form factor  $\overline{\text{SFF}}(t)$  averaged over 1000 GOE Hamiltonians. Right: (c) Shifted correlation function  $\mathcal{C}(t)$  and (d) spectral form factor  $\text{SFF}(t)$  obtained from a single GOE Hamiltonian. Plots (c) and (d) are for  $L = 12$  spins. In all plots, the thin curves are the exact result while the thick curves are a smoothed version obtained by convoluting with a Gaussian kernel. The horizontal dashed lines are the expected plateau values coming from the diagonal ensemble. The increasing oblique dashed lines are fits  $\propto t$ .

### 2.3.3 Numerical evaluation of the fluctuations

In order to quantify the fluctuations of correlations relative to their average in Eq.(19), we consider the variance of  $\mathcal{C}(t)$  normalized by its average, namely

$$\overline{\delta\mathcal{C}^2(t)}/\bar{\mathcal{C}}^2(t), \quad (20)$$

which we compare with the same quantity involving the SFF

$$\overline{\delta\text{SFF}^2(t)}/\overline{\text{SFF}}^2(t), \quad (21)$$

where  $\delta\text{SFF}(t) = \text{SFF}(t) - \overline{\text{SFF}}(t)$  are the fluctuations of the SFF. The results for the GOE case are summarised in Fig. 3, and a similar picture can be drawn for the GUE case. While the SFF has a bounded noise-to-signal ratio, for the correlation function  $\mathcal{C}$ , this ratio increases with the system size  $L$  in the dip and ramp, signaling there that the fluctuations  $\delta\mathcal{C}(t)$  completely dwarf the ensemble average  $\bar{\mathcal{C}}(t)$ .

This underscores a crucial difference between SFF and dynamic correlation, even in models of random matrices. Unlike SFF, dynamical correlations do not self-average when it comes to time averages over small intervals. This is due to fluctuations in matrix elements and, therefore, in the eigenvectors.

Figure 2: Left: (a) Shifted correlation function  $\bar{\mathcal{C}}(t)$  and (b) spectral form factor  $\overline{\text{SFF}}(t)$  averaged over 1000 GUE Hamiltonians. Right: (c) Shifted correlation function  $\mathcal{C}(t)$  and (d) spectral form factor  $\text{SFF}(t)$  obtained from a single GUE Hamiltonian. Plots (c) and (d) are for  $L = 12$  spins. In all plots, the thin curves are the exact result while the thick curves are a smoothed version obtained by convoluting with a Gaussian kernel. The horizontal dashed lines are the expected plateau values coming from the diagonal ensemble. The increasing oblique dashed lines are fits  $\propto t$ .

Figure 3: Normalised fluctuations of the shifted correlation function  $\mathcal{C}(t)$  and the spectral form factor  $\text{SFF}(t)$  averaged over 1000 GOE Hamiltonians at inverse temperature  $\beta = 0$ . The thin curves are the exact result while the thick curves are a smoothed version obtained by convoluting with a Gaussian kernel.

### 3 Many-body Hamiltonian

In this section, we will discuss how the previous results can be extended to generic many-body interacting Hamiltonians of  $L$  constituents that obey ETH. We will show that the ensemble

average of the properly defined two-point functions can be decomposed as

$$\overline{C}(t) = C_{\text{slope}}(t) + C_{\text{RMT}}(t), \quad (22)$$

where in the large  $L$  limit, the first contribution, related to the disconnected part of the level density, encodes all the physical dynamical two-point function

$$C_{\text{slope}}(t) = \int d\omega |f_{e_0}(\omega)|^2 e^{i\omega t}, \quad (23)$$

where  $f_{e_0}(\omega)$  is the smooth function appearing in the off-diagonal ETH ansatz (see below). On the other hand, the second contribution is related to the connected spectral correlations and shall generically feature a long-time ramp behaviour and later a plateau as the SFF:

$$C_{\text{RMT}}(t) \sim \int dt' C_{\text{slope}}(t-t') \text{SFF}_{\text{RMT}}(t') \simeq f_{e_0}^2(0) \text{SFF}_{\text{RMT}}(t). \quad (24)$$

