(Dated: July 20, 2024)

We demonstrate that the interface between S-wave and P-wave paired superfluids in neutron stars induces a neutron supercurrent, akin to the Josephson junction effect in electronic superconductors. The proton supercurrent entrainment by the neutron superfluid generates, in addition to the neutral supercurrent, a charged current across the interface. Beyond the stationary limit, the motions of the neutron vortex line and proton flux tube arrays, responding to secular changes in the neutron star's rotation rate, induce a time-dependent oscillating Josephson current across this interface. We show that such motion produces radiation from the interface, which is phenomenologically significant enough to heat the star and alter its cooling rate during the photon cooling era.

I. INTRODUCTION

Neutron stars are unique objects where quantum physics manifests itself on stellar-size macroscopic scales as their rotational dynamics and magnetic fields are supported by quantized vortex networks extending over macroscopic scales, for reviews see $[1, 2]$ $[1, 2]$ $[1, 2]$. At low densities, their inner crust contains a neutron superfluid, which forms spin-zero Cooper pairs due to nuclear attraction in the ${}^{1}S_{0}$ partial wave channel. At high densities, corresponding to the core of the star, the dominant attractive channel is the ${}^{3}P_{2}$ - ${}^{3}F_{2}$ partial wave channel, i.e., neutrons are paired in a spin-one state [\[3,](#page-4-2) [4\]](#page-5-0). An alternative P-wave channel at high density is ${}^{3}P_{0}$ channel if the ${}^{3}P_{2}$ - ${}^{3}F_{2}$ -pairing is suppressed by the spin-orbit interactions [\[5\]](#page-5-1). The crust-core transition at which bound protons are dissolved into a continuum forming a fluid occurs at a density $n^{\sharp} \approx 0.5 n_0 = 0.08$ fm⁻³ [\[6\]](#page-5-2). As seen from Fig. [1,](#page-0-2) the transition from S - to P -wave neutron superfluid takes place at about the same density. Unbound protons at and above $0.5n_0$ pair in the spin-zero S-state and are admixed with the P-wave neutron superfluid. The transition between S and P -wave superfluids can occur either at a sharp interface, or a mixed phase of these phases occurs within some density domain. We will assume a sharp interface between the two superfluids, but we will briefly comment on the implications of a mixed phase.

The focus of this work is on the interface between two neutral S-wave and P-wave superfluids. We show that a current emerges at this interface, in analogy to Josephson effects in metallic superconductors $[7, 8]$ $[7, 8]$ $[7, 8]$, due to the difference in the phases of these superfluids. Specifically, we show that in the stationary case: (a) a neutron superflow arises at the S -wave – P -wave interface due to the differ-

FIG. 1: Upper panel: Dependence of pairing gaps for neutrons in ${}^{1}S_0$ (solid lines) and ${}^{3}P_2{}^{-3}F_2$ (dash-dotted lines) and for protons in ${}^{1}S_0$ (dashed lines) on baryonic density in units of nuclear saturation density. The upper and lower lines correspond to lower and upper bounds as discussed in Ref. [\[3\]](#page-4-2). Lower panel: Composition of the core of a neutron star at $T = 0$ used to obtain the gaps. The vertical line shows the crust-core interface at the density $n/n_0 = 0.5$.

ence in the phases of these superfluids, i.e., the interface acts as a Josephson junction. An analogous effect in neutral superfluid ultra-cold atomic gases has been observed recently [\[9\]](#page-5-5). (b) Because of the entrainment of the protons by the motion of the neutrons $[10-12]$ $[10-12]$, the neutron superflow induces a charged current through the interface as well. Going beyond the stationary limit, we show that (c) a type of non-equilibrium Josephson effect arises because of the star changes its spin frequency on secular timescales. Neutron superfluid rotates by forming an ar-

ray of quantum vortices and the proton superconductor is type-II at relevant densities and sustains flux tubes that carry the magnetic flux of the star through the superconducting regions $[1, 2, 13-15]$ $[1, 2, 13-15]$ $[1, 2, 13-15]$ $[1, 2, 13-15]$ $[1, 2, 13-15]$. The secular deceleration of neutron stars due to (primarily) their magnetic dipole radiation leads to an expansion of the neutron vortex lattice and neutron vortex lines (and eventually proton flux tubes) crossing the interface. This time-dependent process leads to current oscillations through the interface - an analog of the time-dependent Josephson effect. The dynamics of a coupled network of neutron vortex and proton flux tube arrays are not well understood over time-scale characteristic for glitches and their relaxation due to their complexity. Below, we assume that the flux tubes co-move (on secular time scales) with neutron vortices and show that the crust-core interface radiates electromagnetically. The amount of radiation emitted by the flux tubes is significant enough to deposit phenomenologically important amounts of heat at the crust-core interface, thereby altering the cooling behavior of neutron stars.

