Abstract-Lead optimization is a pivotal task in the drug design phase within the drug discovery lifecycle. The primary objective is to refine the lead compound to meet specific molecular properties for progression to the subsequent phase of development. In this work, we present an innovative approach, Latent Evolutionary Optimization for Molecule Generation (LEOMol), a generative modeling framework for the efficient generation of optimized molecules. LEOMol leverages Evolutionary Algorithms, such as Genetic Algorithm and Differential Evolution, to search the latent space of a Variational AutoEncoder (VAE). This search facilitates the identification of the target molecule distribution within the latent space. Our approach consistently demonstrates superior performance compared to previous state-of-the-art models across a range of constrained molecule generation tasks, outperforming existing models in all four sub-tasks related to property targeting. Additionally, we suggest the importance of including toxicity in the evaluation of generative models. Furthermore, an ablation study underscores the improvements that our approach provides over gradient-based latent space optimization methods. This underscores the effectiveness and superiority of LEOMol in addressing the inherent challenges in constrained molecule generation while emphasizing its potential to propel advancements in drug discovery.

Index Terms—Targeted Molecular Generation, Evolutionary Algorithm, Variational AutoEncoder

I. INTRODUCTION

In the initial stages of drug discovery, the primary objective is the synthesis and design of novel molecules with specific, desired properties. Currently, this task is both expensive and time-consuming, primarily due to the extensive size of the chemical space, estimated to range between 10^{23} and 10^{60} [17] for drug-like molecules. One prevailing approach involves the high-throughput screening of large molecular libraries to identify hit molecules which exhibit desired properties. However, the computational intensity of screening large molecule libraries is a significant challenge. An alternative to screening existing compounds is the de novo design of entirely novel molecules [3]. Early deep generative models [8], [14], [20], [25]–[27] have emerged as powerful tools for systematically exploring the vast chemical landscape. A conventional strategy involves constructing a generative model capable of translating a vector within a latent space into a molecule. Subsequently, exploration or optimization within this latent space helps uncover innovative molecules with desired characteristics. In this context, notations such as SMILES [23], Molecular Fingerprints [15], Graphs [19], and SELFIES [10] have emerged to encode molecular structures into a machine-readable format. Models such as those proposed by Jin et al. [8] and Eckmann et al. [5] utilize graphs and SELFIES respectively for representing molecules. These models follow the aforementioned approach by encoding molecular representations into the latent space and conducting gradient descent optimization [2] searches within that space to generate desired molecules. Another conventional strategy is to utilize Reinforcement Learning for the generation of molecules with specific property constraints [20], [25], [27]. However, these models have not met the expected performance levels in generating molecules with desired properties.

In this study, we present a pioneering methodology termed Latent Evolutionary Optimization for Molecule Generation (LEOMol). This innovative design is geared towards targeted molecule generation, wherein optimization over the latent space is directed by Evolutionary Algorithms [22]. Evolutionary Algorithms are optimization techniques inspired by biological evolution, functioning through the maintenance of a population of candidate solutions. These solutions undergo iterative processes involving selection, recombination (crossover), and mutation operators, aiming to evolve towards improved solutions. The LEOMol design intricately integrates the Variational AutoEncoder (VAE) [9] framework with an optimization search process, leveraging Genetic Algorithm [12] and Differential Evolution [21]. The key characteristics of this work encompass:

- Its application of Genetic Algorithm (GA) and Differential Evolution (DE) search optimization in the latent space to produce drug-like molecules with desirable properties.
- Its capability to generate a substantial proportion of molecules tailored to specific properties while concur-

rently ensuring diversity and faster inference.

- Its proficiency in generating molecules possessing desired properties while preserving similarity to the input molecule — a pivotal aspect in Lead Optimization.
- Introduce the significance of assessing the models with due consideration to the toxicity of the generated molecules.
- Its ability to leverage non-differentiable oracles such as RDKit within the search process in the latent space optimization for targeted molecule generation.