### 3.1 Two-time correlations and SFF within ETH

For definiteness, we focus on infinite temperature and consider 2-level systems, such that the total Hilbert space dimension is  $\mathcal{N} = \dim \mathcal{H} = 2^L$ . Given a generic Hamiltonian  $\hat{H}$  with energy levels  $\{E_i\}_i$ , we define the density of states  $\rho(E)$  of a many-body system as in Eq.(4). It is related to the thermodynamic entropy  $S(E)$  as

$$\overline{\rho(E)} \simeq e^{S(E)}, \quad (25)$$

where  $\overline{\bullet}$  now denotes some form of averaging over an ensemble to be specified. It could be some small perturbation of the system, the disorder in a random Hamiltonian or some energy/time window. In general, one can introduce a thermodynamically well-defined energy density  $e = E/L$  and entropy density  $s(e = E/L) = S(E)/L$  so the density of states is exponentially large in the number  $L$  of degrees of freedom (and the level spacing exponentially small). We will assume that no degeneracies are present in the spectrum.

In the following, we aim to characterize dynamical correlations and thus assume the ETH ansatz for the matrix elements of a local observable  $A$ . The off-diagonal matrix elements are expected to fluctuate as [13]

$$\overline{|A_{ij}|^2} \simeq \overline{\rho(E_{ij}^+)}^{-1} f_{e_{ij}^+}^2(\omega_{ij}) \quad (i \neq j), \quad (26)$$

where  $e_{ij}^+ = E_{ij}^+/L = (E_i + E_j)/(2L)$  is the mean intensive energy and  $\omega_{ij} = E_i - E_j$  is the energy difference. The diagonal matrix elements are characterised by a microcanonical average  $\mathcal{A}(e)$  of order  $\mathcal{O}(1)$  and small fluctuations which lead to

$$\overline{A_{ii}^2} \simeq \mathcal{A}^2(e_i) + \overline{\delta A_{ii}^2}. \quad (27)$$

The fluctuations of diagonal elements are related to those of off-diagonal elements due to the local rotational invariance of the many-body Hamiltonian (see for instance [33]), implying that

$$\overline{\delta A_{ii}^2} \simeq \frac{2}{\beta_{\text{RMT}}} \overline{\rho(E_i)}^{-1} f_{e_i}^2(\omega_{ii} = 0), \quad (28)$$

with  $\beta_{\text{RMT}} = 1$  for real Hamiltonians (GOE-like) and  $\beta_{\text{RMT}} = 2$  for complex Hamiltonians (GUE-like).

An important assumption made in the following is that *the observable  $A$  has an average  $\mathcal{A}(e)$  that does not depend on  $e$ , while  $A$  still fluctuates* as in Eq. (28). This is, for instance, the

case of a local observable protected by some global conservation law in a disordered system. This hypothesis is required to avoid extra terms which could hide the slope-ramp-dip-plateau behaviour we are looking for [28], because of polynomially small/large corrections to the plateau, which may be understood by the fact that the fluctuations of the observable are then driven by the large local excursions of energy.

Drawing inspiration from the previous section on RMT, we now wish to establish a link between the large time behaviour of connected correlation functions defined in Eq. (12) and the SFF. We assume for simplicity that the system is put at infinite temperature ( $\beta = 0$ ) since using a finite temperature is a straightforward generalisation. In the limit of large, yet finite, system size, the ensemble-averaged correlation function reads

$$\overline{C}_c(t) = \frac{1}{2Z} \int dE_1 dE_2 \overline{\rho(E_1)\rho(E_2)} \overline{|A_{E_1, E_2}|^2} e^{i(E_2 - E_1)t} + c.c. - \langle A \rangle^2. \quad (29)$$

