Information-theoretic quantities such as Renyi entropies show a remarkable universality in their late-time behaviour across a variety of chaotic quantum many-body systems. Understanding how such common features emerge from very different microscopic dynamics remains an important challenge. In this work, we address this question in a class of Brownian models with random timedependent Hamiltonians and a variety of different microscopic couplings. In any such model, the Lorentzian time-evolution of the *n*-th Renyi entropy can be mapped to evolution by a Euclidean Hamiltonian on  $2n$  copies of the system. We provide evidence that in systems with no symmetries, the low-energy excitations of the Euclidean Hamiltonian are universally given by a gapped quasiparticle-like band. The eigenstates in this band are plane waves of locally dressed domain walls between ferromagnetic ground states associated with two permutations in the symmetric group  $\mathcal{S}_n$ . These excitations give rise to the membrane picture of entanglement growth, with the membrane tension determined by their dispersion relation. We establish this structure in a variety of cases using analytical perturbative methods and numerical variational techniques, and extract the associated dispersion relations and membrane tensions for the second and third Renyi entropies. For the third Renyi entropy, we argue that phase transitions in the membrane tension as a function of velocity are needed to ensure that physical constraints on the membrane tension are satisfied. Overall, this structure provides an understanding of entanglement dynamics in terms of a universal set of gapped low-lying modes, which may also apply to systems with time-independent Hamiltonians.

### <span id="page-1-0"></span>I. INTRODUCTION

Chaotic quantum many-body systems show the universal phenomenon of thermalization. When an arbitrary initial state is evolved to sufficiently late times, it starts to macroscopically resemble a thermal density matrix  $\rho^{(eq)}$ . This process is independent of most details of the initial state and microscopic dynamics of the system. While thermalization is ubiquitously observed, much remains to be understood both about the mechanism for its robustness across a variety of different microscopic dynamics, and about the effective field-theoretic approaches which can capture its essential aspects. Such an understanding would be valuable not only for quantum manybody physics, but also for understanding the process of black hole formation in quantum gravity, which is an example of thermalization [\[1,](#page-20-2) [2\]](#page-21-0).

Thermalization can be probed by using correlation functions of few-body operators in the time-evolved state, as well as information-theoretic quantities such as the Renyi entropies of a subsystem. For an initial state  $\rho_0$  and a unitary time-evolution operator U, the timeevolved *n*-th Renyi entropy of a subsystem  $R$  is given  $\mathrm{by}$ <sup>[1](#page-1-2)</sup>

$$
S_{n,R}(t) = -\frac{1}{(n-1)} \log \text{Tr}[\rho_R(t)^n],
$$
  
\n
$$
\rho_R(t) = \text{Tr}_{\bar{R}}[U\rho_0 U^{\dagger}], \quad n \ge 2.
$$
 (1)

At late times in chaotic systems,  $S_{n,R}(t)$  saturates to a value that depends only on  $\rho^{(eq)}$ , reflecting the fact that most details of the initial state are forgotten. For example, if  $\rho_0$  is pure and one of the subsystems is much larger than the other, we expect the general behaviour

<span id="page-1-3"></span>
$$
\lim_{t \to \infty} S_{n,R}(t) = \min\left(S_{n,R}(\rho^{(\text{eq})}), S_{n,\bar{R}}(\rho^{(\text{eq})})\right). \tag{2}
$$

The late-time value [\(2\)](#page-1-3) is intuitively expected based on the behaviour of the Renyi entropies in random pure states [\[3](#page-21-1)[–7\]](#page-21-2), and was argued for more systematically in [\[8\]](#page-21-3).

For the evolution of correlation functions during thermalization, it has long been understood that there are universal behaviours not only in the saturation value, but also in the way in which it is approached at late times. For example, one expects the late-time behaviour of correlation functions of any conserved charge density to be governed by hydrodynamic modes, which depend on the conservation law but not on details of the microscopic dynamics.

A lot of evidence has been gathered for a similar universality in the growth of  $S_{n,R}(t)$  in chaotic systems before it approaches its late-time value [\(2\)](#page-1-3), starting with observations of a linear in t regime in a variety of chaotic systems  $[9-11]$  $[9-11]$ . By synthesizing various observations,  $[12]$ conjectured a "membrane formula" to describe entanglement growth in general chaotic quantum many-body systems. This formula was found to hold in two very different examples of analytically tractable chaotic quantum many-body systems: random unitary circuits [\[13–](#page-21-7) [16\]](#page-21-8), which involve a discrete chaotic evolution with random gates, and holographic conformal field theories [\[17\]](#page-21-9). While the result turns out to be the same, the formula is derived in these examples using techniques which are specific to each model.

In this work, we identify the origin of the membrane picture across various examples in a large class of chaotic quantum many-body systems, from a common set of gapped low-lying modes of an effective Hamiltonian. The models we consider have random time-dependent "Brownian" Hamiltonians, with a variety of tunable parameters that allow us to check the robustness of this physical picture. We provide a precise physical interpretation of the "membrane tension" function, the key ingredient of the membrane formula, in terms of the dispersion relation of these modes.

We show that the membrane picture for discrete-time random unitary circuits derived in  $[12, 14-16]$  $[12, 14-16]$  is a specific case where this structure applies, but in most of this work, the time-evolutions we consider are continuous. Moreover, the same set of modes that we find here can in principle be defined in systems with a fixed time-independent Hamiltonian, and even in continuum quantum field theories such as holographic CFTs. It is tempting to speculate that the same modes also govern the late-time evolution of the Renyi entropies in these contexts, and are entanglement analogs of hydrodynamic modes for correlation functions.

In the rest of the introduction, we first briefly review the membrane picture, and then summarize our methods and results.

### <span id="page-1-1"></span>A. Review of membrane picture

For simplicity, let us state the membrane formula in the case of one spatial dimension. Consider the evolution of the Renyi entropy  $S_n(x,t)$  of a pure or mixed state for the left half-line region ending at  $x$ . According to the conjecture of  $[12]$ , this quantity can be expressed as the following minimization problem in any chaotic system. Let us extend the one-dimensional system to a twodimensional slab, with an auxilliary time axis  $\tau$  going from  $\tau = 0$  to  $\tau = t$ , as shown in Fig. [1.](#page-2-1) Then consider all possible lines with different velocities  $v$  starting at  $x$ , and extending into the  $\tau$  direction. At sufficiently late times,  $S_n(x, t)$  is given by:

<span id="page-1-4"></span>
$$
S_n(x,t) = \min_v [s_{n,\text{eq}} \mathcal{E}_n(v) \ t + S_n(x - vt, t = 0)] \tag{3}
$$

Here  $s_{n,\text{eq}}$  is the *n*-th Renyi entropy density of the equilibrium state. The function  $\mathcal{E}_n(v)$  is model-dependent,

<span id="page-1-2"></span><sup>&</sup>lt;sup>1</sup> The  $n \to 1$  limit is the von Neumann entropy.

<span id="page-2-1"></span>FIG. 1. Left: Example of a candidate line appearing in the minimization of [\(3\)](#page-1-4). Right: A cartoon of the membrane tension function function. The first two constraints in  $(4)$  are equivalent to the fact the  $\mathcal{E}(v)$  is tangent to the  $y = v$  line at some  $v = v_B$ .

sally satisfy the following constraints: but is conjectured to always be an even convex function, with a minimum at  $v = 0$ . It is expected to also univer-

<span id="page-2-2"></span>
$$
\mathcal{E}'_n(v_B) = 1\,, \quad \mathcal{E}_n(v_B) = v_B\,, \quad \mathcal{E}_n(v) \ge v \text{ for all } v \tag{4}
$$

for some velocity  $v_B$ , which are necessitated by physical conditions we discuss below. A natural generalization of the formula also holds for multiple intervals and higher dimensions, for details see [\[12\]](#page-21-6).

To understand the physical consequences of this formula, it is useful to understand its prediction for an initial mixed state with volume law entropy with some coefficient s:

<span id="page-2-8"></span>
$$
S_n(x, t = 0) = s \times (x + L/2), \quad 0 \le s \le s_{n, \text{eq}}.
$$
 (5)

where we have assumed that the system has total length L, with positions labelled from  $-L/2$  to  $L/2$ . For such states, [\(3\)](#page-1-4) predicts that

<span id="page-2-6"></span>
$$
S_n(x,t) = S_n(x,t=0) + s_{n,\text{eq}} \Gamma_n(s) t \tag{6}
$$

where the entropy growth rate  $\Gamma_n(s)$  is related to  $\mathcal{E}_n(v)$ through

<span id="page-2-3"></span>
$$
\Gamma_n(s) = \min_v \left( \mathcal{E}_n(v) - \frac{vs}{s_{n,\text{eq}}} \right) . \tag{7}
$$

The constraints [\(4\)](#page-2-2) are equivalent to the physical condition that the entropy of the initial equilibrium state should not grow, i.e.,

<span id="page-2-7"></span>
$$
\Gamma_n(s_{n,\text{eq}}) = 0. \tag{8}
$$

 $v_B$  is the velocity that minimizes [\(7\)](#page-2-3) for  $s = s_{n,\text{eq}}$ , and due to the fact that  $s \leq s_{n,\text{eq}}$ , only velocities  $v \leq v_B$  are physically relevant for the evolution of the entropy.

### <span id="page-2-0"></span>B. Summary of results

In this work, we will consider a family of "Brownian" time-evolutions in lattice systems, with independent random local Hamiltonians acting at each infinitesimal time-step. Various specific examples of such models have

been introduced and studied in the literature over the years [\[18](#page-21-11)[–31\]](#page-21-12). These models are less random than Haarrandom unitary circuits, and have various tunable microscopic parameters. The key simplification of such models is that after averaging over randomness, the Lorentzian evolution  $(U \otimes U^*)^n$  on  $2n$  copies of the system, which governs the evolution of the *n*-th Renyi entropy, can be replaced with a Euclidean evolution on 2n copies with a non-negative frustration-free Hamiltonian  $P_{2n}$  $P_{2n}$  $P_{2n}$ :<sup>2</sup>

<span id="page-2-5"></span>
$$
\overline{(U \otimes U^*)^{\otimes n}} = e^{-P_{2n}t}.
$$
\n(9)

We will explain the precise setup and derive this mapping from Lorentzian to Euclidean evolution in Sec. [II.](#page-4-0) We will sometimes refer to  $P_{2n}$  as the "superhamiltonian" in the discussion below. Due to the mapping in [\(9\)](#page-2-5), the lowenergy properties of the superhamiltonian determine the late-time evolution of quantities such as the n-th Renyi entropy. This allows us to use both physical intuition and precise analytical and numerical techniques from the low-energy physics of quantum many-body systems, and apply them to understanding the physics of thermalization.

For  $n = 1$ , correlation functions of few-body operators in the thermal state or a time-evolved state can be written as transition amplitudes under the evolution operator [\(9\)](#page-2-5). Some hints that the lessons we learn from Brownian models apply more generally come from Refs. [\[30,](#page-21-13) [31\]](#page-21-12), which studied Brownian models with a variety of symmetries, and derived the associated hydrodynamic modes using the low-energy spectrum of  $P_2$ . For example, in models with global  $U(1)$  symmetry, these works used the low-energy gapless modes of  $P_2$  to derive diffusive behaviour of two-point functions of the charge density.

The Renyi entropies can be written as transition am-plitudes under [\(9\)](#page-2-5) for  $n \geq 2$ . We first show that in general Brownian models with any symmetry, we can use the zero energy eigenstates of  $P_{2n}$  to derive a late-time saturation value of  $S_{n,R}(t)$  consistent with the equilibrium approximation of  $[8]$ , and in particular with  $(2)$ . We then specialize to the case of Brownian models with no symmetries, where  $P_{2n}$  generically has an n!-dimensional ground state subspace. The ground state subspace is spanned by states associated with permutations in  $S_n$ , which have a product form between different sites  $i$  of the system:  $\,$ 

$$
\otimes_i |\sigma\rangle_i, \quad \sigma \in \mathcal{S}_n. \tag{10}
$$

The precise definition of  $|\sigma\rangle$  will be given in Sec. [II.](#page-4-0) We will provide more intuitition for why states associated with permutations should be relevant for the late-time behaviour of the Renyi entropies at the end of the introduction.

In one spatial dimension, we find evidence that the low-energy excitations of  $P_{2n}$  in models with no symmetries have the following universal structure. Let us denote

<span id="page-2-4"></span><sup>2</sup> In Haar random circuits, this average maps to a classical statistical mechanics model [\[14,](#page-21-10) [15\]](#page-21-14)

the identity permutation in  $S_n$  by e, and the cyclic permutation  $(n \ n-1 \ n-2...1)$  which sends n to  $n-1$ ,  $n-1$  to  $n-2$ , and so on, by  $\eta$ . The low-energy eigenstates are well-approximated by plane waves of locally dressed domain walls between the states associated with  $\eta$  and e. More explicitly, we find that they can be wellapproximated as

<span id="page-3-0"></span>
$$
|\psi_k\rangle \approx \sum_x e^{-ikx} |\eta\rangle \dots |\eta\rangle_x |\phi\rangle_{x+1,\dots,x+\Delta} |e\rangle_{x+\Delta+1} \dots |e\rangle
$$
\n(11)

where  $\Delta$  is  $O(1)$  in the thermodynamic limit, and  $|\phi\rangle$  is an arbitrary state in the full Hilbert space on 2n copies of  $\Delta$ sites from  $x+1$  to  $x+\Delta$ . We will show that the structure [\(11\)](#page-3-0) of the eigenstates in the thermodynamic limit leads to the membrane formula [\(3\)](#page-1-4) for a half-line region. These eigenstates have a gapped dispersion relation  $E(k)$ , which determines the entanglement growth rate  $\Gamma_n(s)$  of [\(6\)](#page-2-6) through the relation

$$
\Gamma_n(s) = E(is)/s_{n,\text{eq}}.
$$
\n(12)

This in turn determines the membrane tension  $\mathcal E$  through the inverse of [\(7\)](#page-2-3). The natural "multiparticle" versions of these single domain wall excitations give rise to the membrane picture for subsystems consisting of one or more intervals.<sup>[3](#page-3-1)</sup>

We establish the above universal structure of the lowenergy eigenstates of  $P_{2n}$  by studying the following cases:

- 1. We start with the simplest case of a maximally random Brownian Hamiltonian, where the local coupling operators are drawn from the GUE ensemble and the local Hilbert space dimension  $q$  is large. For the second Renyi entropy in this case, the superhamiltonian is analytically tractable, and allows us to explicitly see that the low-energy eigenstates have the form  $(11)$ .
- 2. Next, we consider the second Renyi entropy in the same model at finite local Hilbert space dimension q. Since the superhamiltonian is no longer analytically tractable, we use a version of the variational approach used for extracting low-energy excitations of gapped Hamiltonians in [\[35](#page-21-15)[–37\]](#page-21-16). This method allows us to both verify that the eigenstates are wellapproximated by [\(11\)](#page-3-0), and to extract their dispersion relation  $E(k)$ . In this case, the on-site Hilbert space dimension of the superhamiltonian is sufficiently small that we can also check  $E(k)$  obtained from the variational method with results from exact diagonalization, finding good agreement.
- 3. We then turn to the case of the higher Renyi entropies in the same model, in particular focusing on the third Renyi entropy. While we can no longer use exact diagonalization due to the large on-site Hilbert space dimension of the superhamiltonian, we again use the variational approach to check that the low-energy eigenstates have the structure  $(11)$ , and extract the associated  $E(k)$ .
- 4. Finally, we consider the evolution of  $S_2$  in a class of Brownian models where the coupling operators are fixed to be those of the mixed field Ising model, and only the coefficients appearing next to the operators have time-dependent randomness. For generic values of the coupling strength, the model is expected to be chaotic, except close to a special integrable point. Consistent with this expectation, we find good evidence for the structure  $(11)$  using the variational approach in the general case, and a breakdown of this structure close to the integrable point.

In cases 1, 2, and 4 above, we find that the membrane tensions for the second Renyi entropy resulting from the dispersion relations  $E(k)$  satisfy  $(4)$ , or equivalently  $\Gamma_2(s)$  satisfies [\(8\)](#page-2-7). The case of the third Renyi entropy from point 3 turns out to be more subtle. The naive growth rate  $\bar{\Gamma}_3(s)$  from the dispersion relation of modes [\(11\)](#page-3-0) appears to be non-zero at  $s = s_{3,eq}$ . However, we conjecture that the evolution of  $S_3$  also receives contributions from a second set of modes besides [\(11\)](#page-3-0) in this case. We argue that beyond some value of s, the naive growth rate  $\overline{\Gamma}_3(s)$  should be replaced with the growth rate implied by this second set of modes, which is the same as  $\Gamma_2(s)$ . In terms of the membrane tension, we find that this single first-order phase transition in Γ leads to two phase transitions in terms of  $\mathcal{E}_3(v)$  at velocities  $v_1^* < v_2^* < v_B$ . We have a first-order phase transition at  $v = v_1^*$  and a second-order transition at  $v = v_2^*$ . For  $v < v_2^*, \ \mathcal{E}_3(v)$  is smaller than  $\mathcal{E}_2(v)$ , while for  $v > v_2^*,$  $\mathcal{E}_3(v) = \mathcal{E}_2(v).$ 

While the above discussion of  $\mathcal{E}_3(v)$  uses an assumption about the existence of the second set of modes which should be more carefully checked in future work, it allows us to propose a form of  $\mathcal{E}_3(v)$  at finite q and general v. Hence, we are able to provide a characterization of the phase transitions of  $\mathcal{E}_3(v)$  in a more general regime than previous discussions in random unitary circuits [\[16\]](#page-21-8), where evidence for a phase transition was found using expansions for large  $q$  and large  $v$ . Our physical picture for the origin of the phase transition appears to be similar to the one in [\[16\]](#page-21-8).

The structure of the modes  $(11)$  can be seen as a simple and precise realization of an insight from [\[38\]](#page-21-20) about the crucial role played by permutations in the late-time evolution of the Renyi entropies. Note that the Lorentzian path integral representation of the quantity  $\text{Tr}[\rho_A(t)^n]$ , shown schematically in Fig. [2,](#page-4-1) involves an integrand of the form  $e^{i \sum_{j=1}^n S[\phi_j] - i \sum_{j=1}^n S[\phi'_j]}$ , where  $\phi_i, \phi'_i$  repre-

<span id="page-3-1"></span><sup>3</sup> Note that these effective "particles" which appear in the chaotic systems in this work have an entirely different structure from the quasiparticle picture of Calabrese and Cardy [\[32\]](#page-21-17). The latter applies to integrable systems and gives very different results for the evolution of  $S_{n,A}(t)$  for multiple intervals from the chaotic case [\[33,](#page-21-18) [34\]](#page-21-19).

<span id="page-4-1"></span>FIG. 2.  $\text{Tr}[\rho_A(t)^n]$  can be represented as a Lorentzian path integral on  $2n$  copies of the theory, with n forward and n backward evolutions. The initial conditions of the path integral are determined by  $\rho_0$ , and the final conditions are determined by the pattern of traces in  $\text{Tr}[\rho_A(t)^n]$ .

sent the dynamical fields of the theory along forward and backward contours respectively. Ref. [\[38\]](#page-21-20) noted that we get stationary contributions in this path integral from configurations where each  $\phi_j$  is equal to some  $\phi'_{\sigma(j)}$  for some  $\sigma \in \mathcal{S}_n$ , as the phase in the exponent cancels. From other configurations, in a chaotic system, we should expect rapidly oscillating contributions that cancel among themselves. Based on this observation, [\[8\]](#page-21-3) developed a systematic approximation for the saturation value of  $S_{n,A}(t)$ .

At late times before saturation, it is natural to expect that the dominant configurations should be such that each  $\phi_i$  is *locally* equal to some  $\phi'_{\sigma(j)}$  for some  $\sigma \in \mathcal{S}_n$ , but different permutations can appear in different regions. [\[38\]](#page-21-20) developed a self-consistent numerical scheme based on this idea for evaluating the membrane tension in circuit and Floquet models. The scheme involved a sum over spacetime diagrams, where the contributions from diagrams with large spacetime regions with states orthogonal to the permutation subspace were neglected. In the models considered in this work, we can better understand the suppression of such diagrams due to the high energy of the associated configurations in the Euclidean superhamiltonian. The analog of the summation over diagrams from [\[38\]](#page-21-20) is automatically performed by the low-energy dispersion relation of the superhamiltonian. The structure of low-lying modes in [\(11\)](#page-3-0) provides a natural language for generalization to continuum systems, as we discuss further in the final section.

The plan of this paper is as follows. We introduce the family of models we study and derive the mapping [\(9\)](#page-2-5) from the Lorentzian to the Euclidean time evolution in Sec. [II.](#page-4-0) We discuss the structure of the ground states and derive the equilibrium approximation for these models in Sec. [III.](#page-5-0) We then provide a detailed analysis of both the second and third Renyi entropy in the Brownian local GUE model in Sec. [IV.](#page-6-0) In Sec. [V,](#page-16-0) we discuss the robustness of the same structure in more general Brownian models, and provide numerical results in a Brownian version of the mixed field Ising model.

The results up to this point are all for one spatial di-

mension. For the more challenging case of higher dimensions, we derive the membrane formula in a large  $q$ , small  $v$  limit of the local GUE model in Sec. [VI,](#page-17-0) using a different approach from the one-dimensional case. We end with a number of open questions in Sec. [VII.](#page-19-0) Various technical details as well as a few conceptual points are discussed in the appendices.

