ABSTRACT

With dayside temperatures hot enough to sustain a magma ocean and a silicate atmosphere, lava planets are the best targets to study the atmosphere of a rocky world. In the absence of nightside heating, the entire atmosphere collapses near the day-night terminator, so condensation seems inevitable, but the impact of clouds on radiative transfer, dynamics, and observables has not yet been studied in the non-global atmospheric regime. Therefore, we simulate cloud formation and determine which lava planets should be most affected by clouds. We find that despite the scattering of visible light by clouds, heat advection compensates for the cooling effect of clouds in the atmosphere. On the other hand, surface temperatures are significantly affected and can drop 100-200 K under a cloudy sky. We find that among our targets, HD213885b and HD20329b are most affected by cloud formation: there is a discernable difference between having clouds and not having them, but the precision required to make such an inference is at the limit of current instruments.

Keywords: exoplanet, terrestrial, atmosphere, modelling

1. INTRODUCTION

1.1. Background

Hundreds of Earth-sized planets have been discovered (Adams et al. 2021) but inferring their surface and atmospheric properties remains a significant challenge. Our best options for in-depth characterization of rocky planets are currently ultra-short period planets. Phase curves obtained with the Spitzer Space Telescope have enabled tentative inferences of atmospheres on highly irradiated super-Earths K2-141b (Zieba et al. 2022) and 55 Cnc-e (Demory et al. 2016b,a; Mercier et al. 2022).

A more powerful instrument is needed for definitive atmospheric detection and characterization of thin silicate atmospheres. Indeed, the recently launched *James Webb Space Telescope* (JWST) has observed ultra-short period planets K2-141b (Dang et al. 2021; Espinoza et al. 2021) and 55 Cnc-e (Hu et al. 2024), and will observe TOI-561b (Teske et al. 2023) and K2-22b (Wright et al. 2023). Such observations can provide unique clues about terrestrial planet evolution.

Ultra-short period rocky planets with dayside temperatures $>1800\text{K}$ are theorized to harbour a permanent

dayside magma oceans and are often referred to a lava planets. Since the silicate melt is directly exposed to the atmosphere, atmospheric dynamics are intrinsically dependent on interior dynamics (Dorn & Lichtenberg 2021; Kite et al. 2016; Boukaré et al. 2022). Magma oceans are a common result of planetary formation (Schaefer & Elkins-Tanton 2018) and play a critical role in sequestering volatiles (Moore et al. 2023), so lava planets provide a unique window into the early solar system and Earth (Hirschmann 2012; Zahnle et al. 2020). For a complete overview of silicate outgassing and the corresponding chemistry and radiative-convective dynamics, see Wordsworth & Kreidberg (2022).

Tidally locked planets risk having their atmosphere condense out entirely on the permanent nightside (Wordsworth 2015). However, tidally-locked terrestrial planets may sustain a global atmosphere if the initial outgassed atmosphere is thick enough (Joshi 2003). Therefore, general circulation models (GCMs) are adequate for simulating a thick-atmosphere regime for lava planets such as 55 Cnc-e Hammond & Pierrehumbert (2017). A general source of atmospheric circulation on tidally locked planets can be found in Pierrehumbert &

Hammond (2019). Despite such robust work on lava planet atmospheres, the non-global atmospheric regime is less studied and cannot be simulated with a GCM. Two approaches are therefore used to simulate a thin lava planet atmosphere: either focusing on the dayside radiative transfer or the hydrodynamics.

Radiative transfer simulations of lava planets show a silicate atmosphere with a strong vertical temperature inversion (e.g., Ito et al. 2015; Zilinskas et al. 2022; Piette et al. 2023). These studies often find the atmosphere hotter than the surface as heat cannot be advected to cooler regions. On the other hand, hydrodynamical models of non-global atmospheres often simplify, if not outright ignore radiative transfer (e.g., Castan & Menou 2011; Nguyen et al. 2020). However, this method can trace the horizontal heat and mass transport due to day-night winds. Both approaches ultimately lack self-consistent cloud formation which affects both the fluid dynamics and radiative transfer.

1.2. Objective

In anticipation of JWST observations of lava planets, we simulate cloud formation and quantify their effect on thin-atmospheric dynamics and observations. Although there are many published works specific to exoplanet clouds (for a review see Helling 2019), it is impossible to use a sophisticated cloud model within an existing non-global atmosphere modelling framework. We therefore use a simple parameterization of cloud formation consistent with the turbulent boundary layer model of Nguyen et al. (2022) which is the only published work that have coupled radiative transfer with hydrodynamical processes for non-global atmospheres.

We use this model to simulate the atmospheres of five lava planets: K2-141b (Malavolta et al. 2018), TOI-431b (Osborn et al. 2021), HD20329b (Murgas et al. 2022), HD213885b (Espinoza et al. 2020), and 55-cnc e (Winn et al. 2011, but we note that its recently-published eclipse spectrum suggests a volatile-full planet: Hu et al. 2024). The selected candidates have some of the best signal-to-noise ratios for rocky exoplanets and they will likely be observed extensively. Therefore, we compare these lava planets to predict where cloud formation might be expected.

2. METHODS

2.1. The hydrodynamical model

Thin and tenuous atmospheres are common on moons and dwarf planets of the outer solar system. Huge temperature fluctuations on these bodies induce periods and locations of atmospheric collapse and massive surface

outgassing, e.g., on Io (Tsang et al. 2016) or Pluto (Gladstone & Young 2019). Due to the stark changes in fluid regime, it is difficult to implement GCMs and hydrodynamics are best approximated using boundary layer analysis (Ingersoll et al. 1985). Because the atmospheres of lava planets are expected to behave similarly, the same calculations are useful, if not necessary.

The expectation of synchronous rotation due to tidal locking makes lava planets easier to deal with than solar system objects. Having a permanent dayside and nightside allows for steady-state flow. Due to the complexities in handling non-linear terms around evaporation and condensation, we model a pure atmosphere. We are also forced to neglect atmospheric escape which should happen for lighter volatiles (Ito & Ikoma 2021) but is justified if we track heavy molecules like SiO. Finally, we neglect Coriolis force as to preserve the axial symmetry of tidally locked objects. Generally, for planets with rotational period of multiple days, the km/s wind speeds are strong enough to make Coriolis force insignificant (Castan & Menou 2011). However, our targets have a period of ≤ 1 day and so we acknowledge that Coriolis force may play a large role in dynamics but implementing it is beyond our current capability.

By applying the approximations described above, we can construct a framework that describes the flow along the planetary boundary layer. The formulation of the base evaporation-driven flow is akin to the shallow-water equations of Ingersoll et al. (1985). The equations essentially calculate pressure, winds, and temperature of the atmosphere at half the scale height. Detailed formulation can be found in the Appendix.