As for the rotationally-invariant ensembles considered in Sec. 2.1, the equation above assumes that the probability distribution over eigenvectors and eigenvalues of the Hamiltonian factorises. Next, distinguishing between off-diagonal and diagonal elements of  $A$  and using the ETH ansatz of Eqs. (26-28) leads to

$$\begin{aligned} \overline{C}_c(t) = & \frac{1}{Z} \int_{|\omega| \geq \overline{\rho(E)}^{-1}} dE d\omega \frac{\overline{\rho(E + \omega/2)\rho(E - \omega/2)}}{\overline{\rho(E)}} f_e^2(\omega) e^{i\omega t} \\ & + \frac{1}{Z} \int dE \frac{\overline{\rho(E)^2}}{\overline{\rho(E)}} \left[ \mathcal{A}^2(e) + \frac{2}{\beta_{\text{RMT}}} \frac{f_e^2(0)}{\overline{\rho(E)}} \right] - \langle A \rangle^2, \end{aligned} \quad (30)$$

where  $E = (E_1 + E_2)/2$  and  $\omega = E_1 - E_2$ . Due to the standard saddle-point argument of the ETH, the contribution of the canonical average  $\langle A \rangle^2$  exactly cancels that of the microcanonical average  $\mathcal{A}(e)$ . Shuffling terms between both integrals gives

$$\overline{C}_c(t) = \frac{1}{Z} \int dE d\omega \frac{\overline{\rho(E + \omega/2)\rho(E - \omega/2)}}{\overline{\rho(E)}} f_e^2(\omega) e^{i\omega t} + \left( \frac{2}{\beta_{\text{RMT}}} - 1 \right) \frac{1}{Z} \int dE \frac{\overline{\rho(E)^2}}{\overline{\rho(E)}} f_e^2(0), \quad (31)$$

which, as for the RMT case in Eq. (16), suggests to introduce

$$\mathcal{C}(t) = C_c(t) - \left( 1 - \frac{\beta_{\text{RMT}}}{2} \right) \lim_{t \rightarrow \infty} C_c(t). \quad (32)$$

where  $\lim_{t \rightarrow \infty} C_c(t) = \int dE \frac{\overline{\rho(E)^2}}{\overline{\rho(E)}} f_e^2(0)$ . We are now in the position to evaluate the ensemble average. Looking at Eq. (31), one is left with evaluating the two-point correlations of the density of states  $\overline{\rho(E + \omega/2)\rho(E - \omega/2)}$ . This can be done by separating the disconnected correlations, which capture the short-time physics of the many-body system, from the connected correlations, which are expected to display an RMT behavior. Using Eq. (25), the disconnected part turns out to be

$$\overline{\rho(E + \omega/2)\rho(E - \omega/2)} \simeq \overline{\rho(E)^2} e^{\frac{1}{4L} \frac{d^2 s(e)}{de^2} \omega^2}, \quad (33)$$

with  $\frac{1}{L} \frac{d^2 s}{de^2} = -\beta^2/C$  and  $C$  the heat capacity. This gives a contribution  $C_{\text{slope}}$  to the shifted correlation function  $\mathcal{C}$  defined by

$$C_{\text{slope}}(t) = \frac{1}{Z} \int dE d\omega \overline{\rho(E)} e^{\frac{1}{4L} \frac{d^2 s(e)}{de^2} \omega^2} f_e^2(\omega) e^{i\omega t}. \quad (34)$$

As in the RMT case,  $C_{\text{slope}}$  is expected to give rise to the slope since it comes from the disconnected part of the correlations between energy levels. It is furthermore expected to be self-averaging with respect to the ensemble average, as is usual within the ETH. In the large system size limit, the factor  $\exp(\frac{1}{4L} \frac{d^2 s(e)}{de^2} \omega^2)$  can be dropped and a saddle point approximation (also done for the partition function  $Z$ ) leads to

$$C_{\text{slope}}(t) = \int d\omega f_{e_0}^2(\omega) e^{i\omega t}, \quad (35)$$

where  $e_0$  is such that  $\frac{ds}{de}(e_0) = 0$ .