### <span id="page-4-0"></span>II. SETUP

In this work, we will consider a class of lattice models one or more spatial dimensions with "Brownian" timedependent Hamiltonians. We label one copy of the full Hilbert space  $H$ . The Hamitonians consist of a sum of local random terms  ${H_{\alpha}(t)}$  (shown in Fig. [3\)](#page-5-1) which are uncorrelated for different  $\alpha$  and t:

$$
H(t) = \sum_{\alpha} H_{\alpha}(t), \quad \overline{H_{\alpha}(t)} = 0,
$$
 (13)

<span id="page-4-6"></span>
$$
\overline{H_{\alpha}(t)_{ij}H_{\beta}(t')_{kl}} \propto \delta_{\alpha\beta}\delta(t-t')
$$
 (14)

We can analyze the dynamics under this setup by formally discretizing the time-evolution in small steps of size  $\epsilon$ , and regularizing the delta function between different times by replacing it with  $\frac{1}{\epsilon} \delta_{tt'}$ , so that

<span id="page-4-3"></span>
$$
U(t) = \prod_{j=1}^{t/\epsilon} e^{-i\epsilon H(t_j)}, \quad t_j = j\epsilon.
$$
 (15)

One simple choice, which we will discuss in Sec. [IV,](#page-6-0) will be to take the matrices  $\{H_{\alpha}(t)\}\)$  themselves to be random. A less random class of models is one where we fix some set of local Hermitian operators  ${B_\alpha}$ , and take the coefficients appearing next to them to be random:

<span id="page-4-5"></span>
$$
H(t) = \sum_{\alpha} J_{\alpha}(t) B_{\alpha}, \qquad (16)
$$

where  $\{J_{\alpha}(t)\}\$ are random i.i.d. real numbers drawn from a Gaussian distribution, such that

<span id="page-4-4"></span>
$$
\overline{J_{\alpha}(t)} = 0, \quad \overline{J_{\alpha}(t)J_{\beta}(t')} = \frac{2 g_{\alpha} \,\delta_{\alpha\beta} \,\delta_{tt'}}{\epsilon} \tag{17}
$$

for some arbitrary positive numbers  $g_{\alpha}$ . We can make a variety of choices of  ${B_\alpha}$ , where cases with different symmetries will correspond to different dynamical universality classes  $[30]$ . For example, in a spin-1/2 system in  $d$  spatial dimensions with sites labelled by  $i, j$ , we could consider a case where  $\{B_{\alpha}\} = \{X_i, Z_i, Z_iZ_j\}$  for nearest neighbours  $i, j$ . In this case, the time-evolution does not have any symmetry. Another choice is to take  ${B_{\alpha}} = {Z_j, Z_i Z_j, X_i X_j + Y_i Y_j}.$  These operators commute with the total charge  $\sum_i Z_i$ , so that the timeevolution has a  $U(1)$  symmetry.<sup>[4](#page-4-2)</sup>

<span id="page-4-2"></span><sup>4</sup> We can see the symmetries in each case by computing the commutant of the operators  ${B_\alpha}$  (i.e., the algebra of operators that commute with these terms) [\[30,](#page-21-13) [39\]](#page-21-21).

<span id="page-5-1"></span>

FIG. 3. We consider a family of random time-dependent dim to the structure. Hamiltonians, where individual terms have a spatially local

The dynamical quantities of interest in this work are the *n*-th Renyi entropies  $S_{n,R}(t)$  of a subsystem R. These can be expressed as transition amplitudes on 2n copies of the system  $\mathcal{H}^{\otimes 2n}$ ,

$$
e^{-(n-1)S_{n,R}(t)} = \text{Tr}[\rho_R(t)^n]
$$
  
=  $\langle \eta_R \otimes e_{\bar{R}} | (U(t) \otimes U(t)^*)^{\otimes n} | \rho_0, e \rangle$  (18)

where ∗ denotes complex conjugation, and we have introduced a set of states in  $\mathcal{H}^{\otimes 2n}$ , associated with an operator O acting on H, and permutations  $\sigma \in \mathcal{S}_n$ , which are defined as follows. Let  $|i\rangle$  be basis states for one copy of the system. We define

<span id="page-5-6"></span>
$$
\langle i_1 i'_1 \dots i_n i'_n | O, \sigma \rangle = O_{i_1 i'_{\sigma(1)}} \dots O_{i_n i'_{\sigma(n)}}.
$$
 (19)

In cases where  $O$  is the identity operator, it will be convenient to label the corresponding states simply by the permutation, that is,

<span id="page-5-8"></span>
$$
\langle i_1 i'_1 \dots i_n i'_n | \sigma \rangle = \delta_{i_1 i'_{\sigma(1)}} \dots \delta_{i_n i'_{\sigma(n)}}.
$$
 (20)

In  $(18)$ , e refers to the identity permutation, and  $\eta$  refers to the single-cycle permutation  $(n \ n-1 \ ... 1)$ . Further, we can also consider such states  $|\sigma_R\rangle$  with a fixed permutation on the Hilbert space of some subsystem  $R$ ; in lattice systems with sites labelled by  $i$ , we have  $|\sigma_R\rangle = \otimes_{i \in R} |\sigma\rangle_i$ . The final state in the bra in [\(18\)](#page-5-2) therefore has a domain wall at the boundary  $\Sigma$  between the regions, see Fig. [4.](#page-5-3) From [\(18\)](#page-5-2), the evolution of the Renyi entropy of any initial state can be understood in terms of the backward time-evolution of this domain wall final state under  $(U \otimes U^*)^{\otimes n}$ . We will make use of this perspective, introduced for instance in [\[14,](#page-21-10) [15\]](#page-21-14), in the rest of this work.

Let us label the  $2n$  copies of the system in  $(18)$  by  $f_i, b_i$  for  $i = 1, ..., n$ , corresponding respectively to the n forward evolutions by  $H(t)$  and n backward evolutions by  $H(t)^T$ . On expanding [\(15\)](#page-4-3) for a step of size  $\epsilon$  and using the averages in [\(17\)](#page-4-4), we find

$$
\overline{(U(\epsilon) \otimes U(\epsilon)^*)^{\otimes n}} \approx 1 - \epsilon P_{2n} + O(\epsilon^2)
$$
 (21)

$$
P_{2n} = \sum_{\alpha} J_{\alpha} P_{2n,\alpha}, \quad P_{2n,\alpha} = \left[\sum_{j=1}^{n} (B_{\alpha, f_j} - B_{\alpha, b_j}^T)\right]^2.
$$

<span id="page-5-3"></span>two spatial dimensions. Right: We show the pattern of en-FIG. 4. Left: Example of a domain wall final state relevant for the evolution of the *n*-th Renyi entropy for region  $R$  in tanglement between different copies in the states  $|e\rangle$  and  $|\eta\rangle$ for  $n = 3$ .

<span id="page-5-2"></span>By re-exponentiating  $(21)$ <sup>[5](#page-5-5)</sup>, we find

$$
\overline{(U(t)\otimes U(t)^*)^{\otimes n}} = e^{-P_{2n}t}.
$$
\n(22)

In particular, the average over the random  $J_{\alpha}(t)$  allows us to replace the original Lorentzian time-evolution on 2n copies of the system with a Euclidean evolution, with a non-negative "superhamiltonian"  $P_{2n}$ . We will first briefly discuss the structure of the zero energy ground states of  $P_{2n}$  in Sec. [III,](#page-5-0) and then discuss the structure of its low energy eigenstates in models without conserved quantities in the later sections.

### <span id="page-5-0"></span>III. LATE-TIME SATURATION VALUE

The superhamiltonian [\(21\)](#page-5-4) consists of a sum of positive semidefinite operators, so that its eigenvalues are all non-negative. Any zero energy eigenstate must be "frustration-free," meaning that it is annihilated by each term:

$$
P_{2n} |\psi\rangle = 0 \quad \Leftrightarrow \quad P_{2n,\alpha} |\psi\rangle = 0 \quad \text{for each} \quad \alpha. \quad (23)
$$

One explicit set of zero energy eigenstates of  $P_{2n}$  can be constructed as follows. Let  $\mathcal C$  be the set of all operators which commute with all elements of  ${B_\alpha}$ , which is also known as its commutant algebra [\[39\]](#page-21-21), and characterizes the symmetries of the time-evolution. Let  $\{Q_m\}$  be an orthonormal basis of operators for  $C$ , i.e., they satisfy  $\text{Tr}\left[Q_m^{\dagger}Q_{m'}\right] = \delta_{mm'}$ . Now for any choice of a sequence  $(m_1, ..., m_n)$  and a permutation  $\sigma \in \mathcal{S}_n$ , let us define a state  $|m_1, m_2, ..., m_n; \sigma\rangle$  in  $\mathcal{H}^{\otimes 2n}$ :

<span id="page-5-7"></span>
$$
\langle i_1 i'_1 \dots i_n i'_n | m_1, m_2, \dots, m_n; \sigma \rangle
$$
  
=  $(Q_{m_1})_{i_1 i'_{\sigma(1)}} (Q_{m_2})_{i_2 i'_{\sigma(2)}} \dots (Q_{m_n})_{i_n i'_{\sigma(n)}}$  (24)

<span id="page-5-5"></span><span id="page-5-4"></span><sup>5</sup> In the rest of this work, we will not explicitly indicate overlines, but in all cases the expression  $e^{-(n-1)S_{n,R}(t)}$  should be interpreted as the average of  $e^{-(n-1)S_{n,R}(t)}$  over the randomness in the time-evolution.

Here each  $i_p, i'_p$  labels basis states in  $\mathcal H$  like in [\(19\)](#page-5-6), and runs from 1 to D, the total Hilbert space dimension, and each  $m_k$  goes from 1 to  $d_{\mathcal{C}}$ , the dimension of  $\mathcal{C}$ , and labels an element of  $C$ . Since each  $Q_m$  commutes with all  ${B_\alpha}$ , the above states are zero energy eigenstates of  $P_{2n}$ . Assuming that these states span the ground state subspace of  $P_{2n}$ , <sup>[6](#page-6-1)</sup> we have the following late-time limit of the Euclidean time-evolution operator:

$$
\lim_{t \to \infty} e^{-P_{2n}t}
$$
\n
$$
\approx \sum_{\substack{m_1, \dots, m_n \\ \sigma \in S_n}} |m_1, m_2, \dots, m_n; \sigma\rangle \langle m_1, m_2, \dots, m_n; \sigma|
$$
\n(25)

The above expression assumes that the states in  $(24)$  can be treated as approximately orthonormal, which is true for the purpose of the expression [\(18\)](#page-5-2) when the initial state  $\rho_0$  can access a large effective Hilbert space dimension.[7](#page-6-2)

Putting this projector into [\(18\)](#page-5-2), in the case where the initial state  $\rho_0$  is pure, we find

$$
\lim_{t \to \infty} e^{-(n-1)S_{n,R}(t)} = \sum_{\sigma \in S_n} \langle \eta_R \otimes e_{\bar{R}} | \rho^{(\text{eq})}, \sigma \rangle \qquad (26)
$$

where

<span id="page-6-4"></span>
$$
\rho^{(eq)} = \sum_{m} \text{Tr} \left[ Q_m^{\dagger} \rho_0 \right] Q_m \,. \tag{27}
$$

 $|\rho^{(eq)}, \sigma\rangle$  is defined as in [\(19\)](#page-5-6). See [A](#page-23-0)ppendix A for details of the derivation. It is natural to think of  $\rho^{(eq)}$ defined above as an equilibrium density matrix which coarse-grains over all details of  $\rho_0$  other than the information about the conserved charges. We discuss an explicit example in Appendix [A](#page-23-0) for the case where the time-evolution has a  $U(1)$  symmetry, which makes this interpretation clearer.

It was previously argued in the context of general chaotic quantum many-body systems in [\[8\]](#page-21-3) that the expression [\(26\)](#page-6-3) gives the saturation value of the n-th Renyi entropy in an equilibrated pure state which macroscopically resembles some equilibrium state  $\rho^{(eq)}$ . The Brownian models we consider in this work provide one explicit confirmation of this general argument, with a precise form of  $\rho^{(eq)}$  given by [\(27\)](#page-6-4). The general properties of the expression  $(26)$  are discussed in [\[8\]](#page-21-3). In particular, the sum over permutations ensures that the  $n$ -th Renyi entropy in  $R$  is equal to that in  $R$  at late times, as required by the unitarity of the dynamics. In the thermodynamic limit, it is explained in [\[8\]](#page-21-3) that the dominant permuta-tion in [\(26\)](#page-6-3) is always either  $\sigma = e$  or  $\sigma = \eta$ , leading to the physically expected result in [\(2\)](#page-1-3).

### <span id="page-6-0"></span>IV. BROWNIAN LOCAL GUE MODEL

Let us consider a  $d$ -dimensional lattice, with a  $q$ dimensional Hilbert space at each site. As a first simple model, we take the  ${H_\alpha(t)}$  to be random Hermitian  $q^2 \times q^2$  matrices acting on pairs of nearest neighbours i, j on the lattice, and drawn from the GUE ensemble, so that<sup>[8](#page-6-5)</sup>

$$
\overline{(H_{i,j}(t))_{\alpha\beta}} = 0, \quad \overline{(H_{i,j}(t))_{\alpha\beta}(H_{i,j}(t))_{\delta\gamma}} = \frac{1}{2\epsilon q^2} \delta_{\alpha\gamma} \delta_{\beta\delta}
$$
\n(28)

<span id="page-6-8"></span>By similar steps to the discussion around  $(21)$ , for this model we obtain the following superhamiltonian on  $\mathcal{H}^{\otimes n}$ (again labelling copies with forward evolution  $f_i$  and those with backward evolution  $b_i$ , with  $i = 1, ..., n$ :

<span id="page-6-7"></span>
$$
P_{2n} = \sum_{\langle ij \rangle} P_{2n,ij},
$$
  
\n
$$
P_{2n,ij} = \frac{1}{2} \left[ nI - \sum_{k,l=1}^{n} M_{f_k,b_l}^i M_{f_k,b_l}^j + \frac{1}{q^2} \sum_{1 \le k < l \le n} (S_{f_k}^i S_{f_l}^j + S_{b_k}^i S_{b_l}^j) \right]
$$
 (29)

<span id="page-6-3"></span>where I is the identity operator in  $\mathcal{H}^{\otimes 2n}$ ,  $M_{rs}^{i}$  is the projector onto the maximally entangled state between the copies r and s at site i,  $\|\tilde{MAX}\rangle_{i_r,i_s} = \frac{1}{\sqrt{q}} \sum_{a=1}^q |a\rangle_{i_r} |a\rangle_{i_s},$ and  $S_{rs}^i$  is the swap operator between copies r and s at site *i*, which has the action  $S_{rs}^i |a\rangle_{i_r} |b\rangle_{i_s} = |b\rangle_{i_r} |a\rangle_{i_s}$ .  $P_{2n}$  has a large symmetry group which includes  $S_n \times S_n$ corresponding to permuting the forward and backward copies independently; see [\[40\]](#page-22-0) for a detailed symmetry analysis of Hamiltonians of this kind.

For  $n = 1$ , this superhamiltonian has a unique ground state given by  $\otimes_i |e\rangle_i$ , where  $|e\rangle$  is two-copy state associated with the identity permuation, see Eq.  $(20)$ . Moreover, it is easy to check that it is composed of commuting terms, and is therefore exactly solvable, with a gapped spectrum with discretely spaced energy levels. This leads to a simple exponential decay of infinite-temperature autocorrelation functions of any operator A, which can be written as

$$
\langle A(t)A\rangle_{\beta=0} = \langle A, e | e^{-P_2 t} | A, e \rangle . \tag{30}
$$

This is consistent with the physical expectation from the lack of any symmetries in the time-evolution.

For general  $n$ , if we consider the subspace spanned by states of the form  $\otimes_i |\sigma_i\rangle_i$  for  $\sigma_i \in \mathcal{S}_n$ , then  $P_{2n}$  keeps this subspace closed. Its zero energy ground states are the  $n!$  product states with the same permutation at each site:

<span id="page-6-6"></span>
$$
\otimes_i \left( \frac{1}{q^{n/2}} \ket{\sigma}_i \right), \quad \sigma \in \mathcal{S}_n. \tag{31}
$$

<span id="page-6-1"></span><sup>&</sup>lt;sup>6</sup> This should be true for generic choices of  $B_{\alpha}$ , and is provable in many cases for  $n = 1$  [\[30\]](#page-21-13) but there are exceptions for  $n >$ 2, e.g., when  ${B_\alpha}$  can be written as quadratic operators in fermions [\[26,](#page-21-22) [40\]](#page-22-0). We also discuss this in Section [V.](#page-16-0)

<span id="page-6-2"></span> $^7$  See the example in [A](#page-23-0)ppendix A for a more explicit discussion of this point.

<span id="page-6-5"></span><sup>8</sup> For a recent discussion of the spectrum of this time-dependent Hamiltonian in the case without spatial locality, see [\[41\]](#page-22-1).

These can be thought of as ferromagnets of  $S_n$  degrees of freedom. We hence expect  $P_{2n}$  to be gapped, and the low-energy excitations to be domain-walls between the different ferromagnetic ground states. The structure of the low-energy excitations leads to the membrane picture of entanglement.

The saturation value of the  $n$ -th Renyi entropy in this model obtained from the ground states  $(31)$  is the spe-cial case of [\(26\)](#page-6-3) with  $\rho^{(eq)} = I/D$ , where D is the total Hilbert space dimension. As discussed in [\[8\]](#page-21-3), [\(27\)](#page-6-4) for this case is equal to the average value in random product states [\[3–](#page-21-1)[7\]](#page-21-2). The equilibrium entropy density for each of the Renyi entropies is therefore

$$
s_{n, \text{eq}} = s_{\text{eq}} = \log q. \tag{32}
$$

### <span id="page-7-0"></span>A. Second Renyi entropy

Let us now focus on the structure of the superhamil-tonian [\(29\)](#page-6-7) for the case  $n = 2$ . In this case, we have two degenerate ground states,

<span id="page-7-1"></span>
$$
|G_{\uparrow}\rangle = \otimes_i | \uparrow \rangle_i, \quad |G_{\downarrow}\rangle = \otimes_i | \downarrow \rangle_i. \tag{33}
$$

where

$$
\begin{aligned} \left|\uparrow\right\rangle &= \frac{1}{q} \left|e\right\rangle = \left|\text{MAX}\right\rangle_{f_1 b_1} \left|\text{MAX}\right\rangle_{f_2 b_2}, \\ \left|\downarrow\right\rangle &= \frac{1}{q} \left|\eta\right\rangle = \left|\text{MAX}\right\rangle_{f_1 b_2} \left|\text{MAX}\right\rangle_{f_2 b_1}. \end{aligned} \tag{34}
$$

It will be useful to express  $P_4$  in terms of these spin states. Note that  $|\uparrow\rangle$  and  $|\downarrow\rangle$  are normalized, but do not form an orthonormal basis as  $\langle \uparrow | \downarrow \rangle = 1/q$ . It will be convenient to work in a bi-orthogonal system and introduce the following two states

$$
|\overline{1}\rangle = \frac{q^2}{q^2 - 1} \left( |\overline{1}\rangle - \frac{1}{q} | \downarrow \rangle \right), \quad |\overline{1}\rangle = \frac{q^2}{q^2 - 1} \left( |\downarrow\rangle - \frac{1}{q} | \overline{1}\rangle \right)
$$
(35)

which have the property that  $\langle \bar{s'} | s \rangle = \delta_{ss'}$  for  $s, s' \in \{\uparrow\}$  $, \downarrow$ . We can then write  $P_4$  in the subspace spanned by  $|\uparrow\rangle$ ,  $|\downarrow\rangle$  at each site as follows:

$$
P_4 = A_0 + A_1,
$$
  
\n
$$
A_0 = \sum_{\langle ij \rangle} \left[ I - |\overline{\uparrow}\overline{\uparrow}\rangle \langle \uparrow\uparrow| - |\overline{\downarrow}\overline{\downarrow}\rangle \langle \downarrow\downarrow| \right.
$$
  
\n
$$
- \frac{1}{q} (|\overline{\uparrow}\overline{\downarrow}\rangle + |\overline{\downarrow}\overline{\uparrow}\rangle) (\langle \uparrow\uparrow| + \langle \downarrow\downarrow|) \right]_{i,j}
$$
  
\n
$$
A_1 = \sum_{\langle ij \rangle} \left[ \frac{1}{q^2} (|\overline{\uparrow}\overline{\downarrow}\rangle \langle \downarrow\uparrow| + |\overline{\downarrow}\overline{\uparrow}\rangle \langle \uparrow\downarrow|) \right]_{i,j}
$$
(36)

where  $\langle ij \rangle$  denotes nearest neighboring sites on a lattice, and for instance  $|\uparrow\uparrow\rangle$  denotes  $|\uparrow\rangle_i |\uparrow\rangle_j$ . This representation will be useful as the final state in the expression for

the second Renyi entropy in [\(18\)](#page-5-2) is a domain wall state of the form  $q^L \otimes_{i \in R} \langle \downarrow \rangle_i \otimes_{i \in \bar{R}} \langle \uparrow \rangle_i$ .

While the above representation will be convenient for some of our later analysis, we can also represent A in the following orthonormal basis for one site:

<span id="page-7-5"></span>
$$
|+\rangle = \frac{1}{\sqrt{2(1+\frac{1}{q})}}(|\uparrow\rangle + |\downarrow\rangle), \quad |-\rangle = \frac{1}{\sqrt{2(1-\frac{1}{q})}}(|\uparrow\rangle - |\downarrow\rangle)
$$
\n(37)

Defining the Pauli matrices with respect to these states, where  $|+\rangle$  and  $|-\rangle$  are the eigenstates of the Z operator, we obtain the following representation:

$$
P_4 = \frac{1}{2} \sum_{\langle i,j \rangle} [1 - X_i X_j - \frac{1}{q} (Z_i + Z_j) + \frac{1}{q^2} (Z_i Z_j + X_i X_j)],
$$
\n(38)

In one spatial dimension,  $P_4$  lies on a parameter line of the Heisenberg XYZ spin chain in an external magnetic field known as the "Peschel-Emery" line [\[42,](#page-22-2) [43\]](#page-22-3). On this line, the Hamiltonian is known to lie within the Ising ferromagnetic  $(Z_2$  symmetry broken) phase, and was previously noted to have two frustration-free product ground states, which are of the form [\(33\)](#page-7-1). We discuss this mapping in Appendix [B.](#page-24-0)

<span id="page-7-6"></span>In the rest of this section, we specialize to one spatial dimension. We will consider higher dimensions in Sec. [VI.](#page-17-0)

### <span id="page-7-8"></span><span id="page-7-3"></span>1. Large q limit

<span id="page-7-7"></span>Let us first take a large q limit by ignoring the  $A_1$ term in [\(36\)](#page-7-2), which is  $O(1/q^2)$ . In one spatial dimension, the left eigenstates of the non-Hermitian Hamiltonian  $A_0$ will turn out to be exactly solvable. We assume that the system has L sites labelled from  $x = -L/2$  to  $x =$  $L/2 - 1$  and open boundary conditions (OBC), but we will take  $L \to \infty$  for most purposes. Note that the zero energy left-eigenstates of  $A_0$  are the same as the zero energy eigenstates of the full Hamiltonian  $P_4$ , given by  $(33)$ . Due to this feature,  $A_0$  turns out to be a better first approximation for understanding the structure of the first excited states than the transverse field Ising model obtained by keeping the  $O(1)$  and  $O(1/q)$  terms in [\(38\)](#page-7-3).