2.2. Radiative transfer

Our implementation of radiative transfer largely follows Nguyen et al. (2022) and a detailed formulation can be found in the appendix. Nguyen et al. (2022) split up the radiative transfer into three bands (UV, visible, IR) with an averaged absorption cross-section within each band. To improve on this scheme, we now calculate radiative absorption and emission line by line in the spectrum, doing away with averaging spectral bands. We validate our radiative transfer scheme by directly comparing our wind-free silicate atmosphere with Zilinskas et al. (2022). We find that our atmospheric temperatures match well with theirs (within 5%) whereas the old scheme of Nguyen et al. (2022) can be off by up to 25%, especially for hotter and brighter stars.

We adopt the absorption cross-section of SiO from in Yurchenko et al. (2022). As for the stellar spectra, we found proxy analogues in the MUSCLES treasury sur-

veys for K2-141, TOI-431 and 55-Cnc: their closest analogues are HD85512, HD40307, and HD97658, respectively (France et al. 2016). For our targets of HD213885 and HD20329, their properties are closest to the Sun and so we use the solar spectrum; the spectra are shown on the bottom panel of Fig. 1. Absolute magnitude of each analogue’s spectrum is scaled to the target’s effective stellar temperature and orbital distance.

2.3. Cloud implementation

Clouds are abundant on exoplanets but their modelling and detection have largely been confined to hot Jupiters (Demory et al. 2013) and sub-Neptunes (Kreidberg et al. 2014). Some of these clouds likely consist of silicate material like SiO and MgSiO₃ (Powell et al. 2018; Gao et al. 2021). Although lava planets have exotic atmospheric dynamics, their cloud composition is not, at least by the standards of exoplanets. Cloud particles on lava planets may be analogous to dust found on catastrophically evaporating rocky worlds Curry et al. (2024).

Rapid mass exchange between the surface and the atmosphere of a lava planet may lead to meteorological processes driven by the recycling of rocky material between the surface and atmosphere (Boukaré et al. 2022). Volatile components like Na and K may form clouds due to interactions with stellar winds but these light materials are subjected to atmospheric loss (Ito & Ikoma 2021) or freeze out in nightside alkali glaciers (Nguyen et al. 2020).

Because we are focusing on lava planets with Earth-like bulk composition (excluding 55 Cnc-e), we can reasonably assume that volatiles such as water or CO₂ are absent from the atmosphere (cf. Graham et al. 2021). Silicate condensates remain the dominant constituent but if the dew point is too close to the surface, the silicate vapour may not condense midair but simply deposit directly on the surface of the magma ocean (Schaefer & Fegley 2009). We do not know how much of the SiO vapour will condense into cloud particles nor do we know the specific properties of these particles. Since clouds might have significant impact on the atmosphere of a lava planet, ignoring them altogether is not a viable option. We therefore opt to parameterize cloud effects into our hydrodynamical model in the same spirit as how radiative transfer was implemented, i.e., as simply as possible.

As cloud formation is inherently tied to the condensation rate C , we define a cloud optical depth proportional to C : $\tau_c = f_c C$. The dimensionless f_c parameterizes the fraction of condensible material that actually turns into cloud particles as well as the particle properties that

affects optical depth such as particle size and density. Although much nuance is lost in this formulation, current observations only allow us to probe the temperature of the atmosphere and surface. Therefore, our main aim is to estimate how much clouds affect the overall thermodynamics and see if clouds can produce a detectable signal.

By creating and testing a range of f_c , we are essentially inferring how the planet behaves under varying strength of cloud coverage. This helps to identify important aspects such as minimum detectable cloud formation, which planets are most affected by clouds, and direct inference of cloud properties.

We calculate the resultant opacity (ϵ_c) following Eq. 22. Here we make another simplifying cloud assumption: cloud particles scatter visible light isotropically so that half the incident visible stellar light ($F_{*,\text{vis}}$) is reflected upwards when the cloud opacity is 1. This assumes that the clouds are transparent in the IR and that most of the UV is absorbed by the upper levels of the atmosphere. Note that ignoring cloud absorption in the IR neglects their greenhouse effect, removing significant complexities to the system of equations. This yields F_c , the stellar flux that is reflected because of clouds:

$$F_c = \frac{1}{2} \epsilon_c F_{*,\text{vis}}. \quad (1)$$

Because SiO is nearly transparent at the visible wavelengths (Fig. 1), the atmospheric energy balance is unaffected by F_c . However, the surface energy balance is significantly affected as visible light is absorbed entirely by the surface. This stems from treating the surface as a blackbody but is justified in the expected low geometric albedo of magma surfaces (Essack et al. 2020): the surface energy is calculated from the bulk bolometric flux minus stellar radiation absorbed by the atmosphere plus the emissions from the atmosphere minus visible stellar flux that is reflected by clouds minus latent heat when evaporating. The surface energy balance then becomes:

$$\sigma T_s = F_* - F_{\text{stel}} + F_{\text{RC}} - F_c - Q_{\text{lat}}, \quad (2)$$

where σ is the Stefan-Boltzmann constant. The surface temperature, T_s depends on the overlying atmospheric properties and vice versa (i.e. Eq. 9, Eq. 14), coupling the surface and atmosphere. F_* is the bulk stellar flux, F_{stel} is the stellar flux that has been absorbed by the atmosphere, F_{RC} is the thermal emission from the atmosphere, F_c is the stellar flux that was reflected by clouds, and Q_{lat} is the latent heat of vaporization.

Figure 1. *Top:* the absorption cross-section of SiO (Yurchenko et al. 2022). The blue, green, and red show the UV, visible, and IR range. *Bottom:* the normalized flux of each star using close analogues.

2.4. Simulated observations

This subsection will describe how state variables P, V and T , computed as in the Appendix, are used to simulate observations. Because a lava planet’s atmosphere is so thin and does not extend much past the terminator, transmission spectroscopy of the gravitationally bound atmosphere is challenging (Nguyen et al. 2022). We therefore focus on planetary emission. We first calculate the top-of-atmosphere outgoing radiative flux F_{TOA} :

$$F_{\text{TOA}}(\lambda) = \epsilon_{\lambda} B(\lambda, T) + (1 - \epsilon_{\lambda}) B(\lambda, T_s), \quad (3)$$

where the first term is atmospheric emission and the second surface emission. We take into account the adiabatic profile where $T(P)$ is calculated at the pressure where optical depth is $2/3$. For any location θ , the flux can be calculated and so we convert temperature maps into flux maps.

We convert $F_{\text{TOA}}(\theta)$ into a map of co-latitude (α) and longitude (ϕ) assuming polar symmetry about the sub-

stellar point. We then integrate the flux across the visible hemisphere following Cowan & Agol (2008):

$$F_e(\lambda, \zeta) = \int_0^{\pi} \int_{\zeta - \pi/2}^{\zeta + \pi/2} F(\alpha, \phi, \lambda) \sin^2(\alpha) \cos(\phi - \zeta) d\phi d\alpha, \quad (4)$$

where F_e is the emission signal, ζ is the position of the planet in its orbit ($\zeta = 0$ at superior conjunction and $\zeta = \pi$ at inferior conjunction). Keeping λ constant and varying ζ between 0 and 2π yields a phase curve at wavelength λ . Keeping ζ at 0 while varying λ yields the emission spectrum at eclipse.