We now turn to the connected two-point correlations of the density of states. Since this part is expected to have a random matrix behavior, we generalize Eq. (9) for a many-body system as

$$\overline{\rho(E_1)\rho(E_2)} - \overline{\rho(E_1)}\overline{\rho(E_2)} = \pi^2 \overline{\rho(E_1)}\overline{\rho(E_2)} \mathcal{R}[\mathcal{N}(\Phi(E_1) - \Phi(E_2))], \quad (36)$$

where the function  $\Phi$  is the function relating to spectral unfolding [34] and it is defined as

$$\frac{d\Phi}{dE} = \frac{\pi}{\mathcal{N}} \overline{\rho(E)}. \quad (37)$$

The equation is understood as substituting the density of states  $\frac{\mathcal{N}}{\pi}$  found in the bulk of the Gaussian ensembles by that of the many-body system,  $\overline{\rho(E)}$ . This gives rise to the following random matrix contribution

$$\begin{aligned} C_{\text{RMT}}(t) &= \frac{1}{Z} \int dE d\omega \pi^2 \frac{\overline{\rho(E + \omega/2)}\overline{\rho(E - \omega/2)}}{\overline{\rho(E)}} \mathcal{R}[\mathcal{N}(\Phi(E + \omega/2) - \Phi(E - \omega/2))] f_e^2(\omega) e^{i\omega t} \\ &= \frac{1}{Z} \int dE d\omega \pi^2 \overline{\rho(E)} \mathcal{R}[\pi \overline{\rho(E)} \omega] f_e^2(\omega) e^{i\omega t} \end{aligned} \quad (38)$$

where the last line is a small  $\omega$  expansion valid at large time  $t$ . For large systems, a saddle-point computation yields

$$C_{\text{RMT}}(t) \simeq \pi^2 \int d\omega \mathcal{R}[\pi \overline{\rho(E_0)} \omega] f_{e_0}^2(\omega) e^{i\omega t}. \quad (39)$$

To understand this expression, one has to compare it with the SFF in many-body systems. Here, we reintroduce the temperature as it is convenient to study the SFF as a function of the complex variable  $z = \beta + it$  [35]. The average of the SFF is then given by

$$\overline{\text{SFF}}(t) = \frac{|\overline{Z(\beta + it)}|^2}{\overline{Z(\beta)}^2} = \text{SFF}_{\text{slope}}(t) + \text{SFF}_{\text{RMT}}(t), \quad (40)$$

where, following the steps of the derivation done previously for  $\mathcal{C}$ , the contributions  $\text{SFF}_{\text{slope}}$  and  $\text{SFF}_{\text{RMT}}$  are expressed as

$$\text{SFF}_{\text{slope}}(t) = \sqrt{\left| \frac{d^2 s}{de^2}(e_\beta) \right| \frac{1}{4\pi L}} \int d\omega e^{\frac{1}{4L} \frac{d^2 s(e)}{de^2} \omega^2} e^{i\omega t}, \quad (41)$$

$$\text{SFF}_{\text{RMT}}(t) \sim \int d\omega \pi^2 \mathcal{R}[\pi \overline{\rho(E_\beta)} \omega] e^{i\omega t}, \quad (42)$$

where  $\frac{ds}{de}(e_\beta) = \beta$ . Thus, in the time domain Eq. (39) becomes

$$C_{\text{RMT}}(t) \sim \int dt' C_{\text{slope}}(t - t') \text{SFF}_{\text{RMT}}(t'). \quad (43)$$

This can be interpreted as the SFF smoothed on the scale of the physical correlation function  $\mathcal{C}_{\text{slope}}$ . Note that this is also valid at the level of the single instance, which therefore implies that the fluctuations intrinsic to the SFF also get smoothed out. At times  $t \propto \mathcal{N}$ ,  $\mathcal{C}_{\text{slope}}(t - t')$  acts as a delta function  $\propto \delta(t - t')$  for the slowly varying function  $\text{SFF}_{\text{RMT}}$  and thus in the convolution one retrieves

$$\mathcal{C}_{\text{RMT}}(t) \sim f_{e_0}^2(0) \text{SFF}_{\text{RMT}}(t). \quad (44)$$

While the SFF and  $\mathcal{C}$  seem to behave similarly at late times, it is not the case at early times when both functions are dominated by the slope. From Eqs. (35,41), it appears that  $\mathcal{C}_{\text{slope}}$  decays slower than  $\text{SFF}_{\text{slope}}$  because of  $f^2(\omega)$ . This means that two different dip times are expected for  $\mathcal{C}(t)$  and  $\text{SFF}(t)$ .