To find the low-energy left-eigenstates, note that  $A_0$ has a particularly simple left-action on the domain wall states defined as

$$
\langle D_x | = \langle \downarrow \downarrow \dots \downarrow_x \uparrow_{x+1} \uparrow \dots \uparrow | \tag{39}
$$

<span id="page-7-2"></span>given by

<span id="page-7-4"></span>
$$
\langle D_x | A_0 = \langle D_x | -\frac{1}{q} (\langle D_{x+1} | + \langle D_{x-1} |), \qquad (40)
$$

where we have implicitly defined  $\langle D_{-\frac{L}{2}-1}|=\langle D_{\frac{L}{2}-1}|=0$ at the boundaries. From  $(40)$ , we can immediately see

<span id="page-8-12"></span>FIG. 5. The red data points show the momentum-resolved low-energy spectra for  $P_4$  in [\(36\)](#page-7-2) or [\(38\)](#page-7-3) for  $L = 14$  for  $q = 2$ (left),  $q = 3$  (center),  $q = 4$  (right). These energies are found using exact diagonalization with the twisted boundary conditions described in Appendix [B.](#page-24-0) The energies are almost unchanged between  $L = 12$  and  $L = 14$ . These are compared to the blue curves, which are the dispersion relations obtained from the minimization of the expectation value of  $P_4$  in the states [\(61\)](#page-10-0) for  $\Delta = 4$ ,  $L = 40$  with open boundary conditions.

that the lowest band of left-eigenstates of  $A_0$  above the ground state is given by

<span id="page-8-1"></span>
$$
\langle \psi_k | = \sum_{x=-\frac{L}{2}}^{\frac{L}{2}-2} e^{ikx} \langle D_x | , E(k) = 1 - \frac{2}{q} \cos k . \quad (41)
$$

The spectrum is gapped as we are in the regime  $q \gg 1$ .

Let us now apply this structure to understand the evolution of  $S_2$  for a half-line region to the left of x,

<span id="page-8-0"></span>
$$
e^{-S_2(x,t)} = q^L \langle D_x | e^{-P_4 t} | \rho_0, e \rangle . \tag{42}
$$

It is useful to introduce the states  $|\bar{D}_x\rangle = |\bar{\downarrow}...\bar{\downarrow}_x\bar{\uparrow}_{x+1}...\bar{\uparrow}\rangle$ , and a "domain wall propagator" (considered for instance in [\[38\]](#page-21-20))

<span id="page-8-2"></span>
$$
G(x, y, t) = \langle D_x | e^{-A_0 t} | \bar{D}_y \rangle \tag{43}
$$

in terms of which [\(42\)](#page-8-0) can be written as

<span id="page-8-4"></span>
$$
e^{-S_2(x,t)} = \sum_{y} G(x,y,t)e^{-S_2(y,t=0)}.
$$
 (44)

Here we have used the fact that the action of  $A_0$  does not create additional domain walls, and we can hence insert a resolution of identity  $\sum_{x}|\bar{D}_{x}\rangle\langle D_{x}|$  restricted to the single domain wall subspace in  $(42)$ . Then using  $(41)$ and working in the  $L \to \infty$  limit, we can express [\(43\)](#page-8-2) as

<span id="page-8-10"></span>
$$
G(x, y, t) = \int_{-\pi}^{\pi} \frac{dk}{2\pi} e^{-(E(k) + ikv)t}, \quad v = \frac{x - y}{t}.
$$
 (45)

Let us now take the late-time limit  $t \gg 1$ , and consider v of  $O(1)$  in this limit. Then the integral over k can be evaluated using the saddle-point approximation. The saddle-point value  $k_v$  lies on the imaginary axis, and by deforming the contour to pass through its steepest descent contour we get

<span id="page-8-3"></span>
$$
G(x, y, t) \approx e^{-s_{\text{eq}}\mathcal{E}(v)t}, \quad v = \frac{x - y}{t}
$$
 (46)

where

<span id="page-8-11"></span>
$$
\mathcal{E}(v) = \frac{E(k_v) + ik_v v}{s_{\text{eq}}}, \quad E'(k_v) = -iv. \tag{47}
$$

Now putting  $(46)$  into  $(44)$ , we obtain precisely the membrane formula for the second Renyi entropy in the large t limit: $9$ 

$$
e^{-S_2(x,t)} \approx \sum_{v} e^{-s_{\text{eq}} \mathcal{E}(v)t - S_2(x-vt,t=0)}
$$
  
\n
$$
\implies S_2(x,t) \approx \min_{v} \left[ s_{\text{eq}} \mathcal{E}(v)t + S_2(x-vt,t=0) \right],
$$
\n(48)

where in the second step we have used that  $v \sim O(1)$  and  $t \gg 1$ , and ignored contributions that are smaller than linear in t.

The membrane tension from the dispersion relation  $(41)$  is  $10$ 

<span id="page-8-8"></span>
$$
\mathcal{E}^{\text{(large q)}}(v) = \frac{1}{\log q} \left[ 1 - \frac{2}{q} \sqrt{1 + \left(\frac{qv}{2}\right)^2} + v \operatorname{arcsinh}\left(\frac{vq}{2}\right) \right]
$$
\n(49)

Its strict large q limit is

<span id="page-8-9"></span>
$$
\lim_{q \to \infty} \mathcal{E}(v) = |v| \tag{50}
$$

<span id="page-8-7"></span>.

which satisfies the constraints  $(4)$  in a somewhat degenerate way. As we will discuss in the following sections, the expressions  $(44)-(48)$  $(44)-(48)$  will turn out to apply to more

<span id="page-8-5"></span><sup>&</sup>lt;sup>9</sup> In this discussion, we ignore the difference between  $\overline{S_2(x,t)}$  and  $-\log\left(\overline{e^{-S_2(x,t)}}\right)$ , as in various earlier works including [\[14,](#page-21-10) [15\]](#page-21-14).

<span id="page-8-6"></span><sup>&</sup>lt;sup>10</sup> Note that [\(49\)](#page-8-8) by itself does not satisfy the constraints [\(4\)](#page-2-2) except in the strict large  $q$  limit [\(50\)](#page-8-9). It does satisfy the constraints at finite q if we make the replacement  $q \to q + q^{-1}$ , which can be seen as a simple analytical "toy model" for the membrane tension function, see Appendix [B 3.](#page-26-0)

general cases than the large  $q$  limit of the current model. The modified dispersion relations  $E(k)$  in these cases will lead to other, more general expressions for  $\mathcal{E}(v)$ .

Before discussing these more general cases, let us briefly discuss the form of  $S_2$  for a region consisting of one or more intervals in the large  $q$  limit. Since the "final state" in this case would contain more than one domain wall, we now need to consider "multi-particle" excitations of  $A_0$  involving more than one domain wall. For a state with two or more domain walls, we can check from  $(36)$  that the left-action of  $A_0$  can cause domain walls to annihilate in pairs. It is useful to divide  $A_0$  into two parts,

<span id="page-9-11"></span>
$$
A_0 = A_f + A_c \tag{51}
$$

where  $A_f$  keeps the number of domain walls fixed, while  $A_c$  causes the annihilation of pairs of domain walls.  $A_f$ has a block-diagonal structure, while the whole matrix  $A_0$  has a lower-triangular structure due to  $A_c$ . The energy eigenvalues of  $A_0$  are therefore the same as those of  $A_f$ . Denoting the multiple domain wall states by  $\langle D_{x_1,\ldots,x_k} |, x_1 < x_2 < \ldots < x_n$ , it is easy to check that the domain walls are "non-interacting" under the action of  $A_f$ . Hence, the eigenstates of  $A_f$  take a simple free fermion-like Slater determinant form:

$$
\langle \psi_{k_1,\dots,k_n} \rvert = \sum_{\sigma \in S_n} \text{sgn}(\sigma) \langle \phi_{k_{\sigma(1)},\dots,k_{\sigma(n)}} \rvert,
$$
  

$$
\langle \phi_{k_1,\dots,k_n} \rvert = \sum_{x_1 < x_2 < \dots < x_n} e^{i \sum_{j=1}^n k_j x_j} \langle D_{x_1,\dots,x_n} \rvert \quad (52)
$$

with energies  $E(k_1, ..., k_n)$  given by the sum of the oneparticle energies  $E(k_i)$  in [\(41\)](#page-8-1). Hence, the energies of the multiparticle states under  $A_0$  are also sums of oneparticle energies, $11$  although the eigenstates are more complicated superpositions of [\(52\)](#page-9-1). As we discuss in more detail in Appendix [C,](#page-27-0) this structure leads to the membrane picture for multiple intervals.

### 2. General structure

The key physical properties of  $A_0$  that give rise to the membrane picture in the above discussion are: (i)  $A_0$  is gapped, so that  $e^{-S_2(t)}$  has an exponential decay for any initial state, leading to linear growth of  $S_2(t)$ ; (ii) the one-particle eigenstates of the  $A_0$  are plane waves of domain walls between  $\langle \uparrow |$  and  $\langle \downarrow |$ ; and (iii) domain walls are non-interacting other than the possibility of pair-wise annihilation. In the next section, we will show that properties (i) and (ii) remain robust for the full Hamiltonian

 $P_4$  at finite q. (ii) is robust up to some local "dressing" of the domain walls. In Sec. [IV,](#page-6-0) we will further show that these properties remain robust for Brownian models with fixed coupling operators. We expect that property (iii) is also robust, but this is harder to show explicitly, and we do not comment further on it until the Discussion section [VII.](#page-19-0)

Due to the robustness of (ii), the formulas [\(44\)](#page-8-4) and [\(45\)](#page-8-10) will also apply to the second Renyi entropy in all remaining examples we consider. It is useful at this point to summarize some general consequences of these formulas, which we will use in the later discussion.

For an initial state of the form  $(5)$ , the evolution of  $S_2$ is given by

<span id="page-9-6"></span>
$$
e^{-S_2(x,t)} = e^{-s\left(x + \frac{L}{2}\right)} \int_{-\infty}^{\infty} dv \int_{-\pi}^{\pi} \frac{dk}{2\pi} e^{-(E(k) + ikv - sv)t}
$$
\n(53)

The saddle-point equations for  $v$  and  $k$  in the above integral are:

<span id="page-9-4"></span>
$$
k = -is, \quad E'(k) = -iv \tag{54}
$$

which imply  $(6)$  with the entropy growth rate

<span id="page-9-3"></span>
$$
\Gamma_2(s) = E(is)/s_{\text{eq}}.
$$
\n(55)

where we have used the fact that  $E(k)$  is an even function. Eq. [\(47\)](#page-8-11) is equivalent to the statement that  $\mathcal{E}(v)$  is the Legendre transform of  $-\Gamma(s)$ ,

<span id="page-9-10"></span>
$$
\mathcal{E}(v) = \max_{s} \left( \frac{vs}{s_{\text{eq}}} + \Gamma(s) \right) \tag{56}
$$

<span id="page-9-1"></span>which also follows from [\(7\)](#page-2-3) and was previously noted in [\[12\]](#page-21-6). [12](#page-9-2)

In particular, for an initial pure product state, the entanglement velocity of the second Renyi entropy  $v_{E,2}$  is proportional to the gap in the spectrum:

<span id="page-9-7"></span>
$$
S_2(x,t) = s_{\text{eq}} v_{E,2} t, \quad v_{E,2} = \frac{E(0)}{s_{\text{eq}}}.
$$
 (57)

From  $(55)$ , the constraints  $(4)$  or  $(8)$  are equivalent to the fact that

<span id="page-9-5"></span>
$$
E(is_{\text{eq}})=0.\t\t(58)
$$

Using  $(54)$ , in terms of the dispersion relation,  $v_B$  is given by

<span id="page-9-8"></span>
$$
v_B = -iE'(-is_{\text{eq}}). \tag{59}
$$

Note that the condition [\(58\)](#page-9-5) does not need to be imposed as an external input. The evolution of the entanglement entropy of  $S_2$  for a maximally mixed initial state can be expressed as

<span id="page-9-9"></span>
$$
e^{-S_2^{(\max)}(x,t)} = q^L \langle D_x | e^{-P_4 t} \left( \otimes_i \frac{1}{q} | \uparrow \rangle_i \right) . \tag{60}
$$

<span id="page-9-0"></span><sup>&</sup>lt;sup>11</sup> This is also evident if one performs the basis change of  $(37)$ on  $A_0$  in [\(36\)](#page-7-2) and then performs a Jordan-Wigner transformation of [\(B9\)](#page-25-1) – the resulting Hamiltonian is a non-Hermitian noninteracting Hamiltonian.

<span id="page-9-2"></span> $^{12}$  We do not add  $\sqrt{n}$  subscripts in this formula as it will also apply to the higher Renyis.

By acting with  $e^{-P_4t}$  on the left, we get [\(53\)](#page-9-6) with  $s = s_{eq}$ due to the structure of the low-energy excitations, and by acting on the right, we get a time-independent result due to the fact that  $\otimes_i | \uparrow \rangle_i$  is a zero energy eigenstate of  $P_4$ . [\(58\)](#page-9-5) must always be true to ensure consistency between these results.

One interesting aspect of the condition [\(58\)](#page-9-5) is that it is sensitive to the UV behaviour of the dispersion relation  $E(k)$ , as it involves an  $O(1)$  imaginary value of k. We will return to the implications of this UV sensitivity in the Discussion section.

### <span id="page-10-4"></span>3. Finite q

At finite  $q$ , the  $A_1$  term in [\(36\)](#page-7-2) can send a single domain wall state  $\langle D_x |$  to a three domain wall state  $\langle D_{x-1,x,x+1} |$  and vice versa, so that the exact low-energy eigenstates are no longer plane waves of single domain walls as in [\(41\)](#page-8-1), and the exact energies are also modified. Nevertheless, since the ground states of  $P_4$  are still ferromagnetic states of the form of [\(33\)](#page-7-1), we expect the low-energy excitations to be gapped (dressed) domain walls between the two ground states, similar to  $(41)$ . To numerically determine the momentum-resolved dispersion of the low-energy eigenstates, we study  $P_4$  with symmetry-twisted (antiperiodic) boundary conditions, as discussed in Appendix [B.](#page-24-0) [13](#page-10-1),[14](#page-10-2)

The low-lying spectrum as a function of  $k$  is shown in Fig. [5](#page-8-12) for  $q = 2, 3, 4$ . In all cases, we find that  $P_4$ is gapped, consistent with expectations in the ferromagnetic phase. The gap leads to a linear growth of entanglement for a product state, according to [\(57\)](#page-9-7). To verify the robustness of the membrane picture, we need to further address the following questions:

- 1. For  $q \geq 3, 4$ , we find a single-particle band in the spectrum well-separated from the multi-particle continuum for all  $k$ . It is natural to expect that the eigenstates in this band have a quasiparticle structure [\[35\]](#page-21-15). Can these quasiparticle states be understood as locally dressed versions of the domain wall states in [\(41\)](#page-8-1) in a precise sense?
- 2. For  $q = 2$ , the gap between the single-particle states and the multi-particle continuum vanishes beyond

some value of k. Are there still well-defined quasiparticle states within the continuum at large  $k$ ?

Both questions can be simultaneously addressed using a technique for obtaining low-energy dispersion relations along the lines of [\[35](#page-21-15)[–37\]](#page-21-16). These references introduced a general variational ansatz for low-energy excitations of gapped spin chain systems, starting from the assumption that the ground state is well-approximated by a matrix product state. In the case of the Hamiltonian  $P_4$ , since we know that the exact zero energy eigenstates are the product states  $|\uparrow ... \uparrow \rangle$  and  $|\downarrow ... \downarrow \rangle$ , we can use a particularly simple version of the general ansatz:

<span id="page-10-0"></span>
$$
|\psi_k\rangle = \sum_x e^{-ikx} | \downarrow \dots \downarrow_x \rangle | \phi_{x+1,\dots,x+\Delta} \rangle | \uparrow_{x+\Delta+1} \dots \uparrow \rangle
$$
\n(61)

where  $|\phi_{x+1,...,x+\Delta}\rangle$  is an arbitrary state in the subspace spanned by  $|\uparrow\rangle$ ,  $|\downarrow\rangle$  on  $\Delta$  sites, which has total Hilbert space dimension  $2^{\Delta}$ . <sup>[15](#page-10-3)</sup>

We increase the value of  $\Delta$  starting from 0, and minimize the expectation value  $\langle \psi_k|P_4|\psi_k\rangle$  over all choices of  $|\phi\rangle$  for a given  $\Delta$ . We explain details of the variational optimization in Appendix [D.](#page-28-0) As discussed in [\[35–](#page-21-15)[37\]](#page-21-16), rapid convergence of the dispersion relation on increasing  $\Delta$  indicates that the eigenstates of  $P_4$  are well-approximated by [\(61\)](#page-10-0) for  $O(1)$   $\Delta$ , and this interpretation also holds when the dispersion relation lies within a multi-particle continuum. The results are shown in Fig. [6,](#page-11-0) where we find rapid convergence of the dispersion relation with  $\Delta$ for all values of k for both  $q = 2$  and  $q = 3$ . We also compare the variational dispersion relations to the energies obtained from exact diagonalization in Fig. [5,](#page-8-12) finding good agreement in cases where the latter show a welldefined single-particle band. The expectation value with  $\Delta = 0$  already gives a good approximation for the numerically observed dispersion relation, see Appendix [B 3](#page-26-0) for details.

These results confirm that the low-energy eigenstates relevant for the evolution of  $e^{-S_2(x,t)}$  have the structure of localized domain wall-like states at finite  $q$ , including in the case  $q = 2$  at all k. Putting this structure [\(61\)](#page-10-0) of

<span id="page-10-1"></span><sup>13</sup> We thank Tibor Rakovszky for useful discussions on this.

<span id="page-10-2"></span><sup>14</sup> In summary, the momentum resolution cannot be obtained directly with a finite-size OBC Hamiltonian due to lack of translation-invariance. On the other hand, periodic boundary conditions (PBC) does not allow for an odd number of domain walls. By inserting a symmetry twist at the boundary, one domain wall gets pinned at the boundary while the other can disperse, and we can obtained the momentum-resolved dispersion of a single domain wall. This is expected to match the low-energy spectrum to match that of the OBC Hamiltonian for large system sizes.

<span id="page-10-3"></span><sup>15</sup> The actual dimension of the subspace spanned by the states in [\(61\)](#page-10-0) is slightly smaller than  $2^{\Delta}$  due to the redundancy between certain choices of  $|\phi\rangle$  in the thermodynamic limit. For example, for  $n = 1$ , there is only one linearly independent choice  $|\phi\rangle = |\downarrow\rangle$ , and for  $n = 2$ , we can consider an arbitrary superposition of the form  $|\phi\rangle = \alpha |\downarrow\rangle |\uparrow\rangle + \beta |\uparrow\rangle |\downarrow\rangle$ .

<span id="page-11-0"></span>FIG. 6. In the top panel, we show the results of minimizing the expectation value of  $P_4$  for the Brownian local GUE model, [\(36\)](#page-7-2) within states of the form [\(61\)](#page-10-0) for increasing values of  $\Delta$  from 1 to 4, for  $q = 3$  (left) and  $q = 2$  (right). In the bottom panel, we show more explicitly by plotting  $\log(E_{\Delta} - E_{\Delta+1})$  as a function of  $\Delta$  for a few values of k that the dispersion relations are converging rapidly with  $\Delta$  in both cases, indicating that the domain wall excitations [\(61\)](#page-10-0) are a good approximation to the true eigenstates.

the eigenstates into  $(42)$ , we have:  $16$ 

$$
e^{-S_2(x,t)} \approx \sum_{k} \sum_{y_1, y_2} e^{ik(y_2 - y_1)} e^{-E(k)t}
$$

$$
\langle D_x | (|\downarrow \dots \downarrow_{y_1} \rangle | \phi_{y_1 + 1, \dots, y_1 + \Delta} \rangle | \uparrow_{y_1 + \Delta + 1} \dots \uparrow \rangle)
$$

$$
(\langle \downarrow \dots \downarrow_{y_2} | \langle \phi_{y_2 + 1, \dots, y_2 + \Delta} | \langle \uparrow_{y_2 + \Delta + 1} \dots \uparrow \rangle | \rho_0, e \rangle \quad (62)
$$

Since  $|\phi_{\cdots}\rangle$  is some superposition of configurations of  $|\uparrow\rangle$  and  $|\downarrow\rangle$  spins, for  $\Delta$  of  $O(1)$ , the factor in the last line of [\(62\)](#page-11-2) contains a term proportional to  $e^{-S_2(y_2,t=0)}$ , as well as terms proportional to  $e^{-S_2([-\frac{L}{2},y_2+\Delta_1]\cup[y_2+\Delta_2,y_2+\Delta_3]\cup...\cup[y_2+\Delta_{m-1},y_2+\Delta_m],t=0)}$ for all odd  $m \geq 3$ , for some  $O(1)$   $\Delta_i$ . Since  $\Delta$  is  $O(1)$ , in

the scaling limit of late time and large system size, the differences between these terms can be ignored, and they can be combined into  $ce^{-S_2(x,t=0)}$  for some  $O(1)$  number  $c$ . Similarly, the factor in the first line of  $(62)$  can be replaced with  $\delta_{xy_1}$  in this limit. Hence, the analysis of  $(43)-(48)$  $(43)-(48)$  $(43)-(48)$  also applies to this case, with the change that  $E(k)$  should be used to denote the numerically obtained exact dispersion relation at finite  $q$  from Fig. [5,](#page-8-12) instead of the large-q dispersion relation of  $(41)$ .

<span id="page-11-2"></span>We determine  $\mathcal{E}(v)$  by fitting  $E(k)$  to the general form

<span id="page-11-3"></span>
$$
E(k) = \sum_{n=0}^{N_{\text{max}}} c_n \cos(nk), \qquad (63)
$$

for some finite  $N_{\text{max}}$ , and then numerically solving the equation for  $k_v$  in [\(47\)](#page-8-11). This procedure gives us the membrane tensions in Fig. [7.](#page-12-0) Let us make a few observations about these results:

1. For each q,  $\mathcal{E}(v)$  is convex and satisfies the general constraints [\(4\)](#page-2-2) for  $v_B$  given by [\(59\)](#page-9-8).

<span id="page-11-1"></span><sup>&</sup>lt;sup>16</sup> Note in particular that in the  $q = 2$  case, even though the energies of the multi-particle continuum are comparable to those of the single-particle band, the final state  $\langle D_x |$  has significant overlap only with the eigenstates of the single particle band, so that the approximation in [\(62\)](#page-11-2) is valid.

- 2. The entanglement velocity  $v_{E,2}$  from [\(57\)](#page-9-7) is nonmonotonic as a function of q, increasing up to  $q = 5$ and then decreasing. The eventual decreasing behaviour is consistent with the large  $q$  limit [\(50\)](#page-8-9). Note, however, that the quantity  $s_{eq}v_{E,2}$ , which determines the coefficient of the linear growth of  $S_2$ for a product state with time, increases monotonically with  $q$ .
- 3. The butterfly velocity  $v_B$  from [\(59\)](#page-9-8) monotonically increases with q.