3. RESULTS

3.1. Output from model

All the equations from the previous section together form a self-consistent model that couples the atmosphere and surface along with rudimentary cloud formation. To simulate our specific targets, we apply the planetary parameters listed in Table 1.

Table 1. System parameters used for the hydrodynamical model. Although these values do not show up in the equations mentioned in the previous section with the exception of g , the orbital properties are needed to calculate the incident stellar flux pattern, $F_*(\theta)$, following Kopal (1954).

Planet Name	Radius (R_E)	Stellar Radius (R_*)	Distance (a/ R_*)	Stellar Temp. (K)	g (m/s^2)	Source
K2-141b	1.54	0.681	2.30	4373	21.8	Barragán et al. (2018)
TOI-431b	1.28	0.731	3.32	4850	18.4	Osborn et al. (2021)
HD20329b	1.72	1.13	3.42	5596	24.6	Murgas et al. (2022)
HD213885b	1.74	1.10	3.93	5978	28.5	Espinoza et al. (2020)
55 cnc e	1.87	0.964	3.52	5317	22.3	Bourrier et al. (2018)

We show the initial results without any cloud formation in Fig. 2. We see that atmospheric pressure is directly related to surface temperature: the hotter the surface, the thicker the atmosphere. However, despite having cooler surface temperature, HD213885b and HD20329b have much hotter atmospheres; they also have stronger winds.

We plot the contributions of all radiative terms in Fig. 3. With the exception of K2-141b, most of the atmospheric absorption is in the UV owing the absorption features of SiO in that range. Most of the radiative cooling occurs in the IR although HD213885b and HD20329b are hot enough to emit significant UV radiation.

Despite the enormous magnitude of the radiative fluxes, incoming and outgoing radiation tend to reach equilibrium: the net radiative balance is 1–2 order of magnitude smaller than each individual radiative terms.

3.2. Results with clouds

To review, we parameterized cloud optical effects using the parameter f_c in the Methods section. Note that our simple implementation of clouds neglect certain feedbacks such as the greenhouse effect of clouds. With the assumption that cloud formation must be proportional to the condensation rate C , optical depth and opacity must subsequently also depend on C . Therefore, f_c acts as a substitute to estimate how much of the condensible material becomes cloud, as well as cloud properties such as droplet size; we explore these properties in the Discussion section.

We restrict f_c between 10^2 – 10^4 ; any lower and cloud effects are negligible across all planets while anything higher will make opacity uniformly 1. Because the SiO vapour absorption is weak in the visible, clouds do not directly affect the radiative budget of the atmosphere

but do so via atmosphere–surface interactions. The biggest impact, therefore, is on the surface energy budget as expected from our formulation (see Eq. 2). We show the condensation rate, optical depth, opacity, and surface temperature of cloudy simulations in Fig. 4.

3.3. Simulated observations

Given a global map for surface and atmospheric temperature, we calculate the outgoing radiative flux at the top of the atmosphere using Eq. 3. We fix the time at eclipse and integrate the flux over the visible hemisphere using Eq. 4 at different wavelength λ to yield Fig. 5.

4. DISCUSSION

4.1. On radiative energy balance

We see that the stellar spectrum predictably dictates how hot the atmosphere gets. Despite the surface of K2-141b receiving more bolometric stellar flux than HD20329b and HD213885b, its atmosphere absorbs less stellar flux as the star K2-141 emits mostly in the visible and IR. Meanwhile, HD213885b and HD20329b absorbs more stellar UV and visible radiation, thus providing more heat to their atmospheres.

The coarser radiative scheme of Nguyen et al. (2022) tended to overestimate UV radiative balance while underestimating the IR. With a finer spectral resolution, we see that UV emission never dominates and that SiO spectral features in the IR are strong enough to emit flux even when the pressure is low.

4.2. Vertical temperature profile

One-dimensional radiative-convective models predict that while the lower silicate atmosphere of lava planets does follow an adiabatic profile, there is a sharp temperature inversion at the top of the atmosphere due to shallow UV penetration in the atmosphere Zilinskas et al. (2022); Piette et al. (2023). Hydrodynamical studies, on the other hand, predict that advection of heat weakens this inversion Nguyen et al. (2022).

Figure 2. State variables half a scale height above the surface for selected lava planets. From top to bottom, the panels show pressure, wind speed, atmospheric temperature, and surface temperature. The solutions end when the flow no longer behaves as a continuous fluid and the calculations break down; this is essentially where horizontal mass advection reach near 0 and the atmospheric collapse is complete. K2-141b has the thickest atmosphere as it receives the most stellar flux and therefore has the hottest surface temperature. However, K2-141b’s atmosphere is significantly cooler than HD213885b and HD20329b as atmospheric temperature is largely dependent on stellar UV flux. The temperature jump for 55 Cnc-e at the edge of the atmosphere can be attributed to a dynamical effect described by [Ingersoll et al. \(1985\)](#) where the air viscosity begin to induce significant heating at certain pressure and temperature levels; the same phenomenon can be seen in [Castan & Menou \(2011\)](#).

Although we adopted an adiabatic vertical temperature profile, we can guess what happens when the vertical temperature lapse rate is inverted. This can be done by increasing the β value (this parameter is calculated from vertical pressure integration in Eq. 17). [Nguyen et al. \(2022\)](#) showed that arbitrarily increasing β leads to stronger horizontal flow but an overall cooler atmosphere. Within the calculations, raising β increases the horizontal pressure gradient force, thus increasing wind velocity, V . However, the energy balance does not change so any gains in the kinetic term, $V^2/2$, translate to a loss in the internal heat term, $C_p T$ (see Eq. 8).

The physical reasoning is that because the atmospheric inversion inhibits mixing, horizontal winds are significantly increased, but since energy must be conserved, the air’s internal heat energy must be lower.

When balancing the incoming radiation in the atmosphere, we find that stellar absorption is comparable to surface blackbody absorption for K2-141b, TOI-431b, and 55 Cnc-e; this suggests a rather isothermal T-P profile as there is as much heat from the top as there is at the bottom. However, for HD213885b and HD20329b, there is significantly more stellar absorption than surface absorption. With significantly more heating from the top, most of which is UV flux, we would expect a strong temperature inversion as predicted by [Zilinskas et al. \(2022\)](#). While we have kept a consistent vertical temperature profile in this study to isolate the effects of clouds, we note that future simulations of lava planets should aspire to use self-consistent vertical profiles given the spectrum of the host star.

4.3. Latent and chemical heat

As the radiative terms tend to cancel out, the net energy budget of the atmosphere is controlled by dynamics terms such as latent heat and sensible heat. We show in Fig. 6 that the latent heat is negligible, as predicted by [Kite et al. \(2016\)](#). Even when coupling the latent heat with the atmosphere where radiative transfer is hampered by the absorption cross-section, latent heating changes the atmosphere by less than 5%. However, K2-141b has a relatively larger condensation rate and a relatively lower radiative absorptivity due to its cooler star; temperatures can increase up to 10% when latent heating is accounted for. Sensible heating is still the main driver of the flow and it is composed of heat flux from two directions: horizontally via flow-induced heat advection and vertically via temperature mixing between the surface and atmosphere.