II. STATIONARY CURRENTS ACROSS THE INTERFACE

Consider a set-up where the interface is the yz plane of a Cartesian coordinate system. The $x > 0$ region corresponds to S-wave superfluid characterized by an equilibrium wave function Ginzburg-Landau (GL) parameter ψ_1^{∞} and the $x < 0$ region corresponds to P-wave superfluids with GL parameter $\psi_2^{-\infty}$, see Fig. [2.](#page-1-0) A P-wave superfluid has a more complex order parameter [\[16](#page-5-10)[–21\]](#page-5-11) than the scalar one adopted here, but the spin-dynamics of Cooper pairs is not essential for our discussion.

The general form of the GL equation for the condensate wave function ψ reads

$$
\frac{1}{4m} \left(-i\hbar \mathbf{\nabla} - \frac{2e}{c} \mathbf{A} \right)^2 \psi + \alpha \psi + \beta |\psi|^2 \psi = 0, \qquad (1)
$$

where $\alpha < 0$ in the superfluid state, $\beta > 0$, **A** is the vector potential, $e/0$ is the unit charge, c is the speed of light and m is the mass of a nucleon. The boundary condition at the interface between the superfluids is a generalization of the ordinary GL boundary conditions to account for the tunneling of the pairs across the boundary [\[8\]](#page-5-4)

$$
\boldsymbol{n} \cdot \left(\boldsymbol{\nabla} - \frac{2ie}{\hbar c} \boldsymbol{A}\right) \psi_{1,2} |_{\text{Boundary}} = \pm \frac{\psi_{2,1} |_{\text{Boundary}}}{\zeta}, \quad (2)
$$

where the coefficient ζ^{-1} is proportional to the perme-ability of the barrier between the superfluids [\[7\]](#page-5-3) and n is the unit vector orthogonal to the boundary. The neutron mass current is obtained by variation of the GL functional with respect to the vector potential and taking the limit $A \rightarrow 0$. The current density through the boundary

FIG. 2: Illustration of the local setup to compute the Josephson current. The interface is the yz plane with $x > 0$ corresponding to the S-wave condensate and $x < 0$ to the P-wave condensate. The Josephson current (yellow arrows) flows across the interface parallel to the x-axis. In the case of proton flux tubes the magnetic field \bm{B} is locally along the *z*-axis and the vector potential \boldsymbol{A} varies along the x-axis, while its constant y-component does not contribute to its curl.

is then given by

$$
j_x^{(n)} = -i\hbar \left[\psi_1^* \partial_x \psi_1 - \psi_1 \partial_x \psi_1^* \right]
$$

=
$$
\frac{2\hbar}{\zeta} |\psi_1| |\psi_2| \sin (\chi_1 - \chi_2),
$$
 (3)

where we used $\psi_{1,2} = |\psi_{1,2}| e^{i\chi_{1,2}}$. Eq. [\(3\)](#page-1-1) demonstrates that there is neutron mass current across the interface separating S and P -wave superfluids due to the phase difference of two superfluids. It ignores the additional contribution due to the coupling of neutron and proton condensate – the entrainment effect– which is generated by the proton supercurrent.