We note one subtlety of the above discussion. For any choice of  $\Delta$  at which we choose to truncate the approximation  $(61)$ , there will be small corrections in the exact eigenstate proportional to  $|\downarrow \dots \downarrow_x\rangle |\phi_{x+1,\dots,x+r}\rangle |\uparrow_{x+r+1} \dots \uparrow\rangle$  for  $r > \Delta$ . In principle, there could be initial states  $\rho_0$  with entanglement structures that would lead to a non-trivial competition in [\(42\)](#page-8-0) between the suppression of such components in the eigenstate, and an enhancement of the corresponding overlap factor  $\langle \downarrow ... \downarrow_x | \langle \phi_{x+1,...,x+r} | \langle \uparrow_{x+\Delta+1} ... \uparrow | \rho_0, e \rangle$ . We argue in Appendix  $E$  using a somewhat different approach that such corrections are not important. This argument makes use of the convexity of the numerically obtained membrane tensions in Fig. [7,](#page-12-0) together with the structure of the interaction picture diagrams we get from treating  $A_1$  as a perturbation.

### 4. Comparison to Haar random unitary circuits

It is instructive to rephrase the evolution of the second Renyi entropy in the brickwork Haar random circuits of [\[14,](#page-21-10) [15\]](#page-21-14) in the above language of low-energy modes of a one-dimensional quantum Hamiltonian, as an alternative to the standard discussion in terms of a mapping to a twodimensional classical statistical mechanics problem. In these models, we apply two-site random unitaries drawn with the Haar measure in the pattern shown in Fig. [8.](#page-12-1) The average  $(U(t) \otimes U(t)^*)^{\otimes 2}$  for an even time t can be written in the notation of the previous subsections as

$$
\overline{(U(t)\otimes U(t)^*)^{\otimes 2}} = M^{t/2},
$$
\n
$$
M = \prod_{i=\text{odd}} M_{i,i+1} \prod_{i=\text{even}} M_{i,i+1},
$$
\n
$$
M_{i,i+1} = \left[ |\overline{1}\overline{1}\rangle \langle 1\overline{1}| + |\overline{1}\overline{1}\rangle \langle 1\overline{1}| + |\overline{1}\overline{1}\rangle \langle 1\overline{1}| + \langle 1\overline{1}\overline{1}| \rangle \right]_{i,i+1} \qquad (64)
$$

Note that M is not Hermitian. We can see that  $\langle \uparrow ... \uparrow \rangle$ ,  $\langle \downarrow \dots \downarrow \rangle$  are left eigenstates of M with eigenvalue 1, and that  $\langle \psi_k |$  in [\(41\)](#page-8-1) (with the sum restricted to odd x, hence the momentum restricted to  $-\frac{\pi}{2} < k < \frac{\pi}{2}$ ) is an exact left eigenstate of  $M$  for any value of  $q$ , with eigenvalue  $e^{-2E_{\text{Haar}}(k)}$ , where

$$
E_{\text{Haar}}(k) = \log \frac{q^2 + 1}{2q} - \log \cos k. \tag{65}
$$

<span id="page-12-0"></span>FIG. 7. Top: We show the membrane tension curves for the second Renyi entropy for various q from the fitting of  $E(k)$ to [\(63\)](#page-11-3) with  $N_{\text{max}} = 4$ . ( $N_{\text{max}} = 2, 3$  give similar curves.) For  $q \geq 3$ , we use  $E(k)$  from exact diagonalization, while for  $q = 2$ , we use  $E(k)$  from the variational method for  $\Delta = 4$ , so that [\(4\)](#page-2-2) is only approximately satisfied. Bottom: We show  $v_{E,2}$  and  $v_B$  as a function of q.

<span id="page-12-2"></span><span id="page-12-1"></span>FIG. 8. Structure of the random circuit model of [\[14,](#page-21-10) [15\]](#page-21-14). Each rectangle represents a unitary matrix acting on two sites (each of dimension  $q$ ), drawn with the Haar measure.

Applying the relation [\(47\)](#page-8-11) for this dispersion relation gives a simple derivation of the membrane tension for this case, previously found in [\[12\]](#page-21-6). Unlike the membrane tensions in the Brownian models in the rest of this work,  $\mathcal{E}(v)$ in this model diverges for  $v = 1$  and is not well-defined

for  $v > 1$ , indicating the sharp light-cone in Haar-random circuits.

One difference between the four-copy evolution by [\(64\)](#page-12-2) for the Haar random circuit and the evolution by  $e^{-P_4t}$ for the local GUE model is the fact that a single domain wall can split into multiple domain walls under the latter but not the former. From the discussion of the previous subsection and Appendix  $E$ , we learn that this splitting of the domain walls does not have a qualitative effect on the membrane picture for the second Renyi entropy, and only serves to renormalize the membrane tension. In Appendix  $\bf{F}$ , we give an example of a physical quantity related to operator growth which does show a qualitative difference between Haar random circuits and the GUE model due to this domain wall splitting.

### <span id="page-13-0"></span>B. Higher Renyi entropies

Let us now discuss the structure of the superhamiltonian  $P_{2n}$  of [\(29\)](#page-6-7) in the more general case where  $n \geq 3$ . Recall from the discussion around [\(31\)](#page-6-6) that the relevant Hilbert space at each site has dimension  $n!$ , and is spanned by the states  $\frac{1}{q^{n/2}}|\sigma\rangle_i$ . The ground states are given by ferromagnetic states of the form [\(31\)](#page-6-6). For studying the excitations, it is convenient to introduce the notion of the Cayley distance  $d(\sigma, \tau)$  between two permutations  $\sigma, \tau \in \mathcal{S}_n$ , which is the minimum number of transpositions (swaps)  $(i j)$  needed to go from  $\sigma$  to  $\tau$ . For any  $\sigma, \tilde{\sigma} \in \mathcal{S}_n$  such that  $d(\sigma, \tilde{\sigma}) = 1$ , we have

<span id="page-13-1"></span>
$$
\langle \sigma | \langle \tilde{\sigma} | P_{2n} = \langle \sigma | \langle \tilde{\sigma} | - \frac{1}{q} (\langle \sigma | \langle \sigma | + \langle \tilde{\sigma} | \langle \tilde{\sigma} |) + \frac{1}{q^2} \langle \tilde{\sigma} | \langle \sigma |
$$
\n(66)

Comparing to  $(36)$ , we see that the action of  $P_{2n}$  on states constructed only from any such pair  $\langle \tilde{\sigma} | , \langle \sigma |$  is identical to the action of  $P_4$  on  $\langle \uparrow | , \langle \downarrow |$ . Indeed, this reduction is needed to ensure that we get consistent results on computing the quantity  $\text{Tr}[\rho(t)]^{n-2} \text{Tr}[\rho(t)^2] = \text{Tr}[\rho(t)^2]$  using a general  $P_{2n}$ . Hence, the subspaces spanned by configurations of such pairs  $\{\sigma, \tilde{\sigma}\}\$ are closed under the action of  $P_{2n}$ . Following the discussion in the  $n = 2$  case in Sec. [IV A,](#page-7-0) we have eigenstates of  $P_{2n}$  approximately given by plane waves of domain walls between each  $\sigma$ and  $\tilde{\sigma}$ , with the same dispersion relations as those found in Fig. [5.](#page-8-12) However, the action of  $P_{2n}$  on permutations  $\sigma$ ,  $\tilde{\sigma}$  with  $d(\sigma, \tilde{\sigma}) > 1$  is not as simple as [\(66\)](#page-13-1), and this complicates their analysis, as we discuss below.

Recall from [\(18\)](#page-5-2) that the final state that appears in the expression for  $e^{-(n-1)S_n(x,t)}$  is  $\langle \eta ... \eta_x e_{x+1} ... e |$ , where  $\eta = (n \ n-1 \ n-2 \ldots)$ . Since  $d(\eta, e) > 1$  for  $n > 2$ , it turns out that the subspace spanned by configurations of  $\langle \eta |$  and  $\langle e |$  is not closed, and there is no exact eigenstate of  $P_{2n}$  consisting only of  $\langle \eta |$  and  $\langle e|$ .

To analyze this case, let us start with the following variational ansatz for the excitations of  $P_{2n}$  in the sector with  $|\eta\rangle ... |\eta\rangle$  towards the left boundary and  $|e\rangle ... |e\rangle$ 

<span id="page-13-3"></span>FIG. 9. Convergence with  $\Delta$  of the dispersion relation  $E_n(k)$ for  $n = 3$  in the local GUE model, for  $q = 3$  (top) and  $q = 10$ (bottom). For  $q = 10$ , the curves from  $\Delta = 2$  to  $\Delta = 4$  are almost coincident.

states towards the right boundary<sup>[17](#page-13-2)</sup>

<span id="page-13-4"></span>
$$
|\psi_k\rangle \approx \sum_x e^{-ikx} |\eta...\eta_x\rangle |\phi\rangle_{x+1,...x+\Delta} |e_{x+\Delta+1}...e\rangle ,
$$
\n(67)

where  $|\phi\rangle_{x+1,...x+\Delta}$  is some state in the  $(n!)^{\Delta}$ dimensional Hilbert space consisting of all possible permutation states on  $\Delta$  sites. Like in Sec. [IV,](#page-6-0) we minimize the expectation value  $\langle \psi_k | P_{2n} | \psi_k \rangle$  over all possible choices of  $|\phi\rangle$  for increasing values of  $\Delta$ , and check whether the resulting estimate for the dispersion relation converges with  $\Delta$ . We show the results of this procedure for  $n = 3$  with  $\Delta$  from 0 to 4 in Fig. [9.](#page-13-3) We find rapid convergence for  $\Delta \geq 2$  for all values of q. Like in the case of  $P_2$ , the convergence with  $\Delta$  is increasingly fast for larger  $q$ . We therefore learn that the lowest energy

<span id="page-13-2"></span><sup>17</sup> We look for eigenstates which asymptotically have this form so that they have non-negligible overlap with the final state in the expression for  $e^{-(n-1)S_n(x,t)}$ .

excitations in the relevant sector are well-approximated by [\(67\)](#page-13-4) for  $O(1)$   $\Delta$ .

Let us now discuss the consequences of [\(67\)](#page-13-4) for the time-evolution of the *n*-th Renyi entropy. For general  $n$ , it is useful to define the domain wall propagator (similar to  $(43)$  as

<span id="page-14-5"></span>
$$
G_n(x, y, t) = \langle \eta ... \eta_x e_{x+1} ... e | e^{-P_{2n}t} | \bar{\eta} ... \bar{\eta}_y \bar{e}_{y+1} ... \bar{e} \rangle
$$
 (68)

where  $|\bar{\sigma}\rangle$  is defined such that

$$
\langle \tau | \bar{\sigma} \rangle = \delta_{\sigma \tau} \,. \tag{69}
$$

We assume that the  $n$ -th Renyi entropy in the scaling limit is well-approximated by

<span id="page-14-0"></span>
$$
e^{-(n-1)S_n(x,t)} = \sum_{y} G_n(x,y,t)e^{-(n-1)S_n(y,t=0)}, \quad (70)
$$

which can be justified by arguments analogous to those below  $(62)$ . Putting  $(67)$  and the corresponding dispersion relation  $E_n(k)$  into [\(70\)](#page-14-0), for an initial state with entropy density s for the n-th Renyi entropy, analogous to  $(53)$ , we find

$$
e^{-(n-1)S_n(x,t)} =
$$
  

$$
e^{-(n-1)s(x+\frac{L}{2})} \int_{-\infty}^{\infty} dv \int_{-\pi}^{\pi} \frac{dk}{2\pi} e^{-[E_n(k)+ikv-(n-1)sv]t}
$$
  
(71)

The saddle-point equations for  $v$  and  $k$  are

$$
k = -i(n-1)s \ , \quad E'_n(k) = -iv \tag{72}
$$

which lead to the following growth rate for the *n*-th Renyi entropy:

<span id="page-14-1"></span>
$$
\bar{\Gamma}_n(s) = \frac{E_n (k = -i(n-1)s)}{s_{\text{eq}}(n-1)}.
$$
\n(73)

An example of  $\overline{\Gamma}_n(s)$  from [\(73\)](#page-14-1) for  $n = 3$  and  $q = 8$ (with  $\Delta = 4$ ) is shown in Fig. [10.](#page-15-0) Again, we find this function by fitting  $E_3(k)$  to the form [\(63\)](#page-11-3). The figure also shows  $\Gamma_2(s)$  for the second Renyi entropy from the dispersion relation  $E_2(k)$  for the same value of q. We see that while  $\Gamma_2(s)$  obeys the condition [\(8\)](#page-2-7) needed to ensure that  $S_2(x,t)$  of the equilibrium state should not grow, the curve for  $\bar{\Gamma}_3(s)$  appears to not obey this condition. This implies it gives the unphysical prediction that the  $S_3(x,t)$  of the equilibrium state increases rapidly. By similar reasoning to the discussion around  $(60)$ , we know that this prediction cannot be correct.

In the above discussion, we made the approximation  $e^{-P_{2n}t} \approx \sum_{k} e^{-E_3(k)t} |\psi_k\rangle \langle \psi_k|$  in the expression for  $e^{-(n-1)S_n}$ , for  $|\psi_k\rangle$  from [\(67\)](#page-13-4). The above unphysical conclusion must be prevented by contributions to  $e^{-(n-1)S_n}$ from a different set of energy eigenstates which we have not taken into account. We now conjecture a possible structure of these other eigenstates which can give a simple resolution of the above issue.

Recall from the discussion around [\(66\)](#page-13-1) at the beginning of this section that domain walls between permutations of Cayley distance 1 can still be thought of as elementary excitations of  $P_{2n}$  for  $n > 2$ , although these eigenstates would have a very small overlap with the final state  $\langle \eta ... \eta_x e_{x+1} ... e |$ . A natural guess for a "multiparticle" version of these elementary excitations, which would have significant overlap with the final state, would be of the approximate form

$$
\sum_{x_1 \leq \ldots \leq x_{n-1}} e^{-i(k_1 x_1 + \ldots k_{n-1} x_{n-1})}
$$
\n
$$
|\eta \ldots \eta_{x_1} \eta_{x_1+1}^{(n-1)} \ldots \eta_{x_2}^{(n-1)} \eta_{x_2+1}^{(n-2)} \ldots \eta_{x_3}^{(n-2)} \ldots e_{x_{n-1}+1} \ldots e\rangle
$$
\n
$$
(74)
$$

where we have defined

<span id="page-14-2"></span>
$$
\eta^{(k)} \equiv (k k - 1 \dots 1). \tag{75}
$$

Since  $(74)$ has the structure of a state of  $n-1$  free particles, we would expect the energies of the states [\(74\)](#page-14-2) to be  $\sum_{i=1}^{n-1} E_2(k_i)$ , where  $E_2(k)$  is the dispersion relation found numerically for the second Renyi entropy in Sec. [IV A 3.](#page-10-4) We can check numerically that  $E_3(k)$  obtained from the variational calculation in Fig. [9](#page-13-3) is smaller than the energies of these hypothetical states with free single-transposition domain walls:

$$
E_3(k) < \min_{k_1, k_2 \text{ s.t. } k_1 + k_2 = k} (E_2(k_1) + E_2(k_2)) \, . \tag{76}
$$

<span id="page-14-6"></span>This can be interpreted as the result of an attractive interaction between the single-transposition domain walls, which causes the lowest-energy eigenstates in the relevant sector to be "bound states" of  $n-1$  elementary domain walls of the form  $(67)$ . A similar attractive attraction was also argued for using different techniques in random unitary circuits [\[16\]](#page-21-8).

Even though the lowest excitations are "bound states," states of the form [\(74\)](#page-14-2) may still be present as higher excited states in the spectrum of  $P_{2n}$ . We will assume this in the rest of the discussion.  $18$  Such states would give a contribution  $G_2(x, y, t)^n$  to the domain wall propagator  $G_n(x, y, t)$ , which would be added to contribution from the states [\(67\)](#page-13-4).

By putting this into the expression for  $S_3$ , we would get a sum of two terms:

$$
e^{-2S_3(x,t)} = e^{-2s_{\text{eq}}\bar{\Gamma}_3(s)t} + e^{-2s_{\text{eq}}\Gamma_2(s)t} \tag{77}
$$

From the competition between the two terms, the true growth rate for the third Renyi entropy at late times is given by

<span id="page-14-4"></span>
$$
\Gamma_3(s) = \min\left(\bar{\Gamma}_3(s), \Gamma_2(s)\right). \tag{78}
$$

<span id="page-14-3"></span><sup>18</sup> It would be challenging to numerically check that these states are present in the spectrum by exact diagonalization due to the large on-site Hilbert space dimension of the superhamiltonian, which allows us to access only small system sizes. However, we comment on other methods that can be used to check this in the Discussion.

<span id="page-15-0"></span>FIG. 10. We show the naive growth rate  $\Gamma_3(s)$  from [\(73\)](#page-14-1) alongside  $\Gamma_2(s)$  from the dispersion relation for  $n = 2$ . The vertical lines mark the various significant values of s discussed in the text, and the horizontal one marks  $\Gamma(s) = 0$ . In particular,  $\Gamma_3(s_{\text{eq}}) \neq 0$ , which leads to an unphysical prediction of growth of  $S_3(x, t)$  in an equilibrium state.

At the critical value  $s = s^*$  where  $\bar{\Gamma}_3(s)$  and  $\Gamma_2(s)$  cross (see Fig. [10\)](#page-15-0), [\(78\)](#page-14-4) implies a first-order phase transition in  $\Gamma_3(s)$ . For  $s > s^*$ ,  $\Gamma_3(s) = \Gamma_2(s)$ , so that in particular the constraint  $(8)$  is satisfied. We show the particular case  $q = 8$ , but we find that the curves cross at all values of q that we checked, from  $q = 3$  to  $q = 10$ . The ratio  $s^*/s_{\text{eq}}$  appears to increase monotonically with q.

Using the general formula  $(56)$ , we can find the membrane tension  $\mathcal{E}_3(v)$  as the Legendre transform of  $-\Gamma_3(s)$ . Assuming [\(78\)](#page-14-4), there are three possible sources of the maximum value in the Legendre transform: it could come either from the region  $0 \leq s < s^*$ , where  $\Gamma_3(s) = \overline{\Gamma}_3(s)$ , or from the endpoint at  $s = s^*$ , or from the region  $s > s^*$ . We find three distinct regimes for the behaviour of  $\mathcal{E}_3(v)$ depending on which of these options dominates:

<span id="page-15-2"></span>
$$
\mathcal{E}_3(v) = \begin{cases} \bar{\mathcal{E}}_3(v) & v \le v_1^* \\ \bar{\Gamma}_3(s_*) + \frac{s^*}{s_{\text{eq}}} v & v_1^* \le v \le v_2^* \\ \mathcal{E}_2(v) & v \ge v_2^* \end{cases}
$$
(79)

Here  $\bar{\mathcal{E}}_3(v)$  is the Legendre transform of  $-\bar{\Gamma}_3(s)$  restricted to the regime  $s < s_c$  where it is convex <sup>[19](#page-15-1)</sup>, and  $s_c$  is the value of s at which the second derivative of  $\bar{\Gamma}_3$  changes from negative to positive.  $\mathcal{E}_2(v)$  is the membrane tension for the second Renyi entropy found previously. The two critical velocities are

$$
v_1^* = -s_{\text{eq}} \Gamma_3'(s_c), \quad v_2^* = -s_{\text{eq}} \Gamma_2'(s^*).
$$
 (80)

<span id="page-15-3"></span>FIG. 11. Top: The solid blue curve shows  $\mathcal{E}_3(v)$  from [\(79\)](#page-15-2) for  $q = 8$ .  $\mathcal{E}_2(v)$  is also shown with the dashed orange curve for comparison. Bottom: We show the derivative  $\mathcal{E}'_3(v)$ , which has a discontinuity at  $v = v_1^*$  and is continuous but not differentiable at  $v = v_2^*$ .

In Fig. [11,](#page-15-3) we show the membrane tension of [\(79\)](#page-15-2) obtained from  $\bar{\Gamma}_3(s)$  and  $\Gamma_2(s)$  of Fig. [10,](#page-15-0) and its first derivative. The membrane tension has a first-order phase transition at  $v = v_1^*$ , and a second-order phase transition at  $v = v_2^*$ .

We now make a brief technical note on the difference of the analysis we used above from the  $n = 2$  case. In this discussion of this section, we did not directly use the domain wall propagator [\(68\)](#page-14-5) to derive the membrane tension, but instead found it indirectly as the Legendre transform of  $-\Gamma_3$ . The form of the dispersion relation  $E_3(k)$  is such that the domain wall propagator from the states [\(67\)](#page-13-4),

$$
\bar{G}_3(x, y, t) = \int_{-\pi}^{\pi} \frac{dk}{2\pi} e^{-(E_3(k) + ikv)t}, \qquad (81)
$$

can be used to obtain the membrane tension  $\bar{\mathcal{E}}_3(v)$  only up to  $v_1^*$  by similar steps to [\(47\)](#page-8-11). For  $v > v_1^*$ , the propagator has an oscillating behaviour with time due to a change in the structure of the solutions to the saddle-

<span id="page-15-1"></span><sup>&</sup>lt;sup>19</sup> Note that the Legendre transform of the full function  $-\bar{\Gamma}_3(s)$  is not well-defined as it is not convex.

point equation  $E'_3(k) = -iv$ . The propagator in this regime  $v > v_1^*$  does not contribute to the evolution of the entropy in the combined saddle-point analysis in the integral over v and k for  $e^{-2S_3}$ . From the saddle-point equations [\(71\)](#page-14-6), we get a well-defined result for  $\bar{\Gamma}_3$  for any s. The Legendre transform of  $-\bar{\Gamma}_3$  by itself is again not well-defined beyond  $v_1^*$ , but the Legendre transform of the negative of [\(78\)](#page-14-4) is well-defined, as discussed above, and this should be seen as the definition of the membrane tension for this case. [20](#page-16-1)

In [\[16\]](#page-21-8), the membrane tension for the third Renyi entropy was studied for random unitary circuits. The calculations in that context, which were done in expansions for large  $q$  and large  $v$ , also gave indication of a phase transition in  $\mathcal{E}_3(v)$ . The physical mechanism suggested for the "unbinding" phase transition there appears similar to the one discussed here. From the calculations in the present model at finite  $q$  and general  $v$ , we see that there are two phase transitions in  $\mathcal{E}_3(v)$ . Unlike in the large q random circuit calculation of  $[16]$ , where the critical velocity appeared to be  $v_B$ , we find that both critical velocities are smaller than  $v_B$  at finite q.