The LEOMol model underwent evaluation across four distinct constrained molecule generation tasks pertinent to the Hit generation and Lead Optimization stages of Drug Discovery. In all tasks, LEOMol consistently demonstrated results that were either superior to or comparable with those achieved by state-of-the-art models.

II. RELATED WORKS

Deep generative models leverage a learned latent space to represent the distribution of drug-like molecules. Early works such as Variational AutoEncoders (VAEs) [6], encode SMILES strings to a continuous latent space. Addressing the limitations of SMILES-based representations, more recent models [4], [11] incorporate rules into the decoding process, and [5] replace SMILES with SELFIES to ensure the generation of valid molecules. Junction tree VAEs [8] use scaffold junction trees, offering a framework for the assembly of building blocks into valid molecular graphs. Although these approaches generate valid molecules, they encounter challenges in generating novel molecules with targeted property scores which are out of the training data distribution, due to the inability to incorporate non-differentiable oracles by design.

Graph generative models, an alternative to sequence generation, have also been proposed. These models often use surrogate models to predict molecular properties and guide optimization in the latent space. GCPN [25], GraphDF [14], MARS [24] and MolDQN [27] employ Reinforcement Learning for the systematic creation or modification of molecular graphs. Typically, these methods construct molecules in a stepby-step manner, either atom by atom or fragment by fragment. Although effective in producing molecules with specific properties, these methods are computationally demanding, require numerous calls to property estimation functions, and also require task-specific finetuning.

Prior evolutionary algorithms function by generating the initial population of molecular representations, such as graph or text representations, emphasizing the execution of crossover and mutation operations directly on the input molecular representation itself. GB-GA [7] designs molecules by performing crossover and mutation operations on the graph representations of the molecules. STONED [16] works with the SELFIES representation for constrained molecule design. Despite its ability to generate molecules rapidly, this method still fails to meet the desired property constraints.

In contrast, our approach takes a more holistic approach to molecule generation. Instead of building molecules atom by atom or fragment by fragment, we generate the entire molecule at once by decoding from the latent space. Furthermore, instead of relying on gradient-based methods, we harness the power of Evolutionary Algorithms (EAs) to optimize the latent vectors. This population-based approach leverages diverse candidate molecules and intelligently explores the landscape, leading to a wider range of potential solutions compared to gradient-based methods. Additionally, our Evolutionary Algorithms operate directly on the latent vectors, allowing for fine-grained control over the molecule's properties without directly manipulating its structure, avoiding the need for taskspecific finetuning.

III. METHODOLOGY

We introduce Latent Evolutionary Optimization for Molecule Generation (LEOMol), a novel methodology for constrained molecule design. This approach combines a Variational AutoEncoder (VAE) [9] to learn the real-valued latent representation of drug-like molecules and employs Evolutionary Algorithms, primarily the Genetic Algorithm (GA) and Differential Evolution (DE), to search and create molecules within defined constraints. Figure 1 illustrates the comprehensive workflow of our proposed method, LEOMol.

We choose SELFIES [10] as the molecular representation over SMILES due to its inherent robustness.

Each point in the latent space of a VAE corresponds to a SELFIES representation which is always a valid molecule. In contrast, there are only fragmented, disconnected regions corresponding to the valid representations in SMILES. In the initial step, we pre-train a VAE using the ZINC250k dataset to comprehend both the syntax and semantics of the SELFIES molecular language. Then, we integrate the Genetic Algorithm search optimization with the trained VAE to generate desired molecules. Additionally, we substitute the Genetic Algorithm with the Differential Evolution algorithm as an alternative search optimization strategy. We employ the opensource cheminformatics tool RDKit [13] to compute molecule properties.