### 3.2 Numerical analysis in a many-body Hamiltonian

In this section, we test our predictions for two spin-glass Hamiltonians characterized by two different symmetry classes. We will focus on the infinite temperature regime where no spin-glass phase is expected; see Ref. [36] for spectral correlations in the spin-glass phase at lower temperatures.

To test our predictions for systems with GOE statistics, we consider the *XY spin glass* defined as

$$H = \sum_{i < j} J_{ij} (S_i^x S_j^x + S_i^y S_j^y) \quad (45)$$

where  $J_{ij} \stackrel{\text{iid}}{\sim} \mathcal{N}(0, 1/\sqrt{L})$  and  $\{S_i^\mu\}_\mu$  are the Pauli matrices. Assuming an even number  $L$  of spins and since  $[H, m] = 0$  with  $m = \frac{1}{L} \sum_i S_i^z$  the magnetization, we focus on the magnetization sector  $m = 2/L$  and consider the observable  $A = S_{L/2}^z$ . It can be numerically checked that this model does not have any degenerate levels within a magnetization sector.

#### 3.2.1 GOE spin glass Hamiltonian

Figure 4: Left: Diagonal elements of the local observable  $A$  as a function of the energy density  $E_i/L$  and of the size  $L$ . By order of increasing sizes, the diagonal elements have a standard deviation of 0.20, 0.15, and 0.06. Right: On-shell correlations of order 2 ( $F^{(2)}(\omega)$ ) for  $L = 14$ . The dashed line is a fit done with the sum of two Lorentzians. The inset shows the collapse of data for  $L = 8, 10, 12, 14$  at  $\omega \sim 0$ .

Before proceeding with our analysis, we wish to check the assumptions made in Sec. 3.1.

Figure 5: Left: (a) Shifted correlation function  $\bar{C}(t)$  and (b) spectral form factor  $\overline{\text{SFF}}(t)$  averaged over 1000 XY spin glass Hamiltonians (45) at inverse temperature  $\beta = 0$ . Right: (c) Shifted correlation function  $C(t)$  and (d) spectral form factor  $\text{SFF}(t)$  obtained from a single XY spin glass Hamiltonian (45). Plots (c) and (d) are for  $L = 14$  spins at inverse temperature  $\beta = 0$ . In all plots, the thin curves are the exact result while the thick curves are a smoothed version obtained by convoluting with a Gaussian kernel. The horizontal dashed lines are the expected plateau values coming from the diagonal ensemble. The increasing oblique dashed lines are fits  $\propto t$ .

**1. The average of the observable  $A$  is independent of the energy.** Fig. 4(left) shows how the diagonal elements  $A_{ii} = \langle E_i | A | E_i \rangle$  of the observable vary with the energy density  $E_i/L$  for sizes  $L = 8, 10, 12$ . As expected, the fluctuations from eigenstate to eigenstate rapidly diminish upon increasing the size  $L$  and concentrate around the energy-independent average  $m = 2/L$ , thus verifying assumption 1.

**2. The on-shell correlations of order 2,  $F^{(2)}(\omega) = f_e^2(\omega)$ , have a well-defined limit when  $\omega \rightarrow 0$ .** As in [37],  $F^{(2)}(\omega)$  can be computed for the XY spin glass by simply Fourier transforming the shifted correlation function  $C(t)$  shown in Fig. 5. The result shown in Fig. 4(right) checks assumption 2. It is also worth noticing that  $F^{(2)}(\omega)$  is well fitted by a sum of two shifted Lorentzians at small frequencies, which means that  $C_{\text{slope}}$  displays an exponential decay with oscillations within (as seen in Fig. 5).