### <span id="page-16-0"></span>V. BROWNIAN MODELS WITH FIXED COUPLING OPERATORS

Let us now consider the family of models in  $(16)$ , where the coupling coefficients  ${J_{\alpha}(t)}$  are random and uncorrelated, but the operators  ${B_\alpha}$  are fixed and act on a system with a *q*-dimensional on-site Hilbert space. This is a less random and hence more realistic example of a chaotic system than the one considered in Sec. [IV.](#page-6-0)

The superhamiltonian  $(21)$  for this case still has the property that any of its terms  $P_{2n,\alpha}$  that has support on m sites annihilates configurations of the form  $|\sigma\rangle^{\otimes m}$ on those sites for any  $\sigma \in \mathcal{S}_n$ . This implies that the states [\(31\)](#page-6-6) are still ground states in this case. In cases where the time-evolution has no symmetries, we expect that these are generically a complete basis for the ground state subspace, so that the saturation value of  $S_{n,A}(t)$  is given by the Page value [\[44\]](#page-22-4), and  $s_{eq} = \log q$ .

Unlike in the GUE case, the action of a general  $P_{2n,\alpha}$ can now take a general initial state with different permutation states at different sites into the subspace orthogonal to all the permutation states, hence the effective Hilbert space on each site is now  $q^{2n}$ -dimensional, rather than  $n!$  dimensional in the GUE case. However, since the ground states are still of the ferromagnetic form of [\(31\)](#page-6-6), it is natural to once again conjecture that the lowenergy excitations are well-approximated by the struc-ture in [\(11\)](#page-3-0) for  $O(1)$   $\Delta$ , with the state  $|\phi\rangle_{x+1,\dots,x+\Delta}$  now living in the full  $(q^{2n})^{\Delta}$ -dimensional Hilbert space.

Numerically, it is feasible to test the above conjecture using the variational technique of Appendix [D](#page-28-0) up to  $\Delta =$ 3 for  $q = 2$  and  $n = 2$ , where the maximum Hilbert space dimension of the effective Hamiltonian for the variational problem (see Appendix [D\)](#page-28-0) is  $\lesssim 16^3$ . For concreteness, let us take the set of coupling operators to be the following spin- $1/2$  operators in a one-dimensional system of  $L$  sites:

<span id="page-16-2"></span>
$$
\{B_{\alpha}\} = \{X_i, Z_i, Z_i Z_{i+1}\}.
$$
 (82)

Taking the  $g_{\alpha}$  in the variance of the couplings [\(17\)](#page-4-4) to be some positive numbers  $g_X, g_Z, g_{ZZ}$  respectively. In the discussion below, we will fix  $g_X = g_{ZZ} = 1$ , and consider a variety of different values of  $g_Z$ . We expect this timeevolution to be chaotic for generic values of  $g_Z$ , except at the point  $g_Z = 0$ , where the time-dependent Hamiltonian is only a linear superposition of  $\{X_i\}$  and  $\{Z_iZ_{i+1}\}\$ operators and hence has a quadratic (non-interacting) Majorana fermion representation using the Jordan-Wigner transformation.

We show the results of the variational method for this family of models in Fig. [12,](#page-17-1) which confirms the expectation that the eigenstates have the structure [\(11\)](#page-3-0) for generic  $g_Z$ . The dispersion relation in the cases  $g_Z = 1.0$ and  $g_Z = 0.5$  converges rapidly. For  $g_Z = 0.0$ , corresponding to the free fermion case, the dispersion relation shows slower convergence.

The Brownian free Majorana fermion evolution corresponding to  $g_Z = 0$  was previously studied in [\[26\]](#page-21-22), where it was found that  $P_4$  can be mapped to the ferromagnetic Heisenberg model. The ground state subspace for this case is much larger than the one spanned by  $(33)$ , and it has gapless low-energy excitations which lead to a and it has gapless low-energy excitations which lead to a<br>growth of  $S_2$  proportional to  $\sqrt{t}$  rather than t. Hence, the variational ansatz  $(11)$  is likely to not be a good approximation to the true low energy eigenstates for  $g_z = 0.0$ , consistent with our observations.

The closing of the gap of  $P_4$  (or equivalently vanishing of the entanglement velocity  $v_F$ ) can be seen as a precise information-theoretic signature of a transition from chaotic to free-fermion integrable behaviour in this family of models. Any non-zero  $g_Z$  causes the model to lose its free fermion character and recover the general features of chaotic many-body systems, hence opening up a gap in the thermodynamic limit. At finite system size, we expect a crossover from chaotic to integrable behaviour at small  $g_Z$ , similar to the discussion in [\[26\]](#page-21-22).

While we do not have an independent check of the dispersion relations from exact diagonalization of  $P_4$  in the above family of models (due to the large on-site Hilbert space dimension  $q^4 = 16$ , we have performed the following two consistency checks, which verify that the dispersion relation is close to convergence for  $g_Z = 1.0, 0.5$  and far from convergence for  $g_z = 0.0$ :

1. We directly evaluated the amplitude  $e^{-S_2(x,t)}$  =  $\langle D_x | e^{-P_4 t} | \rho_0, e \rangle$  using the TEBD method for imaginary time evolution [\[45\]](#page-22-5) for an initial pure product state  $\rho_0$ . For generic values of  $g_Z$ , we find that

<span id="page-16-1"></span><sup>20</sup> We thank Raghu Mahajan and Douglas Stanford for helpful discussions on the saddle point analysis.

<span id="page-17-1"></span>FIG. 12. We show the dispersion relations obtained for various values of gz from minimizing  $\langle \psi_k|P_4|\psi_k\rangle$  for  $P_4$  corresponding to the couplings [\(82\)](#page-16-2) within the subspace spanned by the ansatz  $|\psi_k\rangle$  of [\(61\)](#page-10-0), with  $|\phi_{x+1,...,x+\Delta}\rangle$  now interpreted as an arbitrary state in the Hilbert space corresponding to four copies of the spin-1/2 Hilbert space of the original system on  $\Delta$  sites. We find rapid convergence of  $E(k)$  with  $\Delta$  for  $g_Z = 1.0$  (left), 0.5 (center), where we should expect the model to be chaotic, and slower convergence for  $g_Z = 0$  (right), where it is integrable. To check the convergence of the gaps  $E_\Delta(k=0)$  for different  $g_Z$ , we can consider the ratio  $r(g_z) = \frac{E_2(k=0) - E_3(k=0)}{(E_1(k=0) - E_2(k=0)})$ . We find  $r(g_z = 1) = 0.078$ ,  $r(g_z = 0.5) = 0.101$ , and  $r(g_z = 0) = 0.515$ , giving better indication of convergence for  $g_Z \neq 0$ .

this quantity has an exponential decay regime for a large range of times, corresponding to linear growth of the entropy. This gives an independent calculation of the entanglement velocity  $v_{E,2}$  defined in the first equation of [\(57\)](#page-9-7), which can be compared to the one found from the gap of the dispersion relation. For  $g_Z = 1.0, 0.5$ , we find good agreement up to about 10% of the values, which are expected from the level of precision on both sides of the calculation. For  $g_Z = 0$ , we do not see a linear growth regime from TEBD.

2. We find the membrane tensions from the  $\Delta = 3$  dis-persion relations in Fig. [13.](#page-17-2)  $\mathcal{E}(v)$  for  $g_Z = 0.5, 0.1$ approximately obeys the constraints [\(4\)](#page-2-2), while the  $q_Z = 0$  case does not.

### <span id="page-17-0"></span>VI. MEMBRANE PICTURE IN GENERAL SPATIAL DIMENSIONS

Let us briefly discuss how the above picture generalizes to higher spatial dimensions  $d \geq 2$ . It is useful to return to the simplest case of the second Renyi entropy in the Brownian GUE model, where the superhamiltonian  $P_4$  in arbitrary dimensions is given by  $(36)$  or  $(38)$ . To find the second Renyi entropy  $S_2(\Sigma, t)$  of a region R with boundary Σ, the final state in  $(18)$  is a domain wall between  $\langle \downarrow |$  and  $\langle \uparrow |$  along  $\Sigma$ , as shown in Fig. [14\(](#page-18-0)a), which we call  $\langle D_{\Sigma}$ . As a first approximation in the large q limit, let us again ignore the  $A_1$  term of  $(36)$ . Even with this simplification, it is not straightforward in to diagonalize  $A_0$  in the subspace relevant for the evolution of  $\langle D_{\Sigma} |$  for  $d \geq 2$ . However, we can obtain an expression for the evolution of  $S_{2,\Sigma}$  for an infinitesimal time-step of length

<span id="page-17-2"></span>FIG. 13. Membrane tensions for the second Renyi entropy for the model of [\(82\)](#page-16-2), obtained from the  $\Delta = 3$  dispersion relations of Fig. [12](#page-17-1) using the fitting to [\(63\)](#page-11-3) with  $N_{\text{max}} =$ 5. The  $g_Z = 1, 0.5$  cases satisfy the constraints to a good approximation up to small numerical errors. We do not expect the  $q_Z = 0$  case to satisfy the constraints since the variational computation of the dispersion relation does not converge for the  $\Delta$  we can access.

 $\delta t$  by noting that

<span id="page-17-4"></span>
$$
\langle D_{\Sigma} | A_0 = \sum_{x \in \Sigma} \left( \langle D_{\Sigma} | -\frac{1}{q} \left( \langle D_{\Sigma + \vec{n}_x} | + \langle D_{\Sigma - \vec{n}_x} | \right) \right) \tag{83}
$$

where  $\Sigma \pm \vec{n_x}$  correspond to inward or outward deformations of  $\Sigma$  by a single lattice site in the direction normal to the surface at  $x^{21}$  $x^{21}$  $x^{21}$  See Fig. [14](#page-18-0) for an illustration in  $d = 2$ . Hence, close to a small segment of the domain wall, the dynamics in higher dimensions resemble

<span id="page-17-3"></span> $^{21}$  We assume that the shape of the initial surface  $\Sigma$  is such that it does not pinch off and split into two domain walls in time  $\delta t$ .

FIG. 14. In (a), we show we label an arbitrary point x on a surface  $\Sigma$  and show the definition of  $\vec{n}_x$ . In (b) and (c), we show the corresponding states  $\langle D_{\Sigma + \vec{n}_x} |$  and  $\langle D_{\Sigma - \vec{n}_x} |$  appearing on the RHS of [\(83\)](#page-17-4).

<span id="page-18-0"></span>

<span id="page-18-4"></span>FIG. 15. In (a), we show an example of how a single domain wall splits under the acting of  $A_1$  in  $d = 2$ . In (b), we show some of the resulting spacetime diagrams which should renormalize the membrane tension.

the one-dimensional dynamics in  $(40)$  in the direction normal to the surface.

Now by linearizing the evolution of  $\mathcal{Z}_{2,\Sigma}(t)$  =  $e^{-S_2(\Sigma,t)} = \langle D_x | e^{-A_0t} | \rho_0, e \rangle$  for a short time  $\delta t$ , we find

<span id="page-18-3"></span>
$$
\frac{\partial \mathcal{Z}_{2,\Sigma}(t)}{\partial t} = \sum_{x \in \Sigma} \left( \mathcal{Z}_{2,\Sigma}(t) - \frac{1}{q} \left( \mathcal{Z}_{2,\Sigma + \vec{n}_x}(t) + \mathcal{Z}_{2,\Sigma - \vec{n}_x}(t) \right) \right)
$$
\n(84)

By taking continuum approximations for the differences and sums in the above expression, we obtain

<span id="page-18-1"></span>
$$
\frac{\partial \mathcal{Z}_{2,\Sigma}(t)}{\partial t} = -\int_{\Sigma} d^{d-1}x \left[ \left( 1 - \frac{2}{q} \right) - \frac{1}{q} \partial_{n_x}^2 \right] \mathcal{Z}_{2,\Sigma}(t) \tag{85}
$$

For the second Renyi entropy, on ignoring a second derivative term  $\partial_{n_x}^2 S_2(\Sigma, t)$  which is negligible in the scaling limit of large system size and late time, [\(85\)](#page-18-1) is equivalent to

<span id="page-18-2"></span>
$$
\frac{\partial S_2(\Sigma, t)}{\partial t} = s_{\text{eq}} \int_{\Sigma} d^{d-1}x \,\Gamma(s(x)) \tag{86}
$$

where

$$
s(x) = \frac{\partial S_2(\Sigma, t)}{\partial n_x}, \quad \Gamma(s) = \frac{1}{s_{\text{eq}}} \left( 1 - \frac{2}{q} - \frac{1}{q} s^2 \right) \quad (87)
$$

As discussed in [\[12\]](#page-21-6), a differential equation of the form [\(86\)](#page-18-2) is equivalent to the membrane formula in arbitrary dimensions with  $\mathcal{E}(v)$  given by [\(56\)](#page-9-10), which for this case is

$$
\mathcal{E}(v) = \frac{1}{s_{\text{eq}}} \left( 1 - \frac{2}{q} + \frac{qv^2}{4} \right). \tag{88}
$$

independent of the spatial dimension  $d$ . In particular, the above series of steps are valid in the case  $d = 1$ , where on comparing to  $(49)$ , we see that we have obtained the membrane tension we would get from taking first the large q and then the small v limit in  $d = 1$ . Recall that in order to satisfy the constraints  $(4)$ , the higher order terms in both  $v$  and  $1/q$  were important. In order to go beyond the quadratic approximation in  $v$ , we would need to find an alternative to taking the continuum limit in  $(84)$ . The higher order corrections in  $1/q$  would come from incorporating corrections from the term in the last line of [\(36\)](#page-7-2), which causes domain walls to split as shown in Fig. [15](#page-18-4) (a), and gives rise to spacetime diagrams like those in Fig. [15](#page-18-4) (b) which should renormalize the membrane tension. These are analogous to the diagrams for  $d = 1$  discussed in Appendix E<sub>1</sub>, which provided an alternative way of understanding corrections to the dispersion relation and membrane tension away from the large q. It would be interesting to quantitatively incorporate the effects of such diagrams and see whether they lead to a dimension-dependent membrane tension, as observed in holographic CFTs [\[17\]](#page-21-9).

Finally, we note that the superhamiltonian  $P_4$  for the GUE model on any lattice in one or higher dimensions is the Peschel-Emery Hamiltonian of Eq. [\(38\)](#page-7-3) on that lattice. For large  $q$ , the low-energy physics of this Hamiltonian is expected to resemble that of the Transverse-Field Ising Model (TFIM) in the presence of a "weak" field of  $O(1/q)$ , which is the Hamiltonian obtained by ignoring the  $O(1/q^2)$  term in Eq. [\(38\)](#page-7-3). Indeed, as discussed in Sec. [IV A,](#page-7-0) many of the properties of  $P_4$  in one dimension are similar to those of the one dimensional TFIM, e.g., the symmetry broken degenerate ground states and the structure of the low-energy domain wall excitations. It is natural to expect similar connections in higher dimensions too at least for large  $q$ , i.e., the entanglement membrane picture in higher dimensions should be related to the low-energy physics of higher dimensional transverse field Ising models in a weak field. It would be interesting to explore this connection in future work.

### <span id="page-19-0"></span>VII. CONCLUSIONS AND DISCUSSION

In this work, we have identified the microscopic mechanism which is responsible for the emergence of the membrane picture of entanglement dynamics in "Brownian" time-evolutions of the form  $(14)$ . The Lorentzian timeevolution of the Renyi entropies in such models can be mapped to a Euclidean evolution by a "superhamiltonian" living on multiple copies of the system. We first considered a maximally random Brownian GUE model in spatial dimension, where we showed that the membrane picture for the second Renyi entropy emerges from the fact that the low-energy excited states of this superhamiltonian take the form of plane waves of certain locally dressed domain walls between  $Z_2$  symmetry broken ground states. We confirmed this structure using analytical perturbative techniques and exact diagonalization, as well as variational numerical techniques for probing the low-energy eigenstates.

We further used the variational techniques to study the third Renyi entropy, and argued that in this case, the membrane tension exhibits a first order as well as a second order phase transition as a function of velocity. Finally, we provided evidence that the same structure of low-energy modes appears in more generic examples of Brownian models, independent of details of the interactions. The membrane tensions in all cases are determined by the dispersion relations of the low-energy modes, and we showed that they satisfy the expected physical constraints. Collectively, these examples provide an understanding of how universality emerges in the late-time dynamics of entanglement entropies in this class of quantum many-body systems.

While the above derivation of the membrane formula from the microscopic dynamics is specific to this particular class of models, it would be interesting to use these lessons to build an effective theory for more general chaotic systems, including fixed Hamiltonians without any randomness. Some motivation that the structure found here should extend to more general systems comes from considering the  $n = 1$  superhamiltonians (living on two copies of the system) in  $U(1)$ -conserving versions of these models, previously studied in [\[30,](#page-21-13) [31\]](#page-21-12). These papers found that the diffusive behaviour of the two-point functions of the charge density comes from certain gapless low-energy eigenstates of the  $n = 1$  superhamiltonian. These gapless excitations can be seen as a precise realization of the hydrodynamic modes which are expected to govern diffusive behaviour of two-point functions much more generally. Alternative approaches which start from the assumption that such gapless modes exist have previously been used to construct effective field theories of hydrodynamics [\[46,](#page-22-6) [47\]](#page-22-7).

It is then natural to ask whether one can formulate an effective field theory for entanglement dynamics based on the set of low-lying modes living on four or more copies that we found in this work. Note that any such effective field theory would need to contain several new elements relative to those developed in earlier works [\[46,](#page-22-6) [47\]](#page-22-7). The modes leading to the membrane picture differ from hydrodynamic modes in that they are not associated with any symmetry of the time-evolution, and are gapped. [22](#page-19-1) Moreover, even above the gap, the dispersion relation at  $O(1)$  values of the momentum k is physically relevant. In particular, since  $s_{eq} = O(1)$ , a small k expansion of the dispersion relation will not satisfy the condition [\(58\)](#page-9-5); this UV sensitivity suggests that the conventional approach of derivative expansions might not be the right way to formulate the relevant EFT.

In holographic theories, the modes that lead to diffusion in the boundary conformal field theory correspond to quasinormal modes in the bulk gravity dual [\[48\]](#page-22-8). Based on the results of this work, it is natural to ask what the analog of these quasinormal modes is for observables like the n-th Renyi entropy and the von Neumann entropy. It would be interesting to identify such modes in the replicated geometries for the n-th Renyi entropy in the prescription of [\[49,](#page-22-9) [50\]](#page-22-10), as well as their analytic continuation to  $n \to 1$ .

In the context of higher Renyi entropies, a better understanding the phase transition that we found in  $\mathcal{E}_3(v)$ is highly desirable. At a technical level, it would be good use the methods of [\[37\]](#page-21-16) for probing multi-quasiparticle excitations to check the existence of the excited states [\(74\)](#page-14-2), which is assumed in obtaining our expression [\(78\)](#page-14-4). At a conceptual level, there are interesting questions about what this phase transition means informationtheoretically. In particular, beyond  $v_2^*$ , we find that  $\mathcal{E}_3(v)$ becomes equal to  $\mathcal{E}_2(v)$ , which in particular implies that  $v_B$  defined through [\(4\)](#page-2-2) is the same for  $n = 2$  and  $n = 3$ . Is there a simple physical reason why the butterfly velocity according to this definition should be the same for all the Renyi entropies? It would also be good to collect more data on such phase transitions in more general Brownian models and for  $n \geq 4$ , which would require technical improvements to the variational methods used in this work, for instance by combining them with a matrix product state (MPS) ansatz (see  $[51]$  for a review). The physical existence of these transitions in generic non-Brownian models or time-independent systems should also be verified more carefully, for example using direct computations of the entropies.

The methods developed in [\[37\]](#page-21-16) and their extensions could also be useful for a number of related questions. Recall that in the large  $q$  limit, to show the membrane picture for multiple intervals even for the second Renyi

<span id="page-19-1"></span><sup>22</sup> The fact that the modes are gapped is needed to ensure exponential decay of  $e^{-(n-1)S_n}$ , or equivalently linear growth of the entropies.

entropy, we used the fact that multiple domain walls were essentially non-interacting in this limit. For the membrane picture for multiple intervals to be robust at finite  $q$ and in more general cases, the quasiparticles consisting of dressed domain walls should be weakly interacting, which can be checked using such numerical methods. Higher dimensional generalizations of these methods could also be useful in understanding the physical picture for entanglement growth in higher dimensional systems, which were discussed in Section [VI.](#page-17-0)

It is important to understand how the physical picture of this work is modified in cases where the system has conservation laws. The simplest such case one can consider is to take Brownian models like the ones studied in this work with an additional  $U(1)$  conservation law. Renyi entropies in systems with  $U(1)$  conservation are said to show a  $\sim \sqrt{t}$  growth [\[52](#page-22-12)[–54\]](#page-22-13), however a universal underlying mechanism and the extent to which these results hold [\[55,](#page-22-14) [56\]](#page-22-15) is still not clear. In this case, there is an interesting and rather intricate coupling between the domain wall degrees of freedom discussed in this work, and the hydrodynamic degrees of freedom associated with the conserved charge density. We plan to report these on results in upcoming work.

This interplay between the entanglement domain walls and hydrodynamic modes can also be explored for a variety of other symmetries, such as dipole or multipole conservation [\[57](#page-22-16)[–59\]](#page-22-17), or other unconventional symmetries such as quantum many-body scars [\[60,](#page-22-18) [61\]](#page-22-19) and Hilbert space fragmentation [\[39,](#page-21-21) [62\]](#page-22-20), hydrodynamic modes of which were derived using the  $n = 1$  superhamiltonian in [\[30,](#page-21-13) [31\]](#page-21-12).