Next, consider the proton superconductor with the wave function ϕ which is the same on both sides of the interface. We assume there is a charge-neutralizing normal electron fluid at rest. The proton (electric) supercurrent density is given by

$$
j_x^{(p)} = -\frac{i\hbar e}{m_p^*}(\phi^*\partial_x\phi - c.c.) - \frac{i\hbar e}{m_p^*}\kappa_{np}(\psi_1^*\partial_x\psi_1 - c.c.), \text{ (4)}
$$

where κ_{nn} is the entrainment coefficient, accounting for the coupling between the neutron and proton condensates indicated above, and m_p^* is the proton effective mass. Since the proton wave function is the same on both sides of the boundary, the first term of the current vanishes. However, the second term describing the entrained current density is given by

$$
j_x^{(pn)} = j_0 \sin(\chi_2 - \chi_1), \tag{5}
$$

where $j_0 = 2\hbar \kappa_{np} e|\psi_1||\psi_2|/(m_p^*\zeta)$. Assuming $|\psi_1| \simeq |\psi_2|$, i.e., similar in magnitude pairing gaps on both sides of

the junction, we can identify $2|\psi_2|^2$ with n_n^{\sharp} , the neutron number density at the interface and write $j_0 = \eta e n_n^{\sharp} v_{Fn}$, where dimensionless parameter $\eta = \kappa_{np}/(k_F \zeta)$ with k_{Fn} and v_{Fn} being neutron Fermi wave number and velocity. The entrainment coefficient for typical parameters of neutron stars is $|\kappa_{np}| \simeq 0.1$ at low densities [\[22,](#page-5-12) [23\]](#page-5-13).

III. TIME-DEPENDENT CURRENTS ACROSS THE INTERFACE

Neutron stars decelerate under the action of external braking torques, which leads to a decrease in average number of quantum neutron vortices in the superfluid. By continuity, the number of neutron vortices is reduced through their motion away from the rotation axis. Because of the entertainment, neutron vortices carry a fractional flux localized close to their cores. In addition, the stellar magnetic field in the type-II superconducting core exists in the form of proton flux tubes, which will be rearranged by such motion. The average number of proton flux tubes intersecting the area occupied by a single neutron vortex is very large, of the order of $n_{\Phi}/n_V \sim 10^{13}$, where $n_{\Phi} = \bar{B}/\Phi_0$ and $n_V = 2\Omega/\kappa$ are the number densities of proton flux tubes and neutron vortices, \bar{B} is the average magnetic field, $\Phi_0 = \pi \hbar c/e = 2 \times 10^{-7}$ G cm⁻² is the flux quantum and $\kappa = \pi \hbar / m_n^*$ is the quantum of circulation, with m_n^* being the neutron (effective) mass. Thus, the motion of a neutron vortex requires the motion of a cluster of proton flux tubes.

Consider now the problem of a single magnetized neutron vortex or a flux tube crossing the interface between the two superfluids. The vortex is assumed to be locally straight and along the z axis of our setup and the current is flowing along the x axis. The variations of the vector potential are along the x axis, so that the nonvanishing component is $A_x(x) = -H_z(x)y$ (see Fig. [2\)](#page-1-0).

The phase difference between the superfluids in the presence of the magnetic field needs to be written in gauge invariant form

$$
\delta \chi = \chi_1 - \chi_2 - \frac{2\pi}{\Phi_0} \int_2^1 A_x dx = \chi_1 - \chi_2 - \frac{4\pi y H_{0z} \lambda}{\Phi_0},\tag{6}
$$

where λ is the magnetic field penetration depth. To evaluate the integral, we integrate between two points deep in the S-and P-wave superfluids, respectively, and use that the magnetic field of a vortex is given as $H_z(x) =$ $H_{0z} \exp(-x/\lambda)$, where we used the large-distance asymptotic form of the modified Bessel function K_0 . The passage of a vortex/flux tube through the interface induces a time-dependent flux inside the junction. For a proton flux tube, this has a frequency $\omega_p = v_{Lr}/d_p$, where v_{Lr} is the neutron vortex radial velocity and d_p is the inter-flux tube spacing. The maximal value of the flux Φ_{max} will correspond to the case where the vortex line/flux tube coincides with the interface, which has a width of roughly

 $2\xi_n$, where ξ_n is of the order of the coherence length of the neutron superfluid. Therefore, the time-dependent flux can be written as as

$$
\Phi_*(t) = \Phi_{\text{max}} \cos(\omega_p t), \quad \Phi_{\text{max}} = 8\pi \xi H_{0z} \lambda. \tag{7}
$$