The numerical results for the  $\text{SFF}(t)$  and  $C(t)$  are shown for a single Hamiltonian in Fig. 5 (right), and averaging over 1000 Hamiltonians in Fig. 5 (left). The shifted correlation function  $\bar{C}(t)$  exhibits a slope-dip-ramp-plateau behavior, just as the SFF, very visible in the left plot of Fig. 5. However, for the system sizes at our disposal, the ramp is not as linear as in the SFF, pointing to the effect of corrections in the kernel induced by  $f(\omega)$ . Moreover, we note that differently from the SFF, the function  $C$  is not positively defined, so in the slope, it shows negative oscillations. The fact that, instead, it remains positive at large times is a consequence of the predictions that we make about its random matrix component. Moreover, as in RMT, we clearly see that, contrarily to the SFF, the time average of  $C$  does not reproduce the ensemble

average in the ramp.

As a final remark, we add that we have checked that such a slope-ramp-dip-plateau feature is visible also in the Heisenberg spin glass  $H = \sum_{i<j} J_{ij}(S_i^x S_j^x + S_i^y S_j^y)$  where  $J_{ij} \stackrel{\text{iid}}{\sim} \mathcal{N}(0, 1/\sqrt{L})$ .

### 3.2.2 GUE spin-class Hamiltonian

Figure 6: Left: Diagonal elements of the local observable  $A$  as a function of the energy density  $E_i/L$  and of the size  $L$ . By order of increasing sizes, the diagonal elements have a standard deviation of 0.17, 0.10 and 0.06. Right: On-shell correlations of order 2 ( $F^{(2)}(\omega)$ ) for  $L = 14$ . The dashed line is a fit done with a Lorentzian. The inset shows the collapse of data for  $L = 8, 10, 12, 14$  at  $\omega \sim 0$ .

The generalisation of the results obtained in Sec. 2.3.2 for random matrices with GUE statistics and predicted in Sec. 3.1 for many-body systems are tested against the following *chiral spin glass*

$$H = \sum_{i<j<k} J_{ijk} \mathbf{S}_i \cdot (\mathbf{S}_j \times \mathbf{S}_k), \quad (46)$$

where  $J_{ijk} \stackrel{\text{iid}}{\sim} \mathcal{N}(0, 1/L)$ . This is a mean-field model of 3-spin chiral interactions that appear, for instance, in frustrated Hubbard models [38–41]. Notice that [39] has shown that, for indices  $i, j, k$  all different

$$\mathbf{S}_i \cdot (\mathbf{S}_j \times \mathbf{S}_k) = \frac{i}{2} \sum_{l,m,n} \varepsilon_{lmn} S_l^z S_m^+ S_n^- \quad (47)$$

where  $\varepsilon_{lmn}$  is the standard Levi-Civita symbol and  $l, m, n$  take the values of all possible permutations of  $i, j, k$ . From Eq. (47), it follows that  $[H, m] = 0$  with  $m = \frac{1}{L} \sum_i S_i^z$  the magnetization. For an even number  $L$  of spins, the analysis can, therefore, be restricted to the magnetization sector  $m = 2/L$  considering the observable  $S_{L/2}^z$ . Numerically, it appears that this model has a few degenerate levels but, because they are so few, we can forget about them for large systems (i.e.  $L$  greater than  $\sim 10$ ). As in the previous subsection, the assumptions made in Sec. 3.1 are fulfilled as seen in Fig. 6. Moreover, the on-shell correlations  $F^{(2)}(\omega)$  are well fitted by a Lorentzian at small frequency so  $C_{\text{slope}}$  has an exponential decay in time.

The SFF( $t$ ) and  $\mathcal{C}(t)$  were computed through an exact numerical diagonalization of the Hamiltonian (46). The results are shown for a single Hamiltonian in Fig. 7 (right), and averaging over 1000 Hamiltonians in Fig. 7 (left). The slope-dip-ramp-plateau feature is well