Although latent heat is relatively small, the vaporization of the surface and subsequent condensation is not a simple phase change. The magma ocean is principally composed of SiO_2 (assuming a Bulk Silicate Earth composition; [Schaefer & Fegley 2009](#)), while the atmosphere contains mostly SiO, hence evaporation and condensation involve the dissociation and recombination of oxygen atoms. In the context of hot gaseous planets, [Bell & Cowan \(2018\)](#) showed that the energy of dissociation and recombination of hydrogen molecules can be significant. We estimate the energy of the reaction $\text{SiO}_2 \Rightarrow \text{SiO} + (1/2)\text{O}_2$ based on the difference in enthalpy of formation between SiO and SiO_2 (enthalpy of O_2 is 0). With this difference being 811 kJ/mol ([Chase & US](#)),

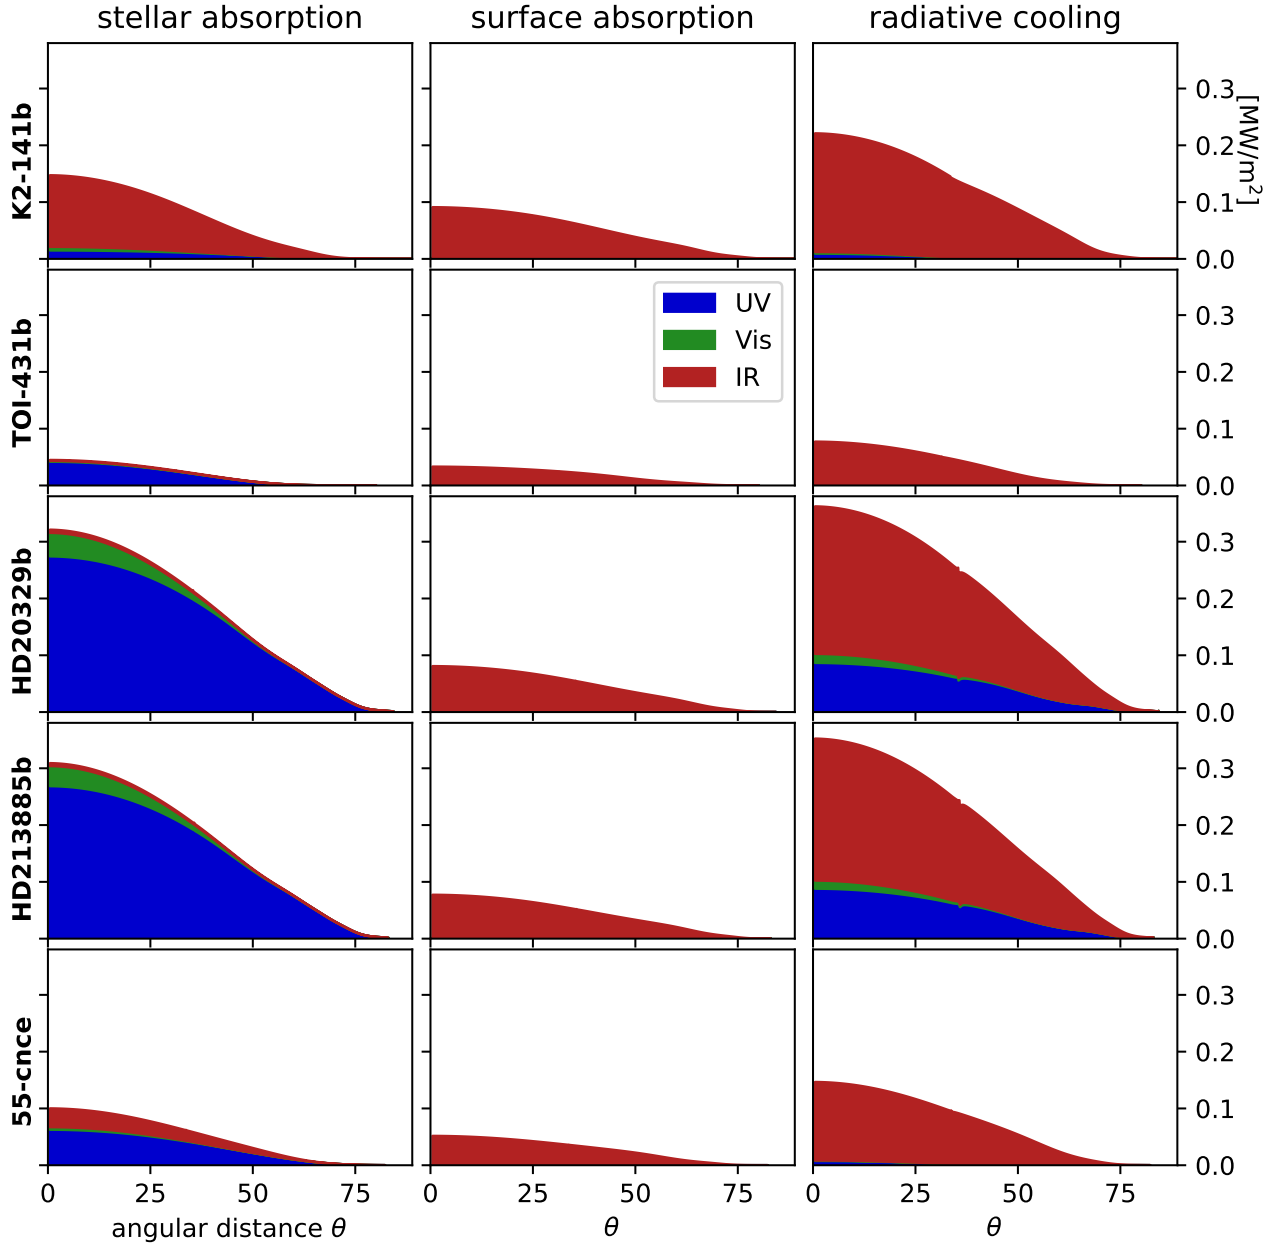

Figure 3. Radiative budget of atmosphere of our five lava planets. The first column shows absorption of stellar flux, the second shows absorption of blackbody radiation from the surface, and the third shows radiative cooling. K2-141 is less UV bright than the other stars, so the stellar absorption of its planet is mostly in the IR. Because of the high UV stellar absorption on HD213885b and HD20329b, their atmospheres become hot enough to emit significant UV radiation.

the energy per unit mass of SiO is 2×10^7 J/kg, an order of magnitude magnitude greater than the latent heat of vaporization (10^6 J/kg, Kite et al. 2016). Unlike the latent heat, this chemical energy may dominate the energy budget, but we leave this problem to future studies, since our current model can only accommodate a single gas species.