A. Variational AutoEncoder

A Variational AutoEncoder (VAE) functions as a generative model, acquiring a probabilistic representation of the training data. It employs an encoder neural network to map input data to a low-dimensional latent space and a decoder neural network to reconstruct the original data based on this latent space representation. The initial step involves encoding a molecule m into its SELFIES representation $\{x_1, x_2, \ldots, x_n\}$, where n denotes the molecular length, and x_i is selected from the predefined SELFIES vocabulary $V = \{s_1, s_2, \ldots, s_d\}$, with d representing the vocabulary size. A latent vector z representing the encoded information of m is passed to the VAE decoder to reconstruct it back, i.e., the conditional distribution p(y|z), where $y = \{x'_1, x'_2, \ldots, x'_n\}$, where x'_i is the predicted SELFIES string.

The pre-training follows the Evidence Lower Bound (ELBO) approach over molecules in the Zinc250k dataset that

Fig. 1: Overview of the proposed LEOMol method: (a) A Variational AutoEncoder (VAE) is pre-trained to acquire the ability to reconstruct and generate drug-like molecules using the SELFIES molecule representation. The pre-trained VAE is subsequently employed in conjunction with (b) Genetic Algorithm and (c) Differential Evolution search strategies to explore the latent space, aiming to optimize the desired molecule.

involves the calculation of: 1) Reconstruction Loss: The loss is determined by calculating the negative log-likelihood between the decoder outputs and the one-hot encoded representation of the input SELFIES string. 2) KL Divergence Loss: The loss is computed as a measure of the difference between the posterior distribution and a chosen prior distribution (typically Gaussian). The KL divergence loss encourages a more structured and interpretable latent space representation. Upon the completion of the training process, the VAE exhibits the capability to generate novel drug-like molecules.

$$\mathcal{L}_{ELBO} = -\mathbb{E}_{q_{\phi}(z|x)}[\log p_{\theta}(x|z)] + \mathrm{KL}(q_{\phi}(z|x)||p(z)) \quad (1)$$

where the first part is the loss for reconstruction, the second part is the KL loss, ϕ represents the parameters of the encoder, θ represents the parameters of the decoder, x is the input data, z is the latent variable, p(z) is the prior distribution, $q_{\phi}(z|x)$ is the posterior distribution, $p_{\theta}(x|z)$ is the likelihood (decoder output), and the expectation is taken over the posterior distribution, usually Gaussian over the latent space.

B. Evolutionary Algorithm Optimization

Evolutionary Algorithms are optimization techniques inspired by natural selection and genetics. These algorithms emulate the process of natural selection, selecting individuals with the highest fitness for reproduction, thereby generating offspring in successive generations. Algorithm 1 Genetic Algorithm for Molecule Optimization

- **Require:** VAE encoder f_{enc} , VAE decoder f_{dec} , Fitness function $F(\cdot)$, no.of generations n_{gen} , crossover probability p_c , mutation probability p_m population size n_m 1: Initialize the population Z
- 2: for i = 1 to n_{aen} do
- 3: Parents \leftarrow Choose fittest individuals from Z
- 4: $Z' = \text{Crossover}(Parents, p_c)$
- 5: $Z'' = \text{Mutation}(Z', p_m)$
- 6: $Z = Z'' \leftarrow$ Update the population
- 7: end for
- 8: $M \leftarrow$ Choose the best individual from Z

1) Genetic Algorithm Approach: The pseudo-code specified in Algorithm 1 describes the operation of the Genetic Algorithm (GA) for optimizing a particular latent vector in the pre-trained Variational Autoendocer (VAE) which when decoded will generate a molecule that satisfies the desired properties. The algorithm selects an initial population from either, (i) randomly sampled latent vectors denoted as Z = $\{z_1, z_2, ..., z_n\}$, following a Normal distribution N(0, 1) or (ii) encoded latent vector $f_{enc}(m)$ if an input molecule mis provided. The determination of the fittest latent vectors is achieved through their evaluation using the fitness score function $F(\cdot)$. Subsequently, the algorithm employs crossover and mutation operations in order over these fittest individuals,

Algorithm 2 Differential Evolution for Molecule Optimization

Require: VAE encoder f_{enc} , VAE decoder f_{dec} , Fitness function $F(\cdot)$, no.of generations n_{gen} , crossover probability p_c , mutation probability p_m , population size n_m

1:	Initialize	the	population	Z
----	------------	-----	------------	---

2: for i = 1 to n_{qen} do $Z' = \phi$ 3: 4: for z in Z do a,b,c = random(Z,3)5: z' = Mutation(z, a, b)6: z'' = Crossover(z', c)7: Insert(Z', z'')8: 9: end for 10: $Z'' = \text{Select}(Z, Z') \leftarrow \text{Update the population}$ if best value(Z'') satisfies constraint then 11: break 12: end if 13: 14: end for

15: $M \leftarrow$ Choose the best individual from Z

to generate a new population.