Substituting the gauge invariant phase difference in the expression for the current density [\(5\)](#page-1-2) we finally find

$$
j = j_0 \sin(\chi_1 - \chi_2 + \phi(t)), \quad \phi(t) = \frac{\Phi_*(t)}{\Phi_0}.
$$
 (8)

We conclude that the passage of a flux tube or a magnetized neutron vortex through the interface induces an oscillating Josephson-like current in the interface. Note that there is a large difference between the neutron and proton inter-vortex distances $d_n \sim 10^{-3}$ cm and $d_p \sim 10^{-10}$ cm due to the phenomenology of neutron stars, specifically the rotation rates and magnetic fields. We thus expect the frequency ω_p associated with proton flux tubes passing through the interface to exceed the frequency $\omega_V = v_{Lr}/d_n$ associated with the neutron vortex lines passing through it by many orders of magnitude.

IV. RADIATION FROM THE INTERFACE OF TWO SUPERFLUIDS

Time-oscillating current will lead to radiation of energy from the interface, as we show below. We start with the formula for the time-average power radiated by an oscillating electric dipole

$$
\langle P \rangle = \frac{2\langle \ddot{p}^2 \rangle}{3c^3} = \frac{2\langle \dot{I}^2 \rangle d^2}{3c^3},\tag{9}
$$

where $\langle \dots \rangle$ denotes a time-average, the dipole moment is $p = qd$ for charge q and dipole length scale d. To obtain the second relation we used the fact that $\dot{p} = \dot{q}d = Id$, where I is the current.

A. Neutron vortex

We begin by estimating the radiation from neutron vortex lines passing through a junction. We assume that the spin axis is along the z direction of the cylindrical or polar direction of the spherical coordinate system, the former dictated by the geometry of the neutron vortex lattice and the latter by the spherical shape of the star, see Fig. [3.](#page-3-0) For the sake of simplicity, we assume that the interface between the superfluids is a cylinder coaxial with the rotation axis, with a height $\ell_z \leq R$ centered at the equator. We also denote by $\ell_{\perp} \sim \xi$ the extent of the junction in the direction perpendicular z. We will assume for the time being the magnetization of the neutron vortex is negligible; in the next subsection, we will turn to the proton flux tubes whose flux differs from that of a neutron vortex only by a fixed numerical factor. To ob-

FIG. 3: Illustration of the computation of radiation (yellow arrows) at the interface between S-and P wave superfluids. A collection of vortices or flux tubes (red lines) cross the interface. The effective macroscopic length over which radiation is taking place of the order of R.

tain the power radiated per neutron vortex line crossing the interface we substitute the expression for the current $I = j(\ell_{\perp} \ell_z)$ which leads to

$$
\langle P_n \rangle = \frac{2\langle j^2 \rangle d^2}{3c^3} \ (\ell_\perp \ell_z)^2. \tag{10}
$$

If a neutron vortex is moving through the interface then the current density will acquire a time-dependent phase

$$
j_x^{(pn)} = j_0 \sin(\chi_1 - \chi_2 + \omega_V t), \tag{11}
$$

where $\omega_V = v_{Lr}/d_n$, d_n is the inter-vortex spacing and

$$
v_{Lr} = -\frac{\dot{\Omega}}{2\Omega}r,\tag{12}
$$

is the radial velocity of the vortex lines which follows from the conservation of vortex number n_V , r is the radial coordinate in the cylindrical coordinate system. The average of j^2 gives

$$
\langle \dot{j}^2 \rangle = (j_0 \omega_V)^2 \langle \cos^2(\chi_1 - \chi_2 + \omega_V t) \rangle = \frac{1}{2} (j_0 \omega_V)^2, (13)
$$

so that the power radiated in Eq. (10) is given by

$$
\langle P_n \rangle \simeq \frac{\hbar}{3} \left(d\ell_{\perp} \ell_z \right)^2 \omega_V^2 \alpha_{em} \left(\eta n_n^{\sharp} \right)^2 \left(\frac{v_F}{c} \right)^2, \quad (14)
$$

where $\alpha_{em} = e^2/\hbar c = 1/137$ is the electromagnetic coupling constant. The radiant power from this mechanism for the entire star $P_{\star,n}$ is then given by multiplying Eq. [\(14\)](#page-3-2) by the number of vortex lines crossing the interface at a given time, which is roughly $N_V = 2\pi R/d_n$. Hence