The superhamiltonians found in this work govern the evolution not only of the Renyi entropies, but also of other interesting dynamical quantities that probe chaos and thermalization. In particular, the out-of-timeordered correlator (OTOC) can also be written as a transition amplitude under  $P_4$ :

$$
\begin{aligned} \text{OTOC}(x, y, t) &= \text{Tr}\big[V_x(t)W_y^\dagger V_x(t)W_y^\dagger\big] \\ &= \langle W_y, \eta|e^{-P_4\,t}|V_x, e\rangle \,. \end{aligned} \tag{89}
$$

where we use the notation of Sec. [II,](#page-4-0) and x and y are the spatial locations of the two operators. By putting the eigenstates of  $P_4$  that we found in  $(11)$  into this expression, we obtain the following expression for the OTOC, previously noted in [\[38,](#page-21-20) [63\]](#page-22-21) (assuming that  $y > x$ , and after an average over unitary rotations of the operators  $V_x, W_y$ , which allows us to write the boundary conditions for this quantity in terms of  $|\uparrow\rangle$ ,  $|\downarrow\rangle$  [\[38\]](#page-21-20)):

<span id="page-20-3"></span><span id="page-20-1"></span>
$$
\text{OTOC}(x, y, t) = \sum_{0 \le v \le \frac{y - x}{t}} e^{-s_{\text{eq}}(\mathcal{E}_2(v) - v)t} \tag{90}
$$

Using the constraints  $\mathcal{E}_2(v_B) = v_B, \mathcal{E}_2(v) \geq v$ , we see that if  $t < (y - x)/v_B$ , then  $v_B$  is included in the sum over v, so that  $\text{OTOC}(x, y, t) \approx 1$ . If  $t > (y - x)/v_B$ , then the OTOC starts to decay, and is dominated by the endpoint contribution from  $v = (y - x)/t$  in [\(90\)](#page-20-3) due to the convexity of  $\mathcal{E}_2(v)$ . By expanding close to  $v = v_B$  and using [\(4\)](#page-2-2), we find the diffusive broadening of the operator front first noted in  $[14, 15]$  $[14, 15]$ :

<span id="page-20-4"></span>
$$
\text{OTOC}(t) \approx \exp\left(-\frac{1}{2}\mathcal{E}_2''(v_B)\frac{(y-x-v_Bt)^2}{t}\right) \tag{91}
$$

A particular case where this structure should applyis in the Brownian SYK model [\[20,](#page-21-23) [21\]](#page-21-24). In this model, there is an alternative effective description in a certain large N limit in terms of collective degrees of freedom known as "scramblons." The diffusive broadening [\(91\)](#page-20-4) is very non-trivial to derive from the Feynman diagrams of the scramblon field theory [\[64\]](#page-22-22). It would be interesting to understand how the effective modes found in the present work emerge from the scramblons in the appropriate latetime limit.

Finally, it would be interesting to understand if these modes provide insights into the entanglement dynamics in a variety of other situations, such as with longrange interactions [\[31,](#page-21-12) [65–](#page-22-23)[67\]](#page-22-24), in Clifford circuits [\[68,](#page-22-25) [69\]](#page-22-26), dual unitary circuits [\[70\]](#page-22-27), or in the presence of measurements [\[71\]](#page-22-28).

### <span id="page-20-0"></span>ACKNOWLEDGEMENTS

We thank Henry Lin and Tibor Rakovszky for early collaboration on this work. We are grateful to Hosho Katsura, Shota Komatsu, Marco Lastres, Hong Liu, Frank Pollmann, Xiaoliang Qi, Raghu Mahajan, Mark Mezei, Lesik Motrunich, and Douglas Stanford for useful discussions, Raghu Mahajan for helpful comments on the draft, and Frank Pollmann for helpful numerical suggestions. SM thanks Lesik Motrunich for collaboration on a previous work [\[30\]](#page-21-13), and Marco Lastres and Frank Pollmann for collaboration on an upcoming work. SV is supported by Google. We acknowledge the hospitality of the Yukawa Institute of Theoretical Physics (YITP), Kyoto during the workshop "Quantum Information, Quantum Matter and Quantum Gravity" (YITP-T-23-01), where this work was initiated.

### <span id="page-23-0"></span>Appendix A: Derivation of the equilibrium approximation for Brownian models

In this Appendix, we provide some details of the derivation of the equilibrium approximation for Brownian models, discussed in Sec. [III,](#page-5-0) as well as some explicit examples.

Let us first justify the assumption that the states  $|m_1, ..., m_n; \sigma\rangle$  defined in [\(24\)](#page-5-7) can be treated as orthonormal. First note that since  $\{Q_m\}$  is an orthonormal basis for C, we have  $\langle m'_1, ..., m'_n; \sigma | m_1, ..., m_n; \sigma \rangle = \prod_j \delta_{m_j, m'_j}$ . Next, consider the overlap between states with  $\sigma \neq \tau$ . For  $\sigma, \tau \in \mathcal{S}_n$ , suppose  $\sigma^{-1}\tau$  has k cycles, with lengths  $l_1, ..., l_k$ respectively. More explicitly, say the cycle decomposition is given by

$$
\sigma^{-1}\tau = (a_{1,1}...a_{1,l_1})(a_{2,1}...a_{2,l_2})...(a_{k,1}...a_{k,l_k}).
$$
\n(A1)

Then we have the following general expression for the overlap:

<span id="page-23-1"></span>
$$
\langle m'_1, ..., m'_n; \sigma | m_1, ..., m_n; \tau \rangle = \prod_{i=1}^k \text{Tr} \left[ Q_{m'_{a_{i,1}}}^\dagger Q_{m_{a_{i,1}}} Q_{m'_{a_{i,2}}}^\dagger Q_{m_{a_{i,2}}} ... Q_{m'_{a_{i,l_i}}}^\dagger Q_{m_{a_{i,l_i}}} \right]
$$
(A2)

In most examples of interest, the products [\(A2\)](#page-23-1) for  $\sigma \neq \tau$  are suppressed compared to 1 in powers of the total Hilbert space dimension. For example, in the case with no symmetries, we only have the option  $m = 1$  corresponding to space dimension. For example, in the case with no symmetries, we only have the option  $m = 1$  corresponding to the normalized identity operator  $I/\sqrt{D}$ , and hence the overlap in  $(A2)$  is  $D^{k-n}$ , where D is the total Hilb dimension. Another simple example we can consider is a spin- $1/2$  chain of length L with conserved  $U(1)$  charge  $\sum_{i=1}^{L} Z_i$ . In this case, we can take take a basis for C consisting of projectors onto sectors with different values of the total spin. Let  $P_0$  be the projector  $|0\rangle\langle 0|$  onto the one-site state with spin  $-1$ , and  $P_1$  the projector  $|1\rangle\langle 1|$  onto the state with spin 1. Then we can take the following basis of  $L + 1$  operators for C:

<span id="page-23-3"></span>
$$
Q_m = \frac{1}{\sqrt{\binom{L}{m}}} \sum_{i_1 < \ldots < i_m} \otimes_{k=1}^m (P_1)_{i_k} \otimes_{p \notin \{i_1, \ldots, i_m\}} (P_0)_p \ , \quad m = 0, \ldots, L \ . \tag{A3}
$$

For this case, we can check that  $\langle m'_1, ..., m'_n; \sigma | m_1, ..., m_n; \tau \rangle$  for  $\sigma \neq \tau$  is either exactly zero, or suppressed in powers of  $\binom{L}{m_i}$ ,  $\binom{L}{m'_i}$ , which are typically large.

Based on the above argument, the states  $|m_1, ..., m_n; \sigma\rangle$  can be treated as an approximately orthonormal basis for the ground state subspace for  $P_{2n}$ . Then by putting [\(25\)](#page-6-8) into the expression [\(18\)](#page-5-2) for the Renyi entropy, we find

<span id="page-23-2"></span>
$$
\lim_{t \to \infty} \overline{\text{Tr}[\rho_A(t)^n]} = \sum_{m_1, \dots, m_n; \sigma} \sum_{\sigma} \langle \eta_R \otimes e_{\bar{R}} | Q_{m_1}, \dots, Q_{m_n}; \sigma \rangle \langle Q_{m_1}, \dots, Q_{m_n}; \sigma | \rho_0, e \rangle \tag{A4}
$$

Now suppose that  $\sigma$  has k cycles, and its cycle structure is

$$
\sigma = (b_{1,1}...b_{1,l_1})(b_{2,1}...b_{2,l_2})...(b_{k,1}...b_{k,l_k}).
$$
\n(A5)

Then

$$
\langle Q_{m_1}, ..., Q_{m_n}; \sigma | \rho_0, e \rangle = \prod_{i=1}^k \text{Tr} \Big[ Q_{m_{b_{i,1}}}^\dagger \rho_0 ... Q_{m_{b_{i,l_i}}}^\dagger \rho_0 \Big] \tag{A6}
$$

In the case where  $\rho_0$  is a pure state, the above expression simplifies to

$$
\langle Q_{m_1}, \dots, Q_{m_n}; \sigma | \rho_0, e \rangle = \prod_{i=1}^n \text{Tr} \left[ Q_{m_i}^\dagger \rho_0 \right] \tag{A7}
$$

Combining this with the other factor inside the sum in  $(A4)$ , we find

$$
\lim_{t \to \infty} \overline{\text{Tr}[\rho_R(t)^n]} = \sum_{\sigma} \langle \eta_R \otimes e_{\bar{R}} | \rho^{(\text{eq})}, \sigma \rangle \tag{A8}
$$

with

$$
\rho^{(eq)} = \sum_{m} \text{Tr} \left[ Q_{m}^{\dagger} \rho_{0} \right] Q_{m} . \tag{A9}
$$

In the case with no symmetries,  $\rho^{(eq)}$  is always the infinite temperature density matrix  $I/D$ . In the spin-1/2  $U(1)$ case discussed above, suppose  $\rho_0$  is an initial state with a fixed total spin q. Then using [\(A3\)](#page-23-3),

$$
\rho^{(eq)} = \frac{1}{\binom{L}{q}} \sum_{i_1 < \ldots < i_q} \otimes_{k=1}^q (P_1)_{i_k} \otimes_{p \notin \{i_1, \ldots, i_q\}} (P_0)_p \tag{A10}
$$

which is the maximally mixed density matrix restricted to the spin  $q$  quantum number sector.

### <span id="page-24-0"></span>Appendix B: Details on the Peschel-Emery Hamiltonian

In this section, we will discuss the details of the GUE superhamiltonian  $P_4$  of Eq. [\(36\)](#page-7-2), show the mapping to the Peschel-Emery Hamiltonian of Eq. [\(38\)](#page-7-3), and discuss numerical and analytical methods to probe its low-energy spectrum.

### <span id="page-24-1"></span>1. Mapping to the Peschel-Emery Hamiltonian

For numerical exact diagonalization, it is convenient to work in the orthonormal basis  $\{|\!+\rangle, |\!-\rangle\}$  of Eq. [\(37\)](#page-7-5), instead of the biorthogonal system  $\{|\uparrow\rangle, |\downarrow\rangle, |\downarrow\rangle\}$  of Eqs. [\(34\)](#page-7-6) and [\(35\)](#page-7-7) that are convenient for analytical calculations discussed in this work. In this biorthogonal system, operators can be given the following matrix representation:<sup>[23](#page-24-2)</sup>

<span id="page-24-3"></span>
$$
\widehat{O} = a_{\uparrow\overline{\uparrow}} |\overline{\uparrow}\rangle\langle\uparrow| + a_{\uparrow\overline{\downarrow}} |\overline{\uparrow}\rangle\langle\downarrow| + a_{\downarrow\overline{\uparrow}} |\overline{\downarrow}\rangle\langle\uparrow| + a_{\downarrow\overline{\downarrow}} |\overline{\downarrow}\rangle\langle\downarrow| \iff O^{(\overline{\uparrow}\overline{\downarrow},\uparrow\downarrow)} = \begin{pmatrix} a_{\uparrow\overline{\uparrow}} & a_{\uparrow\overline{\downarrow}} \\ a_{\downarrow\overline{\uparrow}} & a_{\downarrow\overline{\downarrow}} \end{pmatrix}, \quad a_{s'\overline{s}} := \langle s' | \widehat{O} | \overline{s} \rangle, \tag{B1}
$$

whereas in the orthonormal basis of  $(37)$ , the same operator can be represented as:

$$
\widehat{O} = a_{++} + |\lambda| + |a_{+-}| + |\lambda| - |a_{-+}| - |\lambda| + |a_{--}| - |\lambda| + |\iff O^{(+-,+)} = \begin{pmatrix} a_{++} & a_{+-} \\ a_{-+} & a_{--} \end{pmatrix}, \quad a_{ss'} = \langle s | \widehat{O} | s' \rangle. \tag{B2}
$$

The transformation of the vector (matrix) representations of states (operators) between the biorthogonal system and the orthonormal basis can be compactly described as a similarity transformation. Denoting the vector in the basis  $\{|a\rangle, |b\rangle\}$  with a superscript such as  $v^{(ab)}$ , we can use Eq. [\(37\)](#page-7-5) to directly see that

$$
v^{(+-)} = Sv^{(\bar{\uparrow}\bar{\downarrow})}, \quad S = \begin{pmatrix} \frac{1}{\sqrt{2(1+\frac{1}{q})}} & \frac{1}{\sqrt{2(1+\frac{1}{q})}}\\ \frac{1}{\sqrt{2(1-\frac{1}{q})}} & -\frac{1}{\sqrt{2(1-\frac{1}{q})}} \end{pmatrix}, \quad S^{-1} = \begin{pmatrix} \sqrt{\frac{q+1}{2q}} & \sqrt{\frac{q-1}{2q}}\\ \sqrt{\frac{q+1}{2q}} & -\sqrt{\frac{q-1}{2q}} \end{pmatrix}.
$$
 (B3)

This leads to the relation between the matrix representations of an operator  $\hat{O}$  in the biorthogonal system and orthonormal basis as

$$
O^{(+-,+ -)} = SO^{(\bar{1}\bar{\downarrow}, \uparrow \downarrow)}S^{-1}.
$$
\n(B4)

In the biorthonormal basis, the nearest neighbor term of the superhamiltonian  $P_4$  of Eq. [\(36\)](#page-7-2) reads

$$
H_{nn}^{B} = \begin{pmatrix} 0 & 0 & 0 & 0 \\ -\frac{1}{q} & 1 & \frac{1}{q^2} & -\frac{1}{q} \\ -\frac{1}{q} & \frac{1}{q^2} & 1 & -\frac{1}{q} \\ 0 & 0 & 0 & 0 \end{pmatrix},
$$
 (B5)

with basis elements on the rows (columns) ordered as  $\{\uparrow\uparrow,\uparrow\downarrow,\downarrow\uparrow,\downarrow\downarrow\}$  ( $\{\overline{\uparrow\uparrow},\overline{\uparrow\downarrow},\overline{\downarrow\downarrow},\overline{\downarrow\downarrow}\}\rangle$ ). This can be converted into the orthonormal basis ordered as  $\{++, +-, -+, --\}$  using a similarity transformation with the matrix  $S \otimes S$ :

$$
H_{nn}^{O} = (S \otimes S)H_{nn}^{B}(S^{-1} \otimes S^{-1}) = \frac{1}{2} [\mathbb{1} \otimes \mathbb{1} - X \otimes X - \frac{1}{q}(Z \otimes \mathbb{1} + \mathbb{1} \otimes Z) + \frac{1}{q^{2}}(Z \otimes Z + X \otimes X)],
$$
 (B6)

where X, Y, Z are the 2 × 2 Pauli matrices in the  $\{+\}, \{-\}\}$  basis. This leads to the expression of [\(38\)](#page-7-3) for  $P_4$  on any general lattice. This Hamiltonian has exact frustration-free ground states  $|G_{\uparrow}\rangle$  and  $|G_{\downarrow}\rangle$  are of the form of Eq. [\(33\)](#page-7-1), as evident from the fact that  $H_{nn}^O |\uparrow \uparrow \rangle = H_{nn}^O |\downarrow \downarrow \rangle = 0$ . The representation Eq. [\(B8\)](#page-25-2) in the orthonormal basis of [\(37\)](#page-7-5) also clearly reveals the  $Z_2$  symmetry of the system, and that  $|G_1\rangle$  and  $|G_1\rangle$  spontaneously break this symmetry,

<span id="page-24-4"></span>
$$
Q = \prod_{j} Z_{j}, \quad Q |G_{\uparrow}\rangle = |G_{\downarrow}\rangle, \quad Q |G_{\downarrow}\rangle = |G_{\uparrow}\rangle. \tag{B7}
$$

<span id="page-24-5"></span>Eq. [\(B1\)](#page-24-3), and the matrix representation of operators in that system would be related as  $\widehat{O}(\uparrow\downarrow,\bar{\uparrow}\downarrow)=(\widehat{O}(\uparrow\bar{\downarrow},\uparrow\downarrow))^{T}$ .

<span id="page-24-2"></span> $^{23}$  Note that one could also work in a different biorthogonal system obtained by interchanging the  $\{|\bar{\uparrow}\rangle\,, |\bar{\downarrow}\rangle\}$  and  $\{|\uparrow\rangle\,, |\downarrow\rangle\}$  in

Restricted to one spatial dimension with  $L$  sites labelled from 1 to  $L$ , the Hamiltonian of [\(38\)](#page-7-3) reads

<span id="page-25-2"></span>
$$
H = \frac{1}{2} \sum_{j=1}^{L_{max}} \left[ 1 - X_i X_{j+1} - \frac{1}{q} (Z_j + Z_{j+1}) + \frac{1}{q^2} (Z_j Z_{j+1} + X_j X_{j+1}) \right],\tag{B8}
$$

where  $L_{max} = L - 1$  for OBC and  $L_{max} = L$  for PBC. As we now show, this exactly lies on the Peschel-Emery line [\[42,](#page-22-2) [43\]](#page-22-3) in the Ising ferromagnetic phase. This can be explicitly seen in the fermion language using a Jordan-Wigner transformation with the substitutions

<span id="page-25-1"></span>
$$
X_j = (-1)^{\sum_{k < j} n_k} (c_j^\dagger + c_j), \quad Y_j = -i(-1)^{\sum_{k < j} n_k} (c_j^\dagger - c_j), \quad Z_j = -(-1)^{n_j} = 2n_j - 1,\tag{B9}
$$

where  $c_j^{\dagger}$ ,  $c_j$ , and  $n_j := c_j^{\dagger} c_j$  are the fermion creation, annihilation, and number operators. Up to an overall constant of  $(L-1)/2$ , the Hamiltonian of Eq. [\(B8\)](#page-25-2) then maps to the standard form of the Kitaev Hamiltonian, given by Eq. (4) of [\[43\]](#page-22-3):

$$
H_{\text{Kitaev}} = -t \sum_{j} \left( c_j^{\dagger} c_{j+1} + h.c. \right) - \Delta \sum_{j} \left( c_j^{\dagger} c_{j+1}^{\dagger} + h.c. \right) - \frac{\mu}{2} \sum_{j} \left( n_j + n_{j+1} - 1 \right) + U \sum_{j} \left( 2n_j - 1 \right) \left( 2n_{j+1} - 1 \right), \tag{B10}
$$

with the parameters

$$
\Delta = t = \frac{1}{2}(1 - \frac{1}{q^2}), \ \mu = \frac{2}{q}, \ U = \frac{1}{2q^2} \implies \mu = 4\sqrt{U^2 + tU}.
$$
 (B11)

This satisfies the Peschel-Emery condition for having frustration-free exact ground states [\[43\]](#page-22-3). To relate these parameters to the phase diagram of the Kitaev model in Fig. 1 of [\[43\]](#page-22-3), we can use the parametrization

$$
\frac{\mu}{t} = \frac{4q}{q^2 - 1}, \quad \frac{U}{t} = \frac{1}{q^2 - 1}.
$$
\n(B12)

It is clear that this entire line lies in the Ising  $Z_2$  symmetry broken phase, which is also the topological phase in the Kitaev chain. Large q corresponds to the weak interaction limit, and smaller q to stronger interactions. Moreover,  $q = 1$  is a pathological point, since Eq. [\(B8\)](#page-25-2) becomes a commuting projector Hamiltonian with an integer spectrum.

### <span id="page-25-0"></span>2. Low-Energy Excitations from Twisted Boundary Conditions

We now describe a method to numerically study the low-energy excitations of the Peschel-Emery Hamiltonian of Eq.  $(38)$  using exact diagonalization. Since its exact ground states spontaneously break the  $Z_2$  symmetry of Eq.  $(B7)$ , we expect the low-energy excitations to be gapped Domain Walls (DW) between the two ground states of the form [\(61\)](#page-10-0).

A technical obstacle to obtaining the dispersion relation of the low-energy mode with OBC is the boundary condition. While momentum is not well-defined with OBC due to lack of translation invariance in a finite system, PBC forbids single DW excitations just by geometry, i.e., DWs always occur in pairs with PBC. However, the single DW dispersion relation can be probed by imposing symmetry-twisted boundary conditions (also called anti-periodic BCs) by inserting a symmetry flux into the system, which pins the position of one of the DWs while allowing the other DW to move freely.

A standard procedure for inserting a symmetry flux to any symmetric Hamiltonian H with an on-site internal symmetry  $Q = \prod_j g_j$  is described in [\[72\]](#page-22-29), which we summarize here. The chain with PBC is divided into three contiguous parts A, B, C, and the symmetry operations restricted to each part is defined as  $Q_{\alpha} = \prod_{j \in \alpha} g_j$ ,  $\alpha \in$  ${A, B, C}$ . The Hamiltonian is also divided into three disjoint parts  $H = H_{AB} + H_{BC} + H_{CA}$ , where  $H_{\alpha\beta}$  for  $\alpha, \beta \in \{A, B, C\}$  only contains terms that are completely within the region  $\alpha \cup \beta$ . The twisted Hamiltonian is then given by  $H_{tw} = Q_A H_{AB} Q_A^{\dagger} + H_{BC} + H_{CA}$ . Since the terms of H that are completely within or completely outside of the region A commute with  $Q_A$  (due to its on-site structure), the addition of a symmetry flux only changes the Hamiltonian terms that straddle A and B.

While the twisting breaks the translation symmetry of the system, it preserves a twisted translation symmetry, given by the operator  $T_{tw}$ , which satisfies  $T_{tw}^L = Q$ , where Q is the symmetry operator. The eigenstates of H can hence be labelled by a momentum w.r.t. the twisted translation operator, in particular the symmetry sector corresponding to symmetry Q eigenvalue  $e^{i\theta}$  splits into L sectors labelled by twisted momenta  $k \in (2\pi\mathbb{Z}+\theta)/L$ . For large enough system

sizes, we expect the low-energy excitations of the system with twisted BCs, which are single DWs, matches that of OBC, which are also single DWs. However, the correspondence is not one to one, for example, the symmetry-broken ground states of the OBCs are themselves not the ground states of the Hamiltonian with twisted BCs.