4.4. The effects of clouds on lava planet climate

The formation of clouds has a weaker effect on the atmosphere than on the surface, due to the fact that the atmosphere is optically thin at visible wavelengths even in the absence of clouds. Visible light reflected by clouds would have mostly passed through the atmosphere in any case; it is the surface that loses that energy and thus can cool by 200 K.

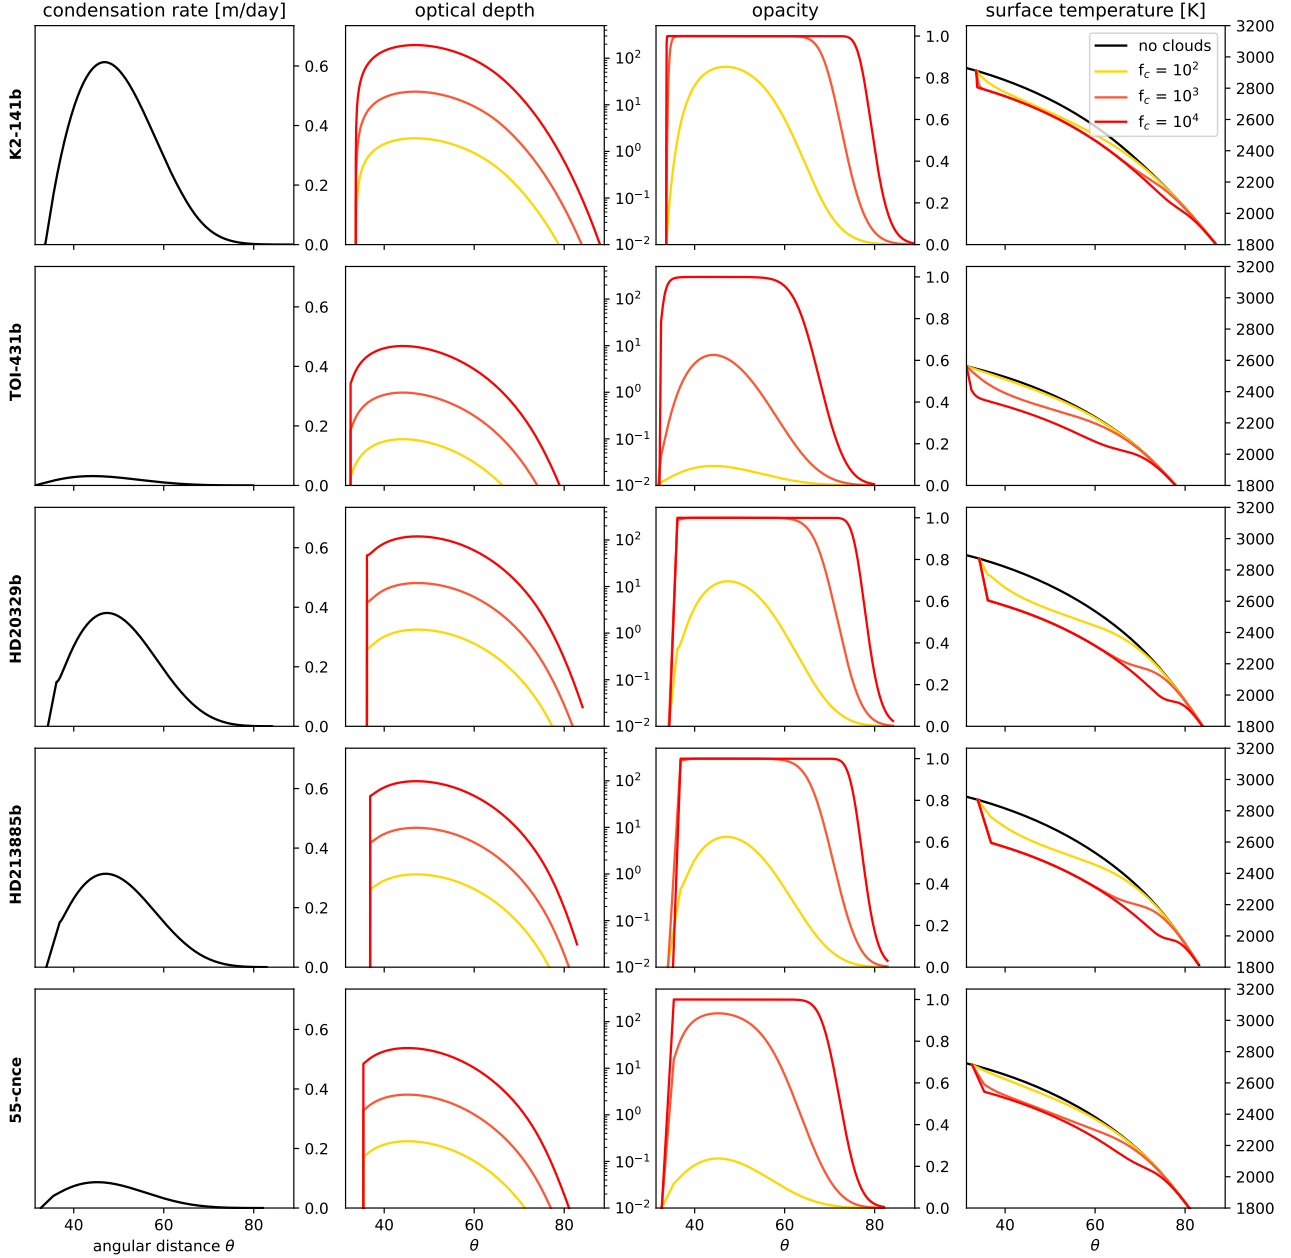

Figure 4. The impact of clouds on lava planet surface temperature. The first column is the condensation rate. We zoom in on θ where condensation occurs. We impose the factors f_c onto the condensation rate to create the optical depth plots shown in the second column, and the opacity is plotted in the third column. The final column is the surface temperature below the cloud deck. Clouds cool the surface significantly (up to 200 K) but the changes in atmospheric temperature are an order of magnitude smaller.