$$
\mathcal{P}_{\star,n} = \langle P_n \rangle N_V = \frac{\pi \hbar \alpha_{em}}{6\tau^2} \left(d\ell_{\perp} \ell_z n_n^{\sharp} \eta \right)^2 \left(\frac{R}{d_n} \right)^3 \left(\frac{v_F}{c} \right)^2
$$

$$
= 1.68 \times 10^9 \tau_6^{-2} R_6^5 \Omega_{100}^{3/2} \text{ erg s}^{-1}, \qquad (15)
$$

where we approximated $d \sim \ell_{\perp} \sim \lambda$ and $\ell_z \sim R$, introduced the lifetime of the pulsar $\tau = \Omega/|\dot{\Omega}|$, used $r = R$ in Eq. [\(12\)](#page-3-3) since the interface is near the crust-core boundary. We also used short-hand notation $\tau_6 = \tau/10^6$ yr, $R_6 = R/10^6$ cm and $\Omega_{100} = \Omega/100 s^{-1}$. The numerical value in Eq. [\(15\)](#page-3-4) is obtained for standard value $R = 10^6$ cm and assuming that the pulsar lifetime is $\tau=10^6$ yr. We chose neutron and proton effective masses $m_n^*/m_n = 0.9$ and $m_p^*/m_p = 0.85$ and an interface density $n_n^{\sharp} = 0.08 \text{ fm}^{-3}$, for which $k_{Fn} = 1.33 \text{ fm}^{-1}$ and $v_{Fn}/c = 0.28 (m_n/m_n^*) = 0.31$. We took $|\kappa_{np}| = 0.1$ and $k_F \zeta = 10$, using that the width of the junction characterized by ζ is of the order of coherence length which is roughly 10 fm $[3, 24]$ $[3, 24]$ $[3, 24]$. The penetration depth for the proton condensate, assuming a proton fraction of 0.01, is $\lambda = (m_p^* c^2 / 4 \pi n_p e^2)^{1/2} = 234.7$ fm. Finally, we used the neutron inter-vortex distance given by $d_n = (\pi \hbar / \sqrt{3} m_n^* \Omega)^{1/2} = 3.56 \times 10^{-3} (100 \text{ s}^{-1} / \Omega)^{1/2} \text{ cm}.$

The value quoted in Eq. [\(15\)](#page-3-4) is far too low to be observationally interesting. For instance, it is far smaller than the heating power due to the Ohmic dissipation of the crustal magnetic field B_{cr} on a typical scale δR

$$
\mathcal{P}_{\rm O} \simeq 10^{27} \left(\frac{B_{\rm cr}}{10^{13} \text{ G}} \right)^2 \left(\frac{10^{23} \text{ s}^{-1}}{\sigma} \right) \left(\frac{\delta R}{0.5 \text{ km}} \right) \text{erg s}^{-1},
$$

where σ is crustal electric conductivity.

B. Proton flux tubes

Next, we consider the crossing of the interface by a proton flux tube. We could treat the magnetized neutron vortex lines similarly, but due to their weaker magnetization and far smaller number compared to the proton flux tubes, we neglect them. The radiation intensity in this case is given by inserting Eq. (8) into Eq. (9) :

$$
\langle P_p \rangle = \frac{2(j_0 \omega_p)^2}{3c^3} (d\ell_\perp^2 \ell_z^2) \langle \cos^2(\chi_1 - \chi_2 + \phi(t)) \sin^2(\omega_p t) \rangle, \tag{16}
$$

We use

$$
\langle \cos^2(\chi_1 - \chi_2 + \phi(t)) \sin^2(\omega_p t) \rangle
$$

= $\frac{1}{4} (1 + J_1(2) \cos(2[\chi_1 - \chi_2])) \approx \frac{1}{4},$ (17)

where $J_1(x)$ is a Bessel function and where we average over the possible phase differences $\chi_1 - \chi_2$. Assuming $\ell \sim \ell_{\perp} \sim \lambda$ and $\ell_z \sim R$ as before, we have

$$
\langle P_p \rangle = \frac{\hbar \alpha_{em}}{24\tau^2} (\lambda^2 R)^2 \left(\frac{R}{d_p}\right)^2 (n_n^{\sharp} \eta)^2 \left(\frac{v_F}{c}\right)^2.
$$
 (18)