Inserting a  $Z_2$  symmetry flux in the PBC Peschel-Emery Hamiltonian of Eq. [\(B8\)](#page-25-2), we obtain the twisted Hamiltonian

<span id="page-26-1"></span>
$$
H_{tw} = \frac{1}{2} \sum_{j=1}^{L-1} \left[ 1 - X_j X_{j+1} - \frac{1}{q} (Z_j + Z_{j+1}) + \frac{1}{q^2} (Z_j Z_{j+1} + X_j X_{j+1}) \right] + \frac{1}{2} \left[ 1 + X_L X_1 - \frac{1}{q} (Z_L + Z_1) + \frac{1}{q^2} (Z_L Z_1 - X_L X_1) \right],
$$
\n(B13)

which has a twisted translation symmetry that satisfies  $T_{tw}^L = \prod_j Z_j$ . Hence we can obtain its eigenstates separately in the  $\prod_j Z_j = +1$  sector, where the momenta are quantized as  $2\pi \mathbb{Z}/L$  and in the  $\prod_j Z_j = -1$ , where the momenta are quantized as  $(2\mathbb{Z}+1)\pi/L$ . It is easy to check that the last term in Eq. [\(B13\)](#page-26-1) has ground states of the form  $\{|\uparrow\downarrow\rangle, |\downarrow\uparrow\rangle\}$  unlike the terms in the sum, which have ground states  $\{|\uparrow\uparrow\rangle, |\downarrow\downarrow\rangle\}$ . Hence in the low-energy spectrum, one DW is pinned to the boundary whereas the other DW can disperse, revealing a clear band of one DW states shown in Fig. [5.](#page-8-12) We have verified that states of similar energies also appear in the spectrum of the OBC Hamiltonian, which shows the correspondence between systems with OBC and twisted BCs. This physics can also be checked in the exactly solvable transverse-field Ising model in the ferromagnetic phase.

### <span id="page-26-0"></span>3. Analytical Estimate of the Dispersion Relation

In this section, we give an estimate of the dispersion relation in the Peschel-Emery model at finite  $q$  by evaluating its expectation value in the state [\(61\)](#page-10-0) with  $\Delta = 0$ . This calculation can be done semi-analytically, and gives a reasonable estimate for the exact dispersion relation. We also show that the corresponding variance is small for large q.

The simplest expression for a single DW state is obtained by setting  $\Delta = 0$  in Eq. [\(61\)](#page-10-0):

<span id="page-26-2"></span>
$$
|\psi_n\rangle := \frac{1}{\sqrt{\mathcal{N}_n}} \sum_{x=1}^{L-1} c_{n,x} |D_x\rangle, \quad \mathcal{N}_n := \sum_{x,x'} c_{n,x}^* c_{n,x'} \langle D_x | D_{x'} \rangle = \sum_{x,x'} c_{n,x}^* c_{n,x'} \frac{1}{q^{|x-x'|}}, \quad c_{n,x} = \exp\left(-i\frac{n\pi}{L}x\right) \tag{B14}
$$

where  $|D_x\rangle = |\downarrow \cdots \downarrow_x \uparrow_{x+1} \cdots \uparrow\rangle$ ,  $\mathcal{N}_n$  is a normalization constant, and we have chosen momentum to be quantized in units of  $\frac{n\pi}{L}$ , which is the case with OBC. While  $|\psi_n\rangle$  is not orthogonal to the ground states  $|G_{\uparrow}\rangle$  and  $|G_{\downarrow}\rangle$ , we find that orthonormalizing it does not change the computations below. For these computations, it is convenient to invoke the representation of the Hamiltonian in the non-orthogonal  $\{\bar{\uparrow}, \bar{\downarrow}\}$  basis, which is different from the biorthogonal and the orthonormal basis discussed in Sec. [B 1.](#page-24-1) Following the discussion there, we can derive the matrix representation of the nearest-neighbor term of Eq. [\(B6\)](#page-24-5) in this basis by a simple transformation (which is not a similarity transformation, since the basis is no longer biorthogonal):

<span id="page-26-4"></span>
$$
H_{nn}^{(NO)} = (S^{-1})^T H_{nn}^O S^{-1} \implies \widehat{H}_{nn} = \left(1 - \frac{1}{q^2}\right)^2 (|\overline{\uparrow\downarrow}\rangle\langle\overline{\uparrow\downarrow}| + |\overline{\downarrow\uparrow}\rangle\langle\overline{\downarrow\uparrow}|). \tag{B15}
$$

With this expression, and denoting the Hamiltonian as  $H = \sum_j h_{j,j+1}$ , where  $h_{j,j+1}$  is the nearest-neighbor term, the expectation value of the energy in the state  $(B14)$ :

$$
E_n := \langle \psi_n | H | \psi_n \rangle = \frac{1}{\mathcal{N}_n} \sum_{x, x'} c_{n, x}^* c_{n, x'} \langle D_x | H | D_{x'} \rangle = \frac{1}{\mathcal{N}_n} \sum_{x, x', j} c_{n, x'}^* c_{n, x'} \langle D_x | \hat{h}_{j, j+1} | D_{x'} \rangle,
$$
  

$$
= \frac{1}{\mathcal{N}_n} \sum_{x=1}^{L-1} c_{n, x}^* c_{n, x} \langle \psi | \hat{H}_{nn} | \psi \rangle = \frac{1}{\mathcal{N}_n} \left( 1 - \frac{1}{q^2} \right)^2 \sum_{x=1}^{L-1} c_{n, x}^* c_{n, x} = \frac{L-1}{\mathcal{N}_n} \left( 1 - \frac{1}{q^2} \right)^2.
$$
 (B16)

where in the second line we have used the fact that  $\hat{h}_{j,j+1} |D_x\rangle = 0$  unless  $x = j$ . We numerically observe that it can be written as

<span id="page-26-3"></span>
$$
E_n = \frac{L-1}{\mathcal{N}_n} \left( 1 - \frac{1}{q^2} \right)^2 = 1 - \frac{2}{q + q^{-1}} \cos\left(\frac{n\pi}{L}\right) + \delta_n,
$$
\n(B17)

where  $|\delta_n|$  appears to be of  $O(1/q^3)$  and decreasing with L for the system sizes we can access. As mentioned in Footnote [10,](#page-8-6) this is precisely the "toy" dispersion relation that gives rise to a membrane tension that satisfied the constraints of [\(4\)](#page-2-2). Indeed, the curves shown in Fig. [6](#page-11-0) obtained using the methods of Appendix [D](#page-28-0) for larger values of  $\Delta$  are also well approximated by Eq. [\(B17\)](#page-26-3) with  $\delta_n = 0$ .

To understand why  $\{|\psi_n\rangle\}$  are good trial states, we compute their energy variances, which are given by

$$
\sigma_n^2 := \langle \psi_n | H^2 | \psi_n \rangle - (E_n)^2 = \frac{1}{\mathcal{N}_n} \sum_{x, x'} c_{n, x}^* c_{n, x'} \langle D_x | H^2 | D_{x'} \rangle - (E_n)^2
$$
  
\n
$$
= \frac{1}{\mathcal{N}_n} \sum_{x=1}^{L-1} c_{n, x}^* c_{n, x} \langle D_x | \hat{h}_{x, x+1}^2 | D_x \rangle + \frac{1}{\mathcal{N}_n} \sum_{x=2}^{L-1} (c_{n, x-1}^* c_{n, x} + c_{n, x}^* c_{n, x-1}) \langle D_{x-1} | \hat{h}_{x-1, x} \hat{h}_{x, x+1} | D_x \rangle - (E_n)^2
$$
  
\n
$$
= \frac{1}{\mathcal{N}_n} \left( 1 - \frac{1}{q^2} \right)^2 \sum_{x=1}^{L-1} c_{n, x}^* c_{n, x} - \frac{1}{q \mathcal{N}_n} \left( 1 - \frac{1}{q^2} \right)^3 \sum_{x=2}^{L-1} (c_{n, x-1}^* c_{n, x} + c_{n, x}^* c_{n, x-1}) - (E_n^{(var)})^2
$$
  
\n
$$
= \frac{L-1}{\mathcal{N}_n} \left( 1 - \frac{1}{q^2} \right)^2 \left[ 1 - \frac{2(L-2)}{q(L-1)} \left( 1 - \frac{1}{q^2} \right) \cos \left( \frac{n\pi}{L} \right) - \frac{L-1}{\mathcal{N}_n} \left( 1 - \frac{1}{q^2} \right)^2 \right],
$$
\n(B18)

where we have evaluated the various matrix elements using the expressions of  $(B15)$ . Using  $(B17)$ , we further obtain

$$
\sigma_n^2 = E_n \left( \delta_n + \cos\left(\frac{n\pi}{L}\right) \left[ \frac{2}{q+q^{-1}} - \frac{2(L-2)}{q(L-1)} \left( 1 - \frac{1}{q^2} \right) \right] \right) \approx E_n \left( \delta_n + \frac{2}{q^3(q^2+1)} \cos\left(\frac{n\pi}{L}\right) \right),\tag{B19}
$$

where in the last step we have used that L large. Since  $|E_n| \sim O(1)$ , we have that  $\sigma_n^2 \sim O(|\delta_n|)$ , which from our numerical observations is  $O(1/q^3)$  and appears to be decreasing with system size L.

# <span id="page-27-0"></span>Appendix C: Multiple intervals and multiparticle excitations

In the main text, we mostly discuss the evolution of the Renyi entropies for the half line region in one spatial dimension. To distinguish the entanglement dynamics in chaotic systems from that in integrable systems like the quasiparticle model [\[32\]](#page-21-17), it is important to also consider the evolution of the Renyi entropies for multiple intervals [\[33,](#page-21-18) [34\]](#page-21-19). In this appendix, we first briefly review the implications of the membrane picture for regions consisting of one or more intervals from  $[12]$ . We then explain how in the large q limit of the GUE model (Section [IV A 1\)](#page-7-8), these results can be obtained from the structure of the multiparticle excitations of  $A_0$ . A similar picture should hold away from this special limit, as we have shown that the lowest excitations of  $P_4$  are quite generally given by well-defined gapped quasiparticles.

Consider the evolution of the entanglement entropy for a single interval. For simplicity, consider the case where the initial state is a pure product state. In applying the membrane formula for the Renyi entropy  $S_n$  to a finite interval  $[x_1, x_2]$ , we need to consider the minimum over all possible velocities in the two configurations (a) and (b) in Fig. [16.](#page-27-1) From the configurations in (a), we get:

<span id="page-27-1"></span>FIG. 16. Two possible membrane configurations for a single interval.

$$
C_a = t \min_{v_1, v_2} [s_{\text{eq}}(\mathcal{E}_n(v_1) + \mathcal{E}_n(v_2))] = 2t \ s_{\text{eq}} v_{E,n}, \quad v_{E,n} = \mathcal{E}_n(0).
$$
 (C1)

From the configuration in (b), since we must have  $(|v_1| + |v_2|)t = x_2 - x_1$  for the membranes to join together,

<span id="page-27-2"></span>
$$
C_b = \min_{v_1, v_2} s_{\text{eq}} \left[ \left( \mathcal{E}_n(v_1) + \mathcal{E}_n(v_2) \right) \frac{(x_2 - x_1)}{|v_1| + |v_2|} \right] = s_{\text{eq}}(x_2 - x_1), \tag{C2}
$$

where we have used the constraints [\(4\)](#page-2-2) to see that the quantity in [\(C2\)](#page-27-2) is minimized for  $|v_1| = |v_2| = v_B$ . Minimizing between  $C_a$  and  $C_b$ , we see a linear growth of entanglement entropy followed by saturation at the thermal value:

$$
S_n^{\text{int}}([x_1, x_2], t) = \begin{cases} 2ts_{\text{eq}}v_{E,n} & t < \frac{(x_2 - x_1)}{2v_{E,s}}\\ (x_2 - x_1)s_{\text{eq}} & t \ge \frac{(x_2 - x_1)}{2v_{E,s}} \end{cases} \tag{C3}
$$

For R consisting of m intervals  $[x_1, y_1] \cup [x_2, y_2] \cup \cdots \cup [x_m, y_m]$ , we have a minimization over a larger set of configurations, which leads to the following result

<span id="page-28-2"></span><span id="page-28-1"></span>
$$
S_{n,R}(t) = \min_{\gamma \in \mathcal{S}_m} \left[ \sum_{i=1}^m S_n^{\text{int}}([x_i, y_{\gamma(i)}], t) \right].
$$
 (C4)

[\(C4\)](#page-28-1) is always non-decreasing as a function of time, in contrast to the evolution of multiple interval entanglement entropy in the integrable quasiparticle model [\[33\]](#page-21-18).

To derive this formula for the Brownian models of this work, we need understand the structure of the "multiparticle" excitations involving more than one domain wall. We will understand this structure for the simplest case of  $A_0$  from  $(36)$ .

For an initial state with two or more domain walls, the action of  $A_0$  can cause domain walls to annihilate in pairs, and it is useful to divide  $A_0$  into parts  $A_f$  and  $A_c$  as discuss below [\(51\)](#page-9-11). The action of  $A_f$  on the multi-domain wall state  $\langle D_{x_1,...,x_k} |, x_1 < x_2 < ... < x_n$ , is given by

$$
\langle D_{x_1,\dots,x_k} | A_f = \sum_{j=1}^k \left( \langle D_{x_1,\dots,x_k} | -\frac{1}{q} \left( \langle D_{x_1,\dots,x_j+1,\dots,x_k} | + \langle D_{x_1,\dots,x_j-1,\dots,x_k} | \right) \right) \tag{C5}
$$

when all  $|x_i - x_j| > 1$ . If any  $x_i, x_j$  are such that  $|x_i - x_j| = 1$ , the action is such that we can simply delete the terms with any repeated  $x_i$  appearing on the RHS of [\(C5\)](#page-28-2). The action of  $A_c$  is

<span id="page-28-3"></span>
$$
\langle D_{x_1,\dots,x_k} | A_c = -\frac{2}{q} (\delta_{x_1+1,x_2} \langle D_{x_3,x_4,\dots,x_k} | + \dots + \delta_{x_{k-1},x_k} \langle D_{x_1,x_2,\dots,x_{k-2}} |), \quad k \ge 2
$$
 (C6)

An initial state with zero or 1 domain walls is annihilated by  $A_c$ .

Due to  $(C5)$ , eigenstates of  $A_f$  take a simple non-interacting, free fermion-like form of  $(52)$  with energies given by the sum of the one-particle energies in [\(41\)](#page-8-1),  $E(k_1, ..., k_n) = \sum_{j=1}^n E(k_i)$ . Hence, the total propagator can be written as

<span id="page-28-5"></span><span id="page-28-4"></span>
$$
\langle D_{x_1,...,x_n} | e^{-A_f t} | \bar{D}_{y_1,...,y_n} \rangle = \prod_{i=1}^n G(x_i, y_i, t).
$$
 (C7)

where  $G(x_i, y_i, t)$  is the single-particle propagator defined in [\(43\)](#page-8-2).

Consider the evolution of  $S_2$  for a region consisting of m intervals,  $R = [x_1, x_2] \cup ... \cup [x_{2m-1}, x_{2m}]$ . Expanding the evolution under  $A_0$  in the interaction picture, treating  $A_c$  as the interaction, we get

$$
e^{-S_{2,R}(t)_{\text{large}}} = q^L \langle D_{x_1, x_2, ..., x_{2m}} | e^{-A_0 t} | \rho_0, e \rangle
$$
\n
$$
= q^L \langle D_{x_1, ..., x_{2m}} | e^{-A_f t} | \rho_0, e \rangle + \int_0^t dt_1 q^L \langle D_{x_1, ..., x_{2m}} | e^{-A_f t_1} A_c e^{-A_f (t - t_1)} | \rho_0, e \rangle + ...
$$
\n
$$
+ \int_0^t dt_1 \int_0^{t - t_1} dt_2 ... \int_0^{t - \sum_{i=1}^{m-1} t_i} dt_m \langle D_{x_1, ..., x_{2m}} | e^{-A_f t_1} A_c e^{-A_f t_2} A_c ... e^{-A_f (t - \sum_{i=1}^m t_i)} | \rho_0, e \rangle
$$
\n(C9)

We can check from [\(C6\)](#page-28-3) that after  $m+1$  insertions of  $A_c$  at any intermediate times, the state  $\langle D_{x_1,...,x_m} |$  necessarily gets annihilated, so that the interaction picture expansion truncates at  $(C9)$ . Using  $(C7)$ and  $(C6)$ , together with the expression [\(46\)](#page-8-3) for the domain wall propagator, we can show that the sum over the  $m$  terms in [\(C9\)](#page-28-4) leads precisely to the minimization of  $(C_4)$  in the scaling limit.

### <span id="page-28-0"></span>Appendix D: Variational approach for low energy excitations of  $P_{2n}$

In the variational calculations discussed in this work, our goal can be stated as follows: we select some orthonormal basis of candidate states,  $\{|\psi_a\rangle\}$ ,  $a = 1, ..., m$  for some m. We then consider a general state in the subspace spanned

by  $\{|\psi_a\rangle\}$ , i.e.,  $|\psi\rangle = \sum_a c_a |\psi_a\rangle$ , and want to minimize the expectation value  $\langle \psi | H | \psi \rangle$  of some Hamiltonian H with respect to the coefficients  $c_a$ , subject to the normalization condition  $\sum_a |c_a|^2 = 1$ . It is easy to see that this minimization problem is equivalent to finding the lowest energy eigenstate of an "effective Hamiltonian" projected to the  $|\psi_a\rangle$  subspace:

$$
(H^{\text{eff}})_{ab} \equiv \langle \psi_a | H | \psi_b \rangle . \tag{D1}
$$

The smallest eigenvalue of  $H^{\text{eff}}$  is the minimized expectation value in the given subspace, and the corresponding eigenvector corresponds to the optimal coefficients  $c_a$ . The calculation shown in Appendix [B 3](#page-26-0) is a trivial  $m = 1$ version of this procedure.

For our Hamiltonian  $P_4$ , we generally look for excitations of the form

<span id="page-29-0"></span>
$$
|\psi_k\rangle = \frac{1}{\sqrt{L}} \sum_{x} e^{-ikx} |\eta\rangle \dots |\eta\rangle_x |\phi\rangle_{x+1,\dots,x+\Delta} |e\rangle_{x+\Delta+1} \dots |e\rangle
$$
 (D2)

It is natural to parameterize the excitations as plane waves due to the translation-invariance of  $P_{2n}$ . For a system with open boundary conditions, this is a natural ansatz in the thermodynamic limit. Taking the form of the excitations to be asymptotically  $|\eta\rangle \cdot |\eta\rangle$  towards the left and  $|e\rangle \cdot |e\rangle$  towards the right ensures that we are in the right sector of the Hilbert space for finding eigenstates of  $P_{2n}$  that contribute to the n-th Renyi entropy of the left half-line. It also ensures that the states we consider have vanishing overlap with any of the ground states in the thermodynamic limit, so that the above minimization procedure will give an estimate of the lowest excited energy with the given momentum, and not the ground state energy.

Now for any given  $\Delta$ , we must find an appropriate orthonormal basis of states of the form [\(D2\)](#page-29-0). Let us start with the simplest non-trivial example of  $\Delta = 2$  for  $P_4$  of the GUE model, where  $|\eta\rangle = q|\downarrow\rangle$ ,  $|e\rangle = q|\uparrow\rangle$ . In this case, the two options  $|\phi\rangle_{x+1,x+2} = |\downarrow\rangle_{x+1} |\uparrow\rangle_{x+2}$  and  $|\phi\rangle_{x+1,x+2} = |\uparrow\rangle_{x+1} |\downarrow\rangle_{x+2}$  span the whole relevant Hilbert space – the other two possibilities are redundant as the the resulting states differ from these cases only by an overall phase in the thermodynamic limit. However, note that the two states

$$
|\psi_k^1\rangle = |\psi_k^{(\downarrow\uparrow)}\rangle = \frac{1}{\sqrt{L}} \sum_{x=1}^{L-1} e^{-ikx} |\downarrow\rangle \dots |\downarrow\rangle_x \; [|\downarrow\rangle_{x+1} |\uparrow\rangle_{x+2}] |\uparrow\rangle_{x+3} \dots |\uparrow\rangle \tag{D3}
$$

<span id="page-29-2"></span><span id="page-29-1"></span>
$$
|\psi_k^2\rangle = |\psi_k^{(\uparrow\downarrow)}\rangle = \frac{1}{\sqrt{L}} \sum_{x=1}^{L-1} e^{-ikx} |\downarrow\rangle \dots |\downarrow\rangle_x \quad |\uparrow\rangle_{x+1} |\downarrow\rangle_{x+2} \quad |\uparrow\rangle_{x+3} \dots |\uparrow\rangle \tag{D4}
$$

are not orthonormal. To find  $H^{\text{eff}}$  in an orthonormal basis, we use the following two steps:

- 1. We find the four matrix elements  $\langle \psi_k^i | P_4 | \psi_k^j \rangle$  directly in the thermodynamic limit. This is easy to do due to the fact that  $\langle ss | (P_4)_{ij} = (P_4)_{ij} | ss \rangle = 0$ , where  $(P_4)_{ij}$  is the nearest neighbor term in  $P_4$ .
- 2. We construct the gram matrix with matrix elements  $\langle \psi_k^i | \psi_k^j \rangle$  semi-analytically for a large value of L and use it to construct an orthonormal basis for the subspace spanned by  $(D3)-(D4)$  $(D3)-(D4)$ . In practice,  $L = 50$  is sufficient for the convergence of the  $O(1)$  coefficients of  $|\psi_k^1\rangle$ ,  $|\psi_k^2\rangle$  in the orthonormal vectors. We then transform  $\langle \psi_k^i|P_4|\psi_k^j\rangle$ found in point 1 to the orthonormal basis to find  $H_{\text{eff}}$ , which is simply a  $2 \times 2$  matrix in this case.

We then plot the lowest eigenvalue of  $H_{\text{eff}}$  obtained for each k to obtain the  $\Delta = 1$  curves in Fig. [6.](#page-11-0) The generalization of this procedure to higher  $\Delta$  for  $P_4$  in the GUE model is straightforward. For the remaining cases of  $P_6$  in the Brownian GUE model and of  $P_4$  in the Brownian mixed field Ising model, again we use the same two steps Let us describe the  $\Delta = 1$  case more explicitly in each case.