Smaller f_c correspond to larger cloud particles, which are radiatively less important. Assuming spherical droplets, we can decompose f_c into cloud particle properties via:

$$f_c = \frac{3}{8} \frac{t}{\rho d} p_e. \quad (5)$$

The density, ρ , of the condensed SiO_2 is 2650 kg/m^3 , p_e is the fraction of condensible material that forms cloud

droplets instead of condensing directly on the surface of the magma ocean—this depends on the altitude at which clouds form. The particle diameter, d , is typically sub-micron to 10s of microns for silicate clouds in hot Jupiter atmospheres (Powell et al. 2018) while dust grain analysis of catastrophically evaporating rocky world yield 0.1–1 micron Budaj (2013). Finally, t is the timescale over which the cloud droplet stays in the at-

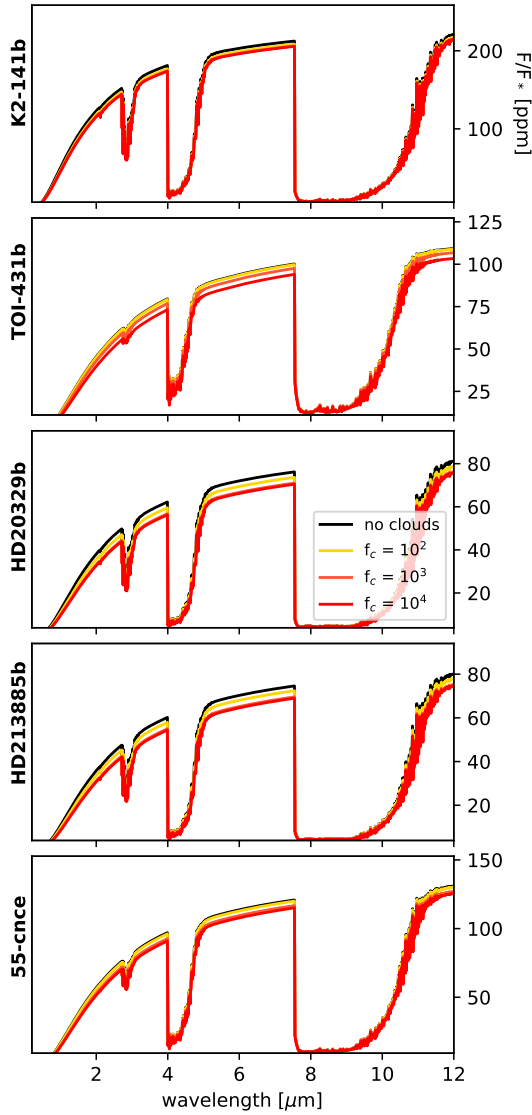

Figure 5. Simulated eclipse spectra of selected planets. The spectrum is calculated from the top-of-the-atmosphere emission which ultimately depends on the temperatures of both the atmosphere and the surface. In strong SiO spectral features, emission originates from upper layers of the atmosphere. For an adiabatic T-P profile, this leads to extremely cold temperature reading and thus the eclipse spectra show deep absorption features. Although clouds do cool the atmosphere slightly, the changes in the eclipse depth are barely visible. Since clouds cool the surface more, the overall blackbody curve of the spectra is lowered and the difference between cloudy and cloudless is seen relatively most clearly on HD20329b and HD213885.

mosphere. Two timescales could be at play: the time it takes for the cloud droplet to fall to the surface or the time it takes for the cloud droplet to be advected from the point of nucleation to where the atmosphere collapses.

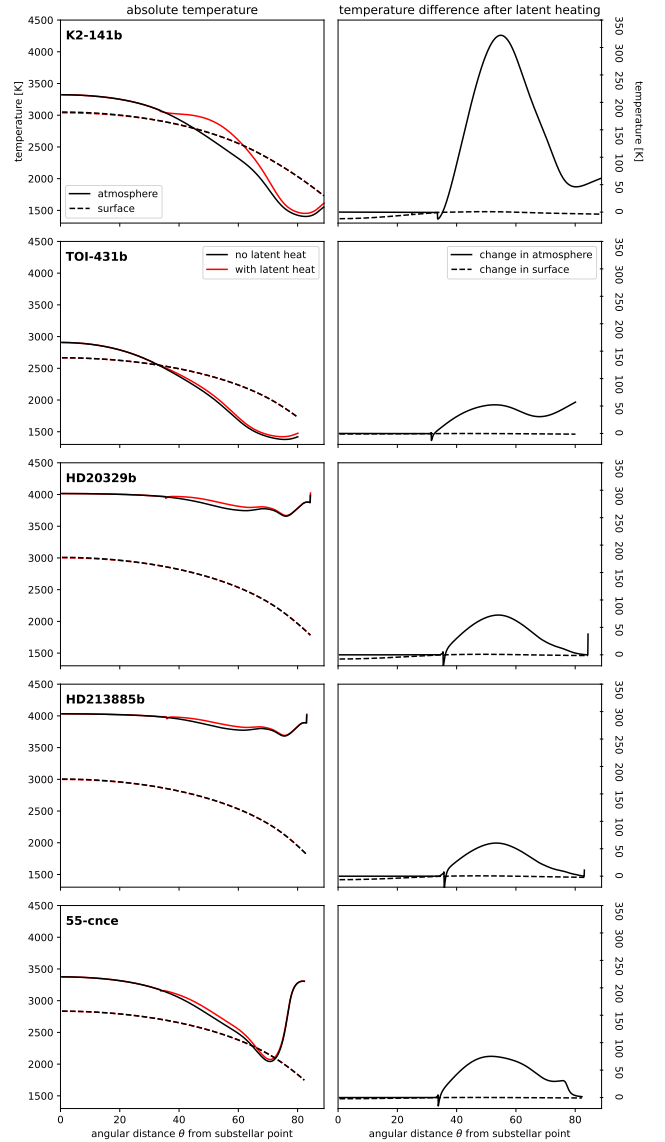

Figure 6. We show the changes in atmospheric and surface temperature when latent heat is implemented self-consistently in our code. Latent heat cools the surface when evaporating and warms the atmosphere when condensing, because we assume that condensation occurs aloft. As predicted by Kite et al. (2016), temperature changes due to latent heating are negligible at the surface but warms the atmosphere a little. However, the changes are minor with the exception of K2-141b where atmospheric temperatures can warm by 10%. This is due to the relatively large condensation rate but relatively low radiative heating and cooling caused by orbiting around a cooler star.

We estimate the terminal velocity of free-falling cloud particles falling through 2500 K gas under an acceleration $g = 25 \text{ m/s}^2$ using Stokes' law: terminal velocity, $V = (2/9)(\rho_c - \rho_a)gr^2/\eta$, where ρ_c is the particle density and ρ_a is the air density. With micron-size particles, the

terminal velocity is a very slow 2×10^{-4} m/s. We surmise that the horizontal advection timescale is likely the limiting factor. It takes ~ 5000 s to transport a parcel of gas 45° of angular distance for a planetary radius of $1.5 R_E$ and a wind speed of 1.5 km/s. Therefore we get $f_c \sim 10^4$ given $d = 10^{-6}$ m, and $p_e = 0.1$.

The effect of clouds on the atmospheric energy budget is minimal because we have assumed clouds are transparent in the IR, but the surface is influenced significantly. Because we have treated the magma ocean as a still surface, it does not have any mechanism to advect heat (cf. Boukaré et al. 2022). Therefore, the surface is entirely dependent on instellation and losing up to half of all visible light due to clouds results in significant temperature decreases that might be detectable due via astronomical observations.

In the simulated eclipse spectra shown in Fig. 4. We see that the greater the cloud opacity, the lower the overall emission. Clouds have the biggest impact on the dynamics of HD213885b and HD20329b due to the high incident stellar radiation at visible wavelengths. However, this difference in overall signal is too small for current instruments to precisely characterize. Ultimately, K2-141b remains the best target lava planet for atmospheric detection because of signal-to-noise but is the worst target to differentiate between cloudy and clear sky conditions.