Figure 7: Left: (a) Shifted correlation function  $\bar{C}(t)$  and (b) spectral form factor  $\bar{\text{SFF}}(t)$  averaged over 1000 chiral spin glass Hamiltonians (46) at inverse temperature  $\beta = 0$ . Right: (c) Shifted correlation function  $C(t)$  and (d) spectral form factor  $\text{SFF}(t)$  obtained from a single chiral spin glass Hamiltonian (46). Plots (c) and (d) are for  $L = 14$  spins at inverse temperature  $\beta = 0$ . In all plots, the thin curves are the exact result, while the thick curves are a smoothed version obtained by convoluting with a Gaussian kernel. The horizontal dashed lines are the expected plateau values coming from the diagonal ensemble. The increasing oblique dashed lines are fits  $\propto t$ .

visible in this spin glass system, in both  $C(t)$  and  $\text{SFF}(t)$ . Similarly to the previous case, the time average fails to reproduce the ensemble average.

### 3.2.3 Characteristic time scales

From Figs. 5 and 7, it appears that for many-body systems, both the SFF and the correlation function  $C$  exhibit a similar ramp and plateau. However, the slope appearing at early times is not universal and is expected to differ for the SFF and  $C$ . Since the dip time  $t_{\text{dip}}$  signals the crossover between the slope and the ramp, it is not the same for the SFF and for  $C$  as seen in Fig. 8. On the contrary, the ramp and the plateau being two universal features, the Heisenberg time  $t_{\text{Heis}}$ , corresponding to the onset of the plateau, is unique.

## 4 Summary and Conclusions

In this work, we have performed an ETH study of the dynamical connected correlation functions. As for the Spectral Form Factor (SFF), the ensemble average of this function exhibits a ramp and a plateau at large times for well-chosen observables. This fact, already observed in the literature, has been described here using ETH arguments. In summary, our key findings are:

Figure 8: Dip times  $t_{\text{dip}}$  and Heisenberg times  $t_{\text{Heis}}$  of the SFF and the correlation function  $\mathcal{C}$  as a function of the Hilbert space dimension  $\mathcal{N}$ . Results for the XY spin glass (45) are in the left plot, and those for the chiral spin glass (46) are on the right. The dip times are extracted at the minimum of the SFF (or  $\mathcal{C}$ ) before the ramp. The Heisenberg times are defined as the first time the SFF (or  $\mathcal{C}$ ) reaches 95% of its plateau value given by the diagonal ensemble.

- In both the RMT and Hamiltonian cases, the symmetry classes are crucial for extracting eigenvalue correlations from properly shifted dynamical correlation functions, defined as  $\mathcal{C}(t) = C_c(t) - (1 - \beta_{\text{RMT}}/2) \lim_{t \rightarrow \infty} \overline{C_c}(t)$ , where  $C_c(t)$  is the connected correlator. This is particularly relevant for the orthogonal ensemble ( $\beta_{\text{RMT}} = 1$ ), where the ramp is not observed without this shift.
- While the ensemble average of the SFF always coincides with a small time-window average, the same does not hold true for correlation functions during the ramp phase. This non-self-averaging behavior of  $\mathcal{C}(t)$  emerges from the large relative fluctuations of the matrix elements of the observable under scrutiny.
- The plateau at long times is associated with the fluctuations of the diagonal matrix elements of the observables in the absence of degeneracies. To appreciate it in the Hamiltonian case, one shall consider an observable  $A$  which does not overlap with the Hamiltonian; hence, the  $\{A_{ii}\}_i$  fluctuate, but their averages do not depend on energy.

There are several directions for further research. For example, it would be interesting to examine the impact of locality on the early non-universal behavior and how it influences the properties of the dip time in Hamiltonian systems. It would be valuable to explore how the transport of other hydrodynamic modes impacts these results for the observables considered here, for the same models but defined on a finite dimensional lattice.

A natural extension would be to generalize this result by studying how multi-time correlation functions encode the higher-order powers of the SFF [23]. In the context of rotationally-invariant random matrices, the powers of the spectral factors are encoded in the free cumulants [15, 32]. One shall investigate its interplay with the eigenvector fluctuations in Hamiltonian systems.

Lastly, it would be interesting to identify other physical observables where eigenvalue correlations manifest in the form of a ramp. Known examples include survival probability [42, 43], and this concept could be extended to the adiabatic gauge potential [44].