For the third Renyi entropy in the GUE model, we need to allow for arbitrary permutations in  $S_3$ . A convenient way to form an orthonormal basis for this case is as follows. Let us label the one-site states associated with permutations other than  $|e\rangle$  and  $|\eta\rangle$  as  $|\sigma_a\rangle$ ,  $a=1, ..., 4$ . First, for each  $|\sigma_a\rangle$ , subtract the components of the state along both  $|\eta\rangle$ and  $|e\rangle$  to get a state  $|\tilde{\sigma}_a\rangle$ . Then find the orthonormal states  $|\tau_a\rangle$ ,  $a = 1, ..., 4$ , in the subspace spanned by  $|\tilde{\sigma}_a\rangle$ . Then for the  $\Delta = 1$  case, the relevant set of five states is

<span id="page-29-3"></span>
$$
|\psi_k^{(\eta)}\rangle = \mathcal{N}(L)\frac{1}{\sqrt{L}}\frac{1}{q^{3L/2}}\sum_{x=1}^L e^{ikx} |\eta\rangle \dots |\eta\rangle_x |\eta\rangle_{x+1} |e\rangle_{x+2} \dots |e\rangle
$$
 (D5)

<span id="page-29-4"></span>
$$
|\psi_k^{(a)}\rangle = \frac{1}{\sqrt{L}} \frac{1}{q^{3L/2}} \sum_{x=1}^L e^{ikx} |\eta\rangle \dots |\eta\rangle_x |\tau_a\rangle_{x+1} |e\rangle_{x+2} \dots |e\rangle, \quad a = 1, ..., 4
$$
 (D6)

Note that we have not included the state with  $|e\rangle$  at x, as this is redundant with the choice [\(D5\)](#page-29-3). The states [\(D6\)](#page-29-4) are already orthonormal among themselves, and orthogonal to  $|\psi_k^{(\eta)}\rangle$  $\langle \binom{n}{k} \rangle$ . The normalization factor  $\mathcal{N}(L)$  in  $|\psi_k^{(\eta)}\rangle$ .  $\binom{n}{k}$  has to be computed numerically, and converges to some  $O(1)$  constant for large enough L. We can then find the matrix elements of  $P_4$  directly in the thermodynamic limit.

For P<sup>4</sup> of [\(21\)](#page-5-4) for the mixed field Ising model couplings in [\(82\)](#page-16-2), we need to consider a 16-dimensional Hilbert space at each site. We can construct an arbitrary one-site orthonormal basis of states  $|a\rangle$ ,  $a = 1, ..., 14$ , which are orthogonal to the permutation subspace spanned by  $|e\rangle$ ,  $|\eta\rangle$ . Then for  $\Delta = 1$ , we can take the orthonormal basis to be

$$
|\psi_k^{(\eta)}\rangle = \mathcal{M}(L)\frac{1}{\sqrt{L}}\frac{1}{q^L}\sum_{x=1}^L e^{ikx} |\eta\rangle \dots |\eta\rangle_x |\eta\rangle_{x+1} |e\rangle_{x+2} \dots |e\rangle
$$
 (D7)

$$
|\psi_k^{(a)}\rangle = \frac{1}{\sqrt{L}} \frac{1}{q^L} \sum_{x=1}^L e^{ikx} |\eta\rangle \dots |\eta\rangle_x |a\rangle_{x+1} |e\rangle_{x+2} \dots |e\rangle, \quad a = 1, ..., 14
$$
 (D8)

where again the normalization factor  $\mathcal{M}(L)$  can be computed numerically for finite L until it converges to some  $O(1)$ number, and the only remaining microscopic inputs needed to compute the matrix elements of  $P_4$  in this basis directly in the thermodynamic limit are the two-site matrix elements such as  $\langle a e | (P_4)_{ij} | b e \rangle$ ,  $\langle \eta a | (P_4)_{ij} | b e \rangle$ , and so on.

### <span id="page-30-0"></span>Appendix E: Arguments using diagrammatic approach in the Brownian GUE model

### <span id="page-30-1"></span>1. Diagrams in interaction picture

In Sec. [IV A 3](#page-10-4) of the main text, we used the structure of the eigenstates for any finite  $q$  to argue that the domain wall propagator, defined as

<span id="page-30-3"></span>
$$
G(x, y, t) = \langle D_x | e^{-At} | \bar{D}_y \rangle \tag{E1}
$$

is given by

<span id="page-30-2"></span>
$$
G(x, y, t) = \int_{-\pi}^{\pi} \frac{dk}{2\pi} e^{-(E(k) + ikv)t} = e^{-s_{\text{eq}}\mathcal{E}(v)t}, \quad v = \frac{x - y}{t}
$$
(E2)

where  $E(k)$  is the exact dispersion relation at finite q, which we obtained numerically. In this appendix, we will use perturbation theory to understand the structure of the diagrams coming from  $A_1$  in [\(36\)](#page-7-2) that correct the large  $q$ propagator from  $A_0$ ,

$$
G_0(x, y, t) = \langle D_x | e^{-A_0 t} | \bar{D}_y \rangle = \int_{-\pi}^{\pi} \frac{dk}{2\pi} e^{-(E_0(k) + ikv)t} = e^{-s_{\text{eq}} \mathcal{E}_0(v)t}.
$$
 (E3)

The resummation of all such diagrams should in principle lead to the exact result  $(E2)$ . Note that we are now using "0" subscripts to denote G, E, and  $\mathcal E$  for  $A_0$  which we found in Sec. [IV A 1,](#page-7-8) to distinguish them from the exact quantities appearing in [\(E1\)](#page-30-3). Quantitatively, the perturbation theory approach is much weaker than the numerical techniques discussed in the main text. In particular, the corrections that we obtain order-by-order in  $1/q$  do not lead to membrane tensions that satisfy the constraints  $(4)$  well at finite q. Moreover, this discussion only applies to  $q \geq 3$ , as the zeroth order Hamiltonian  $A_0$  is gapless for  $q = 2$ . However, one advantage of discussing the diagrams is that they allow us to better explain the connection of our results to the diagrammatic approach used for circuit models in [\[38\]](#page-21-20). The diagrammatic approach in the interaction picture may also be more directly generalizable to higher dimensions than than the dispersion relation approach discussed in the main text.

Let us use the following expansion of the Euclidean time-evolution operator:

<span id="page-30-4"></span>
$$
e^{-P_4t} = e^{-A_0t} - \int_0^t dt_1 e^{-A_0t_1} A_1 e^{-A_0(t-t_1)} + \int_0^t dt_1 \int_0^{t-t_1} dt_2 e^{-A_0t_1} A_1 e^{-A_0t_2} A_1 e^{-A_0(t-t_1-t_2)} + \dots \tag{E4}
$$

Putting this expansion into  $\langle D_x | e^{-P_4 t} | \bar{D}_y \rangle$ , the first term gives the bare propagator  $G_0(x, y, t)$  from the previous section. Recall that the action of  $A_1$  sends a state with one domain wall to a state with three domain walls. For the second term in  $(E_4)$  to contribute to the domain wall propagator, two of the three domain walls created by the action

<span id="page-31-0"></span>FIG. 17. Interaction picture diagrams coming from [\(E4\)](#page-30-4).

Fig. [17](#page-31-0) (a). The resulting contribution to the domain wall propagator is of  $A_1$  must annihilate at an intermediate time  $t_1 + t_1'$  between  $t_1$  and  $t$  due to the action of  $A_c$  defined in [\(C6\)](#page-28-3), see

$$
G(x, y, t) \supset \int_0^t dt_1 \int_0^{t-t_1} dt'_1 \langle D_x | e^{-A_f t_1} A_1 e^{-A_f t'_1} A_c e^{-A_f (t-t_1-t'_1)} | \bar{D}_y \rangle . \tag{E5}
$$

By inserting resolutions of the identity in the energy eigenbasis of  $A_f$  before and after  $A_1$  and  $A_c$ , and doing the integrals over  $t_1'$  and  $t_1$ ,

$$
G(x, y, t) = \int dk e^{-ik(x-y)-E_0(k)t}
$$
  
+ 
$$
\sum_{k, k_1, k_2, k_3} e^{-ik(x-y)-E_0(k)t} \frac{\langle \psi_k | A_1 | \bar{\psi}_{k_1, k_2, k_3} \rangle \langle \psi_{k_1, k_2, k_3} | A_c | \bar{\psi}_k \rangle}{E_0(k) - E_0(k_1, k_2, k_3)} \left( \frac{1 - e^{-(E_0(k_1, k_2, k_3) - E_0(k))t}}{E_0(k_1, k_2, k_3) - E_0(k)} - t \right) + \dots
$$
  
\approx 
$$
\int dk e^{-ik(x-y)-E_0(k)t} (1 - F_1(k)t + \dots), \tag{E6}
$$

$$
F_1(k) = \sum_{k_1, k_2, k_3} \frac{\langle \psi_k | A_1 | \bar{\psi}_{k_1, k_2, k_3} \rangle \langle \psi_{k_1, k_2, k_3} | A_c | \bar{\psi}_k \rangle}{E_0(k) - E_0(k_1, k_2, k_3)}
$$
(E7)

where  $\langle \psi_{k_1,k_2,k_3} |$  was defined in [\(52\)](#page-9-1), and  $| \bar{\psi}_{k_1,k_2,k_3} \rangle$  is defined such that

$$
\langle \psi_{k_1,k_2,k_3} | \bar{\psi}_{k_1,k_2,k_3} \rangle = 1, \quad \langle \psi_{p_1,p_2...p_n} | \bar{\psi}_{k_1,k_2,k_3} \rangle = 0 \quad \text{for } \{p_1,...,p_n\} \neq \{k_1,k_2,k_3\}
$$
 (E8)

In the final expression [\(E6\)](#page-31-1), we have kept only the leading linear-in-t term in the large t limit, ignoring the  $O(1)$  and exponentially suppressed terms. This leading contribution comes from the regime in the diagram Fig. [17](#page-31-0) (a) where  $t'_{1}$  is  $O(1)$ . (The proportionality to t in the second term of [\(E6\)](#page-31-1) comes from the fact that the small bubble of  $O(1)$ size  $t_1'$  can be placed at any value of  $t_1$  from 0 to t.) By summing over the leading contributions at large t from the series of diagrams in Fig.  $18$ , the correction in  $(E6)$  exponentiates to

<span id="page-31-1"></span>
$$
G(x, y, t) = \int dk e^{-ik(x-y) - (E_0(k) + F_1(k))t}
$$
(E9)

+ + + …

<span id="page-31-2"></span>FIG. 18. The set of diagrams which leads to exponentiation of corrections from Fig. [17](#page-31-0) (a).

Similarly, one can check that the leading correction at large  $t$  from the diagram in Fig. [17](#page-31-0) (b), which comes from the third term in  $(E4)$ , is

$$
G(x, y, t) \supset -\int dk e^{-ik(x-y)} e^{-E_0(k)t} (F_2(k)t), \quad F_2(k) = \sum_{k_1, k_2, k_3} \frac{\langle \psi_k | A_1 | \bar{\psi}_{k_1, k_2, k_3} \rangle \langle \psi_{k_1, k_2, k_3} | A_1 | \bar{\psi}_k \rangle}{E_0(k) - E_0(k_1, k_2, k_3)}
$$
(E10)

and exponentiates to give a correction  $F_2(k)$  in the energy. In all, these "renormalize" the bare dispersion  $E_0(k)$  to  $E(k)$ , where

$$
E(k) = E_0(k) + F_1(k) + F_2(k) + \dots
$$
\n(E11)

By extending the same reasoning to higher order terms in the expansion  $(E4)$ , we can see that the exact dispersion relation at finite  $q$  is a resummation of the full set of diagrams in the interaction picture where we have departures from the one domain wall subspace into the multiple domain wall subspace for an  $O(1)$  amount of time at intermediate times. These are precisely analogous to the diagrams considered for circuit and Floquet models in [\[38\]](#page-21-20). Note that the corrections  $F_1(k)$  and  $F_2(k)$  to the dispersion relation  $E_0(k)$  found above can also be independently derived by using a version of Schrodinger picture perturbation theory adapted to the non-Hermitian starting point  $A_0$ .

In the next subsection, we will use a thickened line to denote the exact propagator of  $(E2)$  at finite q, which should now be understood as a sum over the following set of diagrams for  $O(1)$  departures from the one domain wall subspace:

### <span id="page-32-0"></span>2. Argument that configurations where the domain wall splits are subleading for any initial state

Under the action of the full Hamiltonian  $P_4$  in [\(36\)](#page-7-2), a single domain wall state  $\langle D_x |$  can evolve to a state with an arbitrary number of domain walls, so that  $(44)$  for the large q limit should be replaced with the following expression for the exact evolution at finite  $q$ :

<span id="page-32-1"></span>
$$
e^{-S_2(x,t)} = \sum_{y} \langle D_x | e^{-P_4 t} | \bar{D}_y \rangle \langle D_y | \rho_0, e \rangle + \sum_{y_1, y_2, y_3} \langle D_x | e^{-P_4 t} | \bar{D}_{y_1, y_2, y_3} \rangle \langle D_{y_1, y_2, y_3} | \rho_0, e \rangle + \sum_{y_1, \dots, y_5} \langle D_x | e^{-P_4 t} | \bar{D}_{y_1, \dots, y_5} \rangle \langle D_{y_1, \dots, y_5} | \rho_0, e \rangle + \dots
$$
(E12)

where we have inserted a resolution of the identity in the subspace of odd numbers of domain walls to the right of  $e^{-At}$ . Note that for instance  $\langle D_{y_1,y_2,y_3} | \rho_0, e \rangle = e^{-S_2([-\infty, y_1] \cup [y_2, y_3], t=0)}$ .

Using the interaction picture diagrams of the previous section,  $\langle D_x | e^{-P_4 t} | D_{y_1, y_2, y_3} \rangle$  can be expressed as follows in terms of the exact propagator  $G(x - y, t')$ , again up to an overall prefactor which does not have an exponential dependence on t:

$$
\langle D_x | e^{-P_4 t} | \bar{D}_{y_1, y_2, y_3} \rangle = \int_0^t dt_1 \sum_{x_1} G(x - x_1, t_1) G(x_1 - y_1, t - t_1) G(x_1 - y_2, t - t_1) G(x_1 - y_3, t - t_1).
$$
 (E13)

This gives the following contribution to [\(E12\)](#page-32-1), which can be represented by a sum over diagrams shown in Fig. [19](#page-33-1) (a) (for now, let us ignore the dashed line in the figure):

<span id="page-32-2"></span>
$$
e^{-S_2(x,t)} \supset -\frac{1}{q^2} \sum_{y_1, y_2, y_3} \sum_{t_1, x_1} e^{-t_1 s_{\text{eq}} \mathcal{E} \left(\frac{x_1 - x}{t_1}\right) - (t - t_1) s_{\text{eq}} \left[\mathcal{E}\left(\frac{y_1 - x_1}{t - t_1}\right) + \mathcal{E}\left(\frac{y_2 - x_1}{t - t_1}\right) + \mathcal{E}\left(\frac{y_3 - x_1}{t - t_1}\right)\right]} e^{-S_2([- \infty, y_1] \cup [y_2, y_3], t = 0)}
$$
(E14)

If we have a pure product initial state  $\rho_0$  such that the initial value of  $S_2$  for any region is zero, then it is immediately clear that any such contributions where the domain wall splits are exponentially suppressed in time compared to the first term in [\(E12\)](#page-32-1). Even taking into account the contribution from an arbitrary initial state, we can use the convexity of the membrane tensions obtained in Fig. [7](#page-12-0) to show that the first term of [\(E12\)](#page-32-1) dominates, as follows.

Let us fix some arbitrary set of positions  $\bar{y}_1, \bar{y}_2, \bar{y}_3$ . Consider an initial state that is maximally mixed in the region  $[\bar{y}_1, \bar{y}_2]$ , and has maximal entanglement between the degrees of freedom in  $[\bar{y}_2, \bar{y}_3]$  and the degrees of freedom to the left of  $\bar{y}_1$ . See Fig. [19](#page-33-1) (b). For this state, the initial entropy contribution  $S_2([-\infty, y_1] \cup [y_2, y_3], t = 0)$  in [\(E14\)](#page-32-2) is minimized for  $y_1, y_2, y_3 = \bar{y}_1, \bar{y}_2, \bar{y}_3.$ 

<span id="page-33-1"></span>FIG. 19. (a) shows a configuration where the domain wall splits into three, and (b) shows an initial state for which (a) with  $y_1, y_2, y_3 = \bar{y}_1, \bar{y}_2, \bar{y}_3$  minimizes the initial entropy contribution compared to all other configurations where the domain wall splits into three.

Let us now consider the total potential contribution to the  $S_2(x,t)$  from the diagram in Fig. [19](#page-33-1) (a) with  $y_1, y_2, y_3 =$  $\bar{y}_1\bar{y}_2, \bar{y}_3$  for this initial state:

$$
S_{\text{solid}} = s_{\text{eq}} \mathcal{E} \left( \frac{x_1 - x}{t_1} \right) t_1 + s_{\text{eq}} \left[ \mathcal{E} \left( \frac{y_1 - x_1}{t - t_1} \right) + \mathcal{E} \left( \frac{y_2 - x_1}{t - t_1} \right) + \mathcal{E} \left( \frac{y_3 - x_1}{t - t_1} \right) \right] (t - t_1)
$$
(E15)

Let us now compare this contribution to the single domain wall configuration shown with the dashed line (coming from the first term of  $(E12)$ , which contributes

$$
S_{\text{dashed}} = s_{\text{eq}} \mathcal{E} \left( \frac{y_3 - x}{t} \right) t + s_{\text{eq}} (y_2 - y_1) \tag{E16}
$$

Now using the convexity of  $\mathcal{E}(v)$ ,

$$
\mathcal{E}\left(\frac{x_1 - x}{t_1}\right)t_1 + \mathcal{E}\left(\frac{y_3 - x_1}{t - t_1}\right)(t - t_1) \ge \mathcal{E}\left(\frac{y_3 - x}{t}\right)t
$$
\n(E17)

and by similar steps to those leading to  $(C2)$ , by making use of the constraints  $(4)$ ,

$$
\mathcal{E}\left(\frac{y_1 - x_1}{t - t_1}\right)(t - t_1) + \mathcal{E}\left(\frac{y_2 - x_1}{t - t_1}\right)(t - t_1) \ge y_2 - y_1.
$$
\n(E18)

We therefore find that  $S_{\text{dashed}}$  always wins in the minimization problem in the scaling limit. It is clear that if  $S_{\text{dashed}}$ wins even for this choice of initial state, it will also be the dominant contribution for any other choice of initial state.

By a simple extension of this argument, all other diagrams coming from the third and remaining terms in [\(E12\)](#page-32-1) are subleading compared to the first term of  $(E12)$  in the scaling limit.

### <span id="page-33-0"></span>Appendix F: Operator growth interpretation of domain wall splitting

Consider a basis of operators  $O_{\alpha}$  for a single site,  $\alpha = 1, ..., q^2$ , such that  $O_1 = I$ , and satisfying  $\frac{1}{q} \text{Tr}\left[O_{\alpha}^{\dagger} O_{\beta}\right] = \delta_{\alpha\beta}$ . By taking tensor products of these operators, we can also construct a basis  $|O_a\rangle$ ,  $a = 1, ..., q^{2L}$  of operators for the full system, satisfying  $\frac{1}{q^L} \text{Tr}\left[O_a^{\dagger} O_b\right] = \delta_{ab}$ .

Let us introduce the two-copy states  $|O_{\alpha}\rangle$  associated with these operators, such that  $\langle ij|O_{\alpha}\rangle = (O_{\alpha})_{ij}$ . In terms of these states, the four-copy spin states defined in  $(34)-(35)$  $(34)-(35)$  can be shown to be written as

<span id="page-33-3"></span><span id="page-33-2"></span>
$$
|\uparrow\rangle = \frac{1}{q} |I\rangle |I\rangle, \quad |\downarrow\rangle = \frac{1}{q^2} \sum_{\alpha=1}^{q^2} |O_{\alpha}\rangle |O_{\alpha}^{\dagger}\rangle, \tag{F1}
$$

$$
|\bar{\uparrow}\rangle = \frac{1}{q} \left( |I\rangle |I\rangle - \frac{1}{q^2 - 1} \sum_{\alpha=2}^{q^2} |O_{\alpha}\rangle |O_{\alpha}^{\dagger}\rangle \right), \quad |\bar{\downarrow}\rangle = \frac{1}{q^2 - 1} \sum_{\alpha=2}^{q^2} |O_{\alpha}\rangle |O_{\alpha}^{\dagger}\rangle \tag{F2}
$$

It is natural to introduce the notion of a probability that some initial operator A in the full system evolves to some final operator B under the unitary evolution  $U(t)$  [\[14,](#page-21-10) [15,](#page-21-14) [73,](#page-22-30) [74\]](#page-22-31):

$$
P(A \to B, t) = \left| \frac{1}{q^L} \operatorname{Tr} \left[ B^{\dagger} U(t) A U(t)^{\dagger} \right] \right|^2 = \frac{1}{q^{2L}} \left\langle B \left| \left\langle B^{\dagger} \right| \left( U(t) \otimes U(t)^* \right)^{\otimes 2} \left| A \right\rangle \right| A^{\dagger} \right\rangle \tag{F3}
$$

Using  $(F1)$ , for any initial operator A and some position x in the system, we define  $P(A, x, t)$  as

$$
P(A, x, t) \equiv \sum_{O_a \text{ ending to the left of } x} P(A \to O_a, t) = \frac{1}{q^{\frac{L}{2} - x}} \langle D_x | (U(t) \otimes U(t)^*)^{\otimes 2} | A \rangle | A^{\dagger} \rangle \tag{F4}
$$

where " $O_a$  ending to the left of x" means that the  $O_a$  is equal to the identity for all sites to the right of x. This is the total probability that the operator  $A$  evolves to an operator that has support only on the left of  $x$ . Now consider two different kinds of initial operators A from the basis  $O_a$  ending at some point  $y_2$  (meaning that A has a non-trivial operator  $O_\alpha \neq I$  at  $y_2$ , but is equal to the identity everywhere to the right of  $y_2$ ). One type of operator has non-trivial operators at all sites to the left of  $y_2$ , while the other is equal to the identity at some  $y_1 < y_2$  and nontrivial at all other  $y < y_2$ . Consider the quantity  $P_1 - P_2$ , where

$$
P_1 = \langle P(A, x, t) \rangle_{A \text{ ending at } y_2 \text{, identity at } y_1}, \quad P_2 = \langle P(A, x, t) \rangle_{A \text{ ending at } y_2 \text{, non-trivial at } y_1} \tag{F5}
$$

where  $\langle \rangle$  denotes the average over all basis operators  $O_a$  with the property described in the subscript. Using [\(F2\)](#page-33-3),

$$
P_1 - P_2 = q^{x-y_2-1} \langle D_x | (U(t) \otimes U(t)^*)^{\otimes 2} | \overline{\downarrow} \dots \overline{\downarrow}_{y_1-1} \overline{\uparrow}_{y_1} \overline{\downarrow}_{y_1+1} \dots \overline{\downarrow}_{y_2} \uparrow_{y_2+1} \dots \uparrow \rangle
$$
(F6)

In random unitary circuits, since a single domain wall does not split, we have  $P_1 = P_2$ , indicating that the evolution of the endpoint of an operator is independent of its internal structure, which is consistent with a maximally random time-evolution. In the Brownian GUE model,  $P_1 - P_2$  is highly suppressed at late times, but non-zero, indicating that there is some slight sensitivity of the operator growth to the internal structure. However, such effects do not modify qualitative features of the dynamics such as the validity of the membrane picture for the second Renyi entropy.