Crossover Consider two parents, P_1 and P_2 , selected randomly from an elite list. The crossover operation, denoted as C, can be expressed as:

$$C_{i} = \begin{cases} P_{1i} & \text{if } r > CR \\ P_{1i} & \text{if } r \le CR \text{ and } i \le CP \\ P_{2i} & \text{if } r \le CR \text{ and } i > CP \end{cases}$$
(2)

for i = 1, 2, ..., L, where: C_i represents the *i*-th gene of the offspring C, P_{1i} and P_{2i} are the *i*-th genes of parents P_1 and P_2 , respectively, CR is the predefined crossover rate, CP is a randomly selected crossover point within the gene length L, r is a random number uniformly distributed in the interval [0, 1].

This process is repeated until a new set of child individuals, matching the length of the original population, is generated.

Mutation In the creation of the new population, a random gene is chosen within the genetic sequence length for each individual. Following this selection, a random value is drawn from a normal distribution with a standard deviation of 0.1 and added to the chosen gene, causing a minor modification in its value. This process is then replicated for each additional child individual in accordance with the specified mutation rate.

$$C^{(MP)} = \begin{cases} C^{(MP)} + \mathcal{N}(0, \sigma^2) & \text{if } r < MR \\ C^{(MP)} & \text{otherwise} \end{cases}$$
(3)

Where MR is the predefined mutation rate and MP is the randomly selected mutation point within the gene length L and r is a random number uniformly distributed between 0 and 1.

2) *Differential Evolution Approach*: The pseudo code specified in Algorithm 2 describes the operation of Differential Evolution (DE) algorithm. The DE algorithm, comparable

to Genetic Algorithms (GA), operates within the domain of Evolutionary algorithms, entailing the iterative evolution of a solution population. However, DE distinguishes itself by its approach to updating the initial population, employing a sequential application of mutation and crossover strategies. The algorithm applies mutation and crossover operations to the initial population, subsequently replacing its individuals with the fittest candidates resulting from these operations.

Mutation The iterative execution of mutation involves processing each individual within the population. For every individual, a selection is made of three random individuals (excluding the current one). Subsequently, the mutation operation is implemented by incorporating a weighted difference between two of the three randomly chosen individuals prior to the current individual, scaled by the mutation rate.

$$C' = C + MR \cdot (P_a - P_b) \tag{4}$$

Where C is the unique individual chosen from the population and and the P_a , P_b are the two of the three randomly selected individuals.

Crossover Following the generation of the mutated individual, a selection of indices spanning the gene length is made based on the crossover rate. The values at these selected indices are then interchanged with those of a third randomly chosen individual, culminating in the creation of the ultimately modified individual. This sequence of mutation and crossover operations is systematically applied to each individual within the existing population, collectively shaping the composition of the updated population. This iterative process persists for a total of n_{gen} iterations.

$$C'^{(k)} = \begin{cases} P_c^{(k)} & \text{if } r < CR\\ C'^{(k)} & \text{otherwise} \end{cases}$$
(5)

Where P_c is the third randomly selected individual and r is a random number uniformly distributed between 0 and 1.

The iterative process involving mutation and crossover operations on latent vectors will persist until a superior latent vector aligning with the specified molecular properties is attained. The optimization procedure concludes upon the achievement of such a latent vector.