5. CONCLUSIONS

Clouds are a fundamental part of a planet’s meteorology. Lava planets are most likely to have, at minimum, non-global atmospheres. In this regime, clouds should appear as the atmosphere starts to condense out. Therefore, we simulated the atmosphere of lava planets K2-141b, TOI-431b, HD20329b, HD213885b, and 55-cnc e to see which of these planets are best for cloud detection and characterization.

With or without clouds, our calculations show that atmospheric temperature is more dependent on the stellar spectrum than bolometric flux. HD213885b and HD20329b, whose stars emit more UV light, have a hotter atmosphere than K2-141b despite receiving less instellation.

We implement clouds by scaling the optical depth to the condensation rate using the f_c parameter to roughly approximate weak, medium, to strong cloud effects. We find that atmospheric properties are not significantly affected by visible light scattering of clouds: the existing heat advection from the evaporating region through sensible heat as well as latent is enough to offset clouds. The surface is more affected by clouds and the effect is predictably stronger for greater optical instellation. As such, the overall effect of clouds is best seen on HD213885b and HD20329b but is still challenging to distinguish.

Implementing an adiabatic profile up to the top of atmosphere create deep absorption features which render the spectroscopic signature of clouds to be indistinguishable; adopting the silicate T-P profiles of Zilinskas et al. (2022) and Piette et al. (2023) should yield more accurate observables which may reveal an opportunity to detect clouds but the results of such 1D models must be reconciled with atmospheric dynamics.

APPENDIX

5.1. Base hydrodynamical formulation

The framework for the hydrodynamical calculation is a system akin to the shallow-water equations describing the conservation of mass (Eq. 6), momentum (Eq. 7), and energy (Eq. 8) following [Ingersoll et al. \(1985\)](#):

$$\partial_x(\rho h V) = m E, \quad (6)$$

$$\partial_x(\rho h V^2) = -\partial_x \int_z P dz + \tau, \quad (7)$$

$$\partial_x \left(\rho h V \left(\frac{V^2}{2} + C_p T \right) \right) = Q_{\text{sens}} + Q_{\text{lat}} + Q_{\text{RC}}, \quad (8)$$

where x and z denote the horizontal and vertical direction coordinates. P , V , and T are state variables pressure, velocity, and temperature. Variables ρ and h are air density and column thickness. Parameters m and C_p are the molecular mass and heat capacity respectively. Eq. 6 describes how the change of material moving along the flow is controlled by the mass exchange between the surface and the atmosphere via evaporation, E . Eq. 7 describes how the momentum of the air parcel is controlled by the horizontal pressure gradient force and surface drag, τ . Eq. 8 describes how the kinetic energy and internal heat energy of the parcel is controlled by the energy fluxes which includes sensible (Q_{sens}), latent (Q_{lat}), and radiative heating terms (Q_{RC}) and is expanded upon later in the text.

The mass flux, E [molecules/s/m²], is the term that describes what is added and what is removed from the atmosphere. This is controlled by evaporation:

$$E = \frac{P - P_v(T_s)}{m \sqrt{2\pi R T_s}}, \quad (9)$$

where P_v is the saturated vapour pressure taken from [Miguel et al. \(2011\)](#) and T_s is the surface temperature. R is the gas constant. To further calculate the fluxes, such as surface drag τ and components of Q , we define a mean flow velocity $V_e = mE/\rho$ and an eddy velocity $V_d = V_*^2/V$. The frictional velocity V_* is calculated iteratively from the implicit relation with V :

$$V = 2.5 V_* \log \left(\frac{9.0 V_* H \rho}{2\eta} \right), \quad (10)$$

where H is the scale height, ρ is the density, and η is the temperature dependent viscosity¹. With these velocities, we further define advection coefficients that describe how heat and momentum is dynamically transferred between the surface and atmosphere, w_a and w_s :

$$w_a = \frac{2V_d^2}{V_e + 2V_d}, \quad (V_e > 0) \quad (11a)$$

$$w_s = \frac{V_e^2 + 2V_d V_e + 2V_d^2}{V_e + 2V_d}, \quad (11b)$$

$$w_a = \frac{V_e^2 - 2V_d V_e + 2V_d^2}{-V_e + 2V_d}, \quad (V_e \leq 0) \quad (12a)$$

$$w_s = \frac{2V_d^2}{-V_e + 2V_d}. \quad (12b)$$

¹ $\eta = 1.8 \times 10^{-5} (T/291)^{3/2} (411)/(T+120)$ following Sutherland's ideal gas formula ([Castan & Menou 2011](#))

The above equations yield the dimensionless advection factors when there is net evaporation ($V_e > 0$) and deposition ($V_e \leq 0$). These parameters are then used to calculate the frictional drag, τ and sensible heat, Q_{sens} :

$$\tau = -\rho V w_a, \quad (13)$$

$$Q_{\text{sens}} = \rho \left(w_s C_p T_s + w_a \left(\frac{V^2}{2} + C_p T \right) \right). \quad (14)$$

In Eq. 14, the first term is the heat contribution from the surface and the second term is the atmospheric advection. The latent heat term Q_{lat} , is simply:

$$Q_{\text{lat}} = L m C, \quad (15)$$

where L is the latent heat of vaporization and C is the condensation rate. This term is defined such that latent heat is added to the atmosphere when condensing but is taken away from the surface when evaporating; this term will subsequently show up in the surface energy balance equation. The last remaining flux term is the pressure gradient force where we must integrate the vertical pressure with respect to height from a specified altitude to infinity:

$$\int_{z=z_0}^{\infty} P dz = \int_0^{P_0} \frac{\Phi}{g} dP = \frac{C_p}{g} \int_0^{P_0} (T_0 - T) dP. \quad (16)$$

Eq. 16 switches from the local z altitude coordinates to P levels by substituting the geopotential variable Φ . By expressing Φ as work done by moving the air parcel vertically under the gravitational acceleration g , we can relate it to enthalpy which yields a function dependent on the pressure-temperature profile. For an adiabatic profile, completing the vertical integration yields:

$$\frac{C_p}{g} \int_0^{P_0} (T_0 - T) dP = \frac{C_p P_0 T_0 \beta}{g}, \quad (17)$$

where $\beta = R/(R + C_p)$. Eq. 17 essentially provides an analytical solution to the pressure integral of a specific profile but one can generate another temperature profile and solve Eq. 16 numerically.