The result for the star is then obtained by multiplying this result with the number of proton flux tubes N_{Φ} = $2\pi R/d_p$, where the inter-flux distance is given by

$$
d_p = \left(\frac{2}{\sqrt{3}n_{\Phi}}\right)^{1/2} = 1.55 \times 10^{-10} \text{ cm}, \qquad (19)
$$

with $n_{\Phi} = B/\Phi_0 = 4.8 \times 10^{19} (B/10^{13} \text{G}),$ which leads to $\mathcal{P}_{\star,p} = (d_n^3/2d_p^3)\mathcal{P}_{\star,n}$ or, explicitly,

$$
\mathcal{P}_{\star,p} = \frac{\pi \hbar \alpha_{em}}{12\tau^2} (\lambda^2 R n_n^{\sharp} \eta)^2 \left(\frac{R}{d_p}\right)^3 \left(\frac{v_F}{c}\right)^2
$$

= $1.02 \times 10^{31} \tau_6^{-2} R_6^5 B_{13}^{3/2} \text{ erg s}^{-1},$ (20)

where $B_{13} = B/10^{13}$ G. This amount of heating is phenomenologically interesting, and can greatly exceed the Joule heating in the crust due to magnetic field decay.

The radiation from the junction will heat the interface of the two superfluids, and due to the high thermal conductivity of the material, the entire isothermal core. Notably, this heating mechanism does not depend on the temperature and should be of interest for the late-time cooling of neutron stars, when surface photon emission is the dominant cooling mechanism. The heating, however, depends on the spin characteristics of the neutron star, and a complete study would require a self-consistent solution of thermal and rotational evolution. Regardless, we can estimate the surface temperature at which photon cooling is balanced by Josephson radiation heating. Equating $P_{\star,p}$ given by Eq. [\(20\)](#page-4-3) to the standard blackbody luminosity from the star's surface $L_{\gamma} = 4\pi\sigma R^2 T_s^4$ where R is the star radius, T_s is the surface temperature and σ is the Stefan-Boltzmann constant, we find that equilibrium is achieved for $T_s = 3.5 \times 10^5$ K, which is typical for neutron stars around a few times 10^6 yr old.

V. CONCLUSIONS AND OUTLOOK

In this work, we argued that the interface between Swave and P-wave superfluids can function like a Josephson junction, where a supercurrent arises from the phase differences of the two superfluids. Beyond this stationary effect, the movement of neutron vortices and proton flux tubes generates a time-dependent Josephson-like current, oscillating at a frequency determined by the vortex velocity and inter-vortex spacing. We further demonstrate that this oscillating current produces radiation at the interface, which is phenomenologically significant for proton flux tubes and can impact the late-time cooling of neutron stars. The heating rate is independent of temperature but depends on the spin frequency and its derivatives, as well as the strength of the magnetic field. To evaluate the phenomenological effects of radiation from oscillating currents, it is essential to simulate the cooling process of neutron stars, incorporating the discussed heating mechanism.

Here we assumed a sharp interface between the S-wave and P-wave superfluids. However, suppose the transition between these phases occurs through a mixed phase. In that case, the radiation effect will be amplified due to the "stacking" of multiple Josephson-like junctions along the path of a flux tube or vortex. To evaluate the phenomenological effects of radiation from oscillating currents, it is essential to simulate the cooling process of neutron stars, incorporating the discussed heating mechanism. Such thermal cooling simulations must also integrate the neutron star's secular deceleration dynamics under braking torques, such as magnetic dipole radiation while accounting for the long-term evolution of the magnetic field.

Finally, the entrainment-induced non-stationary Josephson currents and radiation proposed here may have analogs in other systems, for example, in ultra-cold atomic systems, where Josephson junctions have been recently manufactured [\[9\]](#page-5-5). Entrainment would require mixtures of atoms, whereas the electric current and radiation would require a charged component or artificial gauge fields [\[25\]](#page-5-15). Such a setup is expected to work with any combination of Fermi or Bose condensates, whether interfacing with each other or forming mixtures.