IV. EXPERIMENTS

To demonstrate the efficacy of our LEOMol approach in the realm of molecular generation, we evaluated our model against the state-of-the-art generative models across various molecular generation objectives:

a) **Property Optimization** The primary aim here is to generate molecules while maximising property scores. This holds particular significance in the field of drug development, where the objective is to identify molecules characterized by highly optimized properties of interest.

b) Property Targeting The objective here is to generate molecules satisfying property scores within a predefined interval. This is essential in the creation of virtual libraries of molecules designed to align with specific molecular properties.

TABLE I: The table illustrates the top three molecules characterized by the highest Quantitative Estimate of Druglikeness (QED) and Penalized LogP scores produced by each model. The term LL denotes the application of a length limit constraint on the number of atoms within the molecules during the generation process. The baseline results are derived from [5].

c) Constrained Property Optimization The objective here is to generate novel molecules that simultaneously adhere to a predefined similarity threshold with the input molecules, while also enhancing the desired properties. This becomes particularly crucial during lead optimization, where the objective is to refine the molecular properties of lead molecules while preserving their structural similarity.

Dataset The Variational AutoEncoder (VAE) was pretrained with the ZINC250k molecule dataset. The optimization tasks discussed in this section utilized the same dataset.

Configuration

In line with the experimental setup of the LIMO [5] model, the Variational AutoEncoder (VAE) was pre-trained for 18 epochs using the Adam Optimizer with a learning rate of 0.001. The experiments consistently utilized the same pretrained VAE and maintained a latent space dimension of 1024. After performing hyperparameter optimization, we determined a crossover rate of 0.8, a mutation rate of 0.4, a total of 20 generations and a population size of 20 for optimizing penalized logP. Subsequently, these hyperparameters were applied uniformly across all additional property optimization tasks. We customized uniquely tailored fitness scoring functions for each experiment, aligning precisely with the specific task requirements outlined in the provided problem statement. For predicting molecule properties, we utilized RDKit as our property predictor. All experiments were conducted on a single T4 GPU and 8 CPU cores with 52 GB of memory.

Baselines A comparative analysis was conducted between the implemented methodology and several state-of-the-art molecular generation algorithms, namely JT-VAE [8] and LIMO [5]. These algorithms utilize Variational AutoEncoders (VAEs) for the generation of molecular graphs and SELFIES representations, respectively. Furthermore, a comparison was undertaken with GCPN [25], GraphDF [14], and MolDQN [27]. These approaches employ reinforcement learning strategies, with the reward computed using RDKit, for the generation of target molecules.

A. Property Optimization

Setup To demonstrate the effectiveness of LEOMol in optimizing properties, the focus was directed towards the maximization of two molecular attributes: Penalized LogP (P-LogP) [8] and Quantitative Estimate of Drug-likeness (QED) [1]. LogP represents the logarithm of the partition coefficient of a solute between octanol and water. P-LogP is derived by subtracting the Synthetic Accessibility (SA) score and the count of long cycles from the LogP score. The QED score serves as an indicator of drug-likeness. The P-LogP metric exhibits an unbounded range, whereas the QED score ranges between 0 and 1, with the maximum known QED score being 0.948. The determination of the fitness score for each molecule was based on its property score.

TABLE III: Performance in similarity-constrained penalized logP maximization, for each method and minimum similarity threshold (δ), the average improvement and standard deviation are provided for molecules meeting the similarity threshold. Additionally, the percentage of refined molecules adhering to the similarity constraint (%SUCC.) is included. The baseline results are sourced from [5].

δ	JT-VAE		GCPN		MOLDQN		LIMO		LEOMolGA		LEOMol _{DE}

w. Constraint	100	0.883	0.8204 ± 0.0352	100	0.885	0.7782 ± 0.0557	

fitness score =
$$P_s(m)$$
 (6)

where m is the generated molecule and $P_s(\cdot)$ is the property predictor.