With the exception of Q_{RC} , equations 9, 13, 14, and 17 show how all of the fluxes are calculated in equations 6-8. The next step is to convert the local coordinates to global coordinates in terms of θ , the angular distance from the substellar point. Steps detailing the full conversion can be found in [Ingersoll et al. \(1985\)](#) but the net result is shown:

$$\frac{1}{r \sin(\theta)} \frac{d}{d\theta} \left(\frac{V_* P_* \sin(\theta)}{g} \right) = m E, \quad (18)$$

$$\frac{1}{r \sin(\theta)} \frac{d}{d\theta} \left(\frac{(V_*^2 + \beta C_p T_*) P_* \sin(\theta)}{g} \right) = \frac{\beta C_p T_* P_*}{g r \tan(\theta)} + \tau, \quad (19)$$

$$\frac{1}{r \sin(\theta)} \frac{d}{d\theta} \left(\frac{(V_*^2/2 + C_p T_*) V_* P_* \sin(\theta)}{g} \right) = Q_{\text{sens}} + Q_{\text{lat}} + Q_{\text{RC}}, \quad (20)$$

The asterisk subscript on the state variables denotes its value at the of the turbulent boundary layer. Because surface drag induces a logarithmic vertical wind profile, the wind speed at half the scale height is closest to the weighted mean flow of the air column. Therefore, the turbulent boundary layer is taken to be at half the scale height to harmonize our treatment of mass, momentum, and energy advection.

The equations are solved as a set of ordinary differential equation with respect to θ . We use the “shooting” method where we guess the boundary conditions at the substellar point. Because we are dealing with non-linear mass, momentum, and energy fluxes, a steady-state solution is particularly sensitive to the initial conditions. The only definitive condition is $V(0) = 0$; for $T(0)$ and $P(0)$, we iteratively have to solve for the conditions that is most numerically stable as described in [Nguyen et al. \(2022\)](#). Once a stable solution is established, the flow inevitably reaches supersonic speed and we linearly interpolate the transition from subsonic to supersonic flow.

As the atmosphere gradually condenses out, there comes a point when the atmosphere transitions into an exosphere where molecules behave less like a continuous fluid and more like independent particles in ballistic motion. As the flow regime changes, our calculations fail. The result is a spatially bounded atmosphere spanning more or less a hemisphere with steady state evaporation and condensation.

5.2. radiative transfer formulation

To calculate the radiative contributions to the atmosphere and surface, we first define the vertical optical depth, τ_d as a function of pressure:

$$\tau_d = x_a P_* / mg, \quad (21)$$

where x_a is the wavelength-dependent absorption cross-section (see [Fig. 1](#)). The absorptivity/emissivity ϵ of the overlying atmospheric column is related to the optical depth:

$$\epsilon = 1 - e^{-\tau_d}. \quad (22)$$

The emissivity ϵ helps to calculate the individual radiative contribution from stellar radiation absorption (F_{stel}), surface blackbody radiation (F_{surf}), and radiative cooling (F_{RC}). The total heat contribution from radiative transfer, Q_{RT} becomes:

$$\begin{aligned} Q_{\text{RT}} &= F_{\text{stel}} + F_{\text{surf}} - 2F_{\text{RC}} - F_c \\ &= \int_{\lambda} \epsilon(\lambda) F_*(\theta, \lambda) d\lambda + \int_{\lambda} \epsilon(\lambda) B(T_s, \lambda) d\lambda - 2 \int_{\lambda} \epsilon(\lambda) B(T, \lambda) d\lambda - \epsilon \end{aligned} \quad (23)$$

where F_* is the stellar flux and B is the Planck blackbody function which depends on both wavelength and temperature. Since lava planets are so close to their star, parallel ray approximations no longer hold and F_* is not easily solvable; we use the formulation of [Kang et al. \(2023\)](#) to account for finite light source effect. Note that the radiative cooling term is doubled to signify that the atmosphere radiates both down into the ground and outwards into space.

Although [Eq. 23](#) is identical to what we had in [Nguyen et al. \(2022\)](#) barring cloud reflection, we have significantly improved the numerical integration of the stellar flux and blackbody radiation. Previously, we averaged the emissivity across the entire ultraviolet and infrared wavelength bands, while neglecting wavelengths in the optical completely. The problem is that the absorption cross-section of SiO varies enormously with changing temperature and pressure. We therefore calculate absorption and emission line by line with varying pressure and temperature ahead of the simulation. Stellar absorption depends mostly on pressure and a function of $F_*(P)$ is extracted for easy implementation. Radiative cooling is much more tricky as it depends on both pressure and temperature, therefore a lookup table of flux is generated (see [Fig. 7](#) to quickly determine the radiative transfer terms.

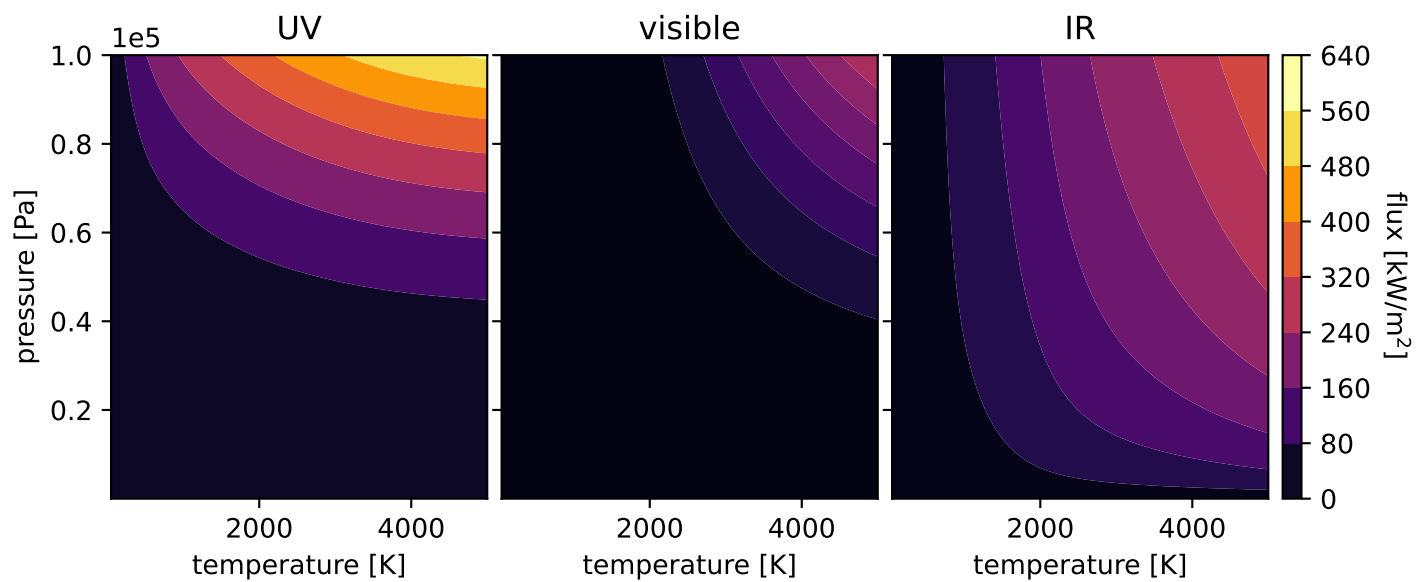

Figure 7. Radiative cooling as a function of pressure and temperature: We calculate the radiative cooling and separate the fluxes into three channel: UV (left), visible (middle), and IR (right).