Results Table I presents the outcomes related to the top three unique and high-property molecules identified by each model. Notably, the P-LogP metric shows a significant dependence on the molecule's length. Unlike models such as GCPN, MOLDQN, and LIMO, which adhere to length constraints, the LEOMol approach demonstrates notable advancements, particularly in the task of P-LogP maximization. It is important to highlight that the MARS model, characterized by the absence of length restrictions, exhibits the capability to generate extended carbon chains, thereby yielding heightened P-LogP scores.

B. Property Targeting

Setup In the task, two molecular properties, specifically LogP and Molecular Weight, were identified. Distinct property ranges were subsequently assigned for each property. The prescribed target ranges are articulated as follows: $-2.5 \leq$ LogP < -2, 5 < LogP < 5.5, 150 < MW < 200, and500 < MW < 550. Evaluation of the task is based on two primary metrics: Success (%) and Diversity. Success (%) is determined by calculating the percentage of generated molecules that adhere to the specified property target constraints out of the total number of generated molecules. Diversity, conversely, is computed as one minus the average pairwise Tanimoto similarity between the Morgan fingerprints [18] of the generated molecules. To perform this assessment, a set of 100 molecules was generated, and subsequently, both Success (%) and Diversity values were computed based on the defined property constraints. This thorough analysis yields insights into the effectiveness and diversity of the generated molecules concerning the specified LogP and Molecular Weight ranges. Within the fitness function, an additional variable denoted as t was incorporated into the scoring function, representing the midpoint of the property range.

fitness score =
$$P_s(m) - t$$
 (7)

Results The results of the LEOMol model, in comparison with state-of-the-art models pertaining to this specific task, are delineated in Table II. The outcomes indicate that the proposed approach surpasses other models significantly across all four sub-tasks, manifesting commendable success rates and comparable diversity scores. Particularly noteworthy is the performance in sub-tasks characterized by $5 \le \log P \le 5.5$ and $150 \le MW \le 200$, where our method exhibited a notable 82.8% and 31.4% relative improvement in Success (%) compared to the second-best performing model (GCPN). Furthermore, our approach showcased substantial advancements over other state-of-the-art Variational AutoEncoder (VAE) models, namely JT-VAE and LIMO.

C. Constrained Property Optimization

Setup In this experimental setting, a total of 800 molecules were systematically chosen based on their lowest P-LogP scores from the ZINC250k dataset, following the assessment methodology elucidated in [8]. The primary aim at this stage is to generate innovative molecules characterized by heightened P-LogP scores, all while maintaining a significant degree of resemblance to the aforementioned set of 800 molecules. The quantification of similarity is accomplished through the application of the Tanimoto similarity metric, which involves a comparative analysis of the Morgan fingerprints associated with each molecule. To effectively address this dual objective, adjustments were made to the computation of a similarity constraint, denoted as $sim(G, G_0)$, into the fitness function.

fitness score =
$$\begin{cases} P_s(M), & \text{if } \sin(G, G_0) \ge \delta \\ P_s(M) - \lambda * (\delta - \sin) & \text{if } \sin(G, G_0) < \delta \\ (8) \end{cases}$$

Results The results are systematically presented in Table III. Despite not achieving a 100 percent success rate within the (0.2 and 0.4) similarity constraints, our approaches consistently demonstrated substantial improvements in P-LogP across all similarity thresholds. This highlights the reliable performance of LEOMol, even in environments characterized by multiple constraints.

V. ANALYSIS

A. Toxicity Optimization

In this context, a novel optimization task is introduced, emphasizing the improvement of molecular properties while concurrently ensuring their non-toxic nature. The inclusion of toxicity considerations in the optimization process is essential since molecules, even when compliant with all property constraints, are deemed unsuitable for advancement to subsequent stages of drug discovery if they demonstrate toxicity. So, we endeavor to optimize molecules while ensuring the containment of their toxicity through the utilization of LEOMol. The significance of incorporating a toxicity constraint in property optimization was examined through an experiment. This experiment involved the generation of molecules with elevated QED scores both with and without the imposition of a toxicity constraint. The assessment of these tasks relies primarily on three metrics: the proportion of non-toxic molecules, the diversity observed among the generated molecules, and the standard deviation and mean values of QED scores for the generated molecules. A collection of 100 molecules was generated for each sub-task, and the fitness score varied correspondingly based on the specific objective in question. To predict the toxicity of the generated molecules, we employed a neural network trained on the MoleculeNet dataset, which forms an integral component of the fitness score function. Due to the novelty of this task, there are presently no established baselines for conducting comparative analyses.

fitness score =
$$\begin{cases} P_s(M), & \text{for QED} \\ P_s(M) - g_{\theta}(M), & \text{for TO + QED} \end{cases}$$
(9)

where $g_{\theta}(\cdot)$ is the network model for predicting toxicity of the generated molecule. where $g_{\theta}(M) = 1$ indicates M is a Toxic molecule and $g_{\theta}(M) = 0$ indicates M is a Non-Toxic Molecule.

Based on the outcomes presented in Table IV, it is evident that, in the absence of the toxicity constraint, the molecules were appropriately optimized to exhibit higher QED scores. However, only 18% of these optimized molecules demonstrated non-toxic properties, while the remaining 82% were found to be toxic and unsuitable. Upon the imposition of the toxicity constraint into the fitness function, comparable QED scores were maintained, resulting in the generation of entirely non-toxic molecules with commendable diversity. Consequently, these results indicate the importance of validating models and approaches based on their ability to generate non-toxic molecules.

Fig. 2: Density plots illustrating property scores of molecules produced through Genetic Algorithm, Gradient Descent Algorithm searches and Random sampling technique within the VAE latent space for tasks involving QED score Maximization and SA score Minimization.

VI. ABLATION STUDY

To empirically evaluate the effectiveness of LEOMol, a comparative analysis was conducted involving three distinct approaches: a) employing Genetic Algorithm (GA) search within the Variational AutoEncoder (VAE) latent space, b) utilizing Gradient Descent Algorithm (GD) search, and c) employing random sampling within the VAE latent space. Notably, in the GD search approach, the utilization of RDKit is precluded due to its non-differentiable nature. Consequently, a network was trained to predict molecular properties by utilizing the VAE decoder output as input. The experimental analysis focused on two critical tasks in the drug discovery timeline: maximizing Quantitative Estimation of Drug-likeness (QED) and minimizing Synthetic Accessibility (SA). It is essential to underscore that the same VAE, pretrained on the ZINC250K dataset, was employed for both tasks, ensuring consistency in the experimental setup.

The results are illustrated in Figure 2. For both tasks, a total of 200 molecules were generated using three distinct approaches. Density plots were then constructed based on the property scores of the molecules. The outcomes demonstrate

the superior efficiency of the Genetic Algorithm (GA) search in producing the desired molecules compared to the Gradient Descent Algorithm (GD) search and random sampling technique.

VII. DISCUSSION AND CONCLUSION

We introduced LEOMol, a lightweight generative modeling framework designed for efficient de novo drug design. The Evolutionary Algorithm in LEOMol exhibits remarkable flexibility, enabling the seamless integration of non-differentiable property predictors. This capability, which is constrained in previous gradient-based latent search optimization methods, allows for a more comprehensive approach for molecular optimization. Our in-depth experimental analysis demonstrates the consistent superiority of our approach over prior state-of-theart models in both property optimization and property targeting tasks. Notably, the findings highlight the higher effectiveness of our Genetic Algorithm (GA) search in generating desired molecules compared to both Gradient Descent Algorithm (GD) search and random sampling techniques. We emphasized the significance of incorporating toxicity as a constraint in the evaluation of optimization methodologies. The application of LEOMol in Drug Discovery shows promise due to its ability to rapidly generate desired molecules while maintaining a 100% validity score through the use of SELFIES. This capability is expected to accelerate both hit generation and lead optimization stages, effectively and rapidly advancing the forefront of drug discovery. Incorporating advanced techniques for selecting parents from elite indices and exploring alternative Evolutionary Algorithms for latent space exploration, are a promising direction for future work.
