Since the discovery of two-dimensional ferroelectric and ferromagnetic materials, the van der Waals (vdW) heterostructures constructed by ferroelectric and ferromagnetic monolayers have soon become the ideal platforms to achieve converse magnetoelectric functions at the nanoscale, namely to use electric field to control magnetization. In this Letter, by employing density functional theory calculations and dynamic simulations of atomic spin model, we study the key role of interfacial Dzyaloshinshii-Moriya interaction (DMI) in CrI₃-In₂Se₃ vdW heterostructures. Our work demonstrates feasible DMI torques pumped by ferroelectric switching, which can drive current-free and low-energy consumption domain wall motion. Moreover, such interfacial DMI can also significantly enlarge the Walker field in magnetic field-driven domain wall technique.

Originated from spin-orbit coupling (SOC), Dzyaloshinshii-Moriya interaction (DMI) plays a vital role in modern spintronics. By coupling neighbor spins in the antisymmetric form $H_D = \mathbf{D} \cdot (\mathbf{S}_i \times \mathbf{S}_j)$ [\[1\]](#page-4-0), DMI can lead to many noncollinear spin textures, e.g. canting antiferromagnetism, chiral domain walls, as well as skyrmions [\[2–](#page-4-1)[6\]](#page-4-2). It is well known that noncollinear spin textures usually produce nontrivial spin-electron scattering for transportation, which can contribute to topological (quantum) Hall effects and motion of quasi-particles [\[7–](#page-4-3)[12\]](#page-4-4), facilitating functional manipulations at the nanoscale. Because the presence of DMI relies on the lack of space-inversion symmetry, DMI widely exists in those non-centrosymmetric magnetic materials. In particular, helimagnets such as $Mn_xFe_{1-x}Si$, $Fe_xCo_{1-x}Si$, and FeGe, in which the DMI causes spiral orders and/or skyrmions, have attracted lots of attentions [\[13–](#page-4-5)[17\]](#page-4-6). Besides, the asymmetric interfaces in artificial heterostructures or superlattices, can also produce the interfacial DMI which leads to various emergent phenomena [\[3,](#page-4-7) [18](#page-4-8)[–23\]](#page-5-0).

Reversibility of DMI vector provides a promising route to control the chirality of magnetism. Multiferroics allows the coexistence of more than one ferroic order within a single phase material, which provide a platform to control DMI vector via electric field or mechanical methods [\[24](#page-5-1)[–26\]](#page-5-2). For some specific multiferroic systems, e.g. $BiFeO₃$, due to the locking between oxygen octahedral distortions and dipole moments, the DMI vector can be reversed by ferroelectric switching, leading to the fipping of canting moment [\[27,](#page-5-3) [28\]](#page-5-4). By reversing the DMI vector, the topological spin textures or solitons can be manipulated [\[29–](#page-5-5)[32\]](#page-5-6). Following this mechanism, Yu et al demonstrated the chirality-dependent skyrmion-skyrmion interactions [\[33\]](#page-5-7).

The magnetic chirality also widely exists in domain walls, and thus DMI also plays an essential role in do-

main wall dynamics [\[34–](#page-5-8)[39\]](#page-5-9). For example, the reversal of DMI vector can produce a dissipative transverse motion during the chirality switching, as demonstrated in perovskite multiferroics [\[40,](#page-5-10) [41\]](#page-5-11). Comparing with the scenario based on current-dependent torques [\[42–](#page-5-12)[44\]](#page-5-13), such a pure electric field control has the advantage for its lower energy consumption, which has been coined as a new class of "DMI torques" [\[45\]](#page-5-14).

Van der Waals (vdW) heterostructures are ideal platforms to design electronic devices with controllable DMI, benefiting from their high-usage interfaces and easy control of stacking modes. As a widely studied system, α -In₂Se₃ monolayer was theoretically predicted to be ferroelectric [\[46\]](#page-5-15), which was then fabricated and con-

firmed in experiments [\[47\]](#page-5-16). After that, $In₂Se₃$ -based heterostructures have been theoretically studied and designed for nonvolatile electric field manipulations of various physical properties, including magnetism [\[48,](#page-5-17) [49\]](#page-5-18), topological states or spin textures [\[50](#page-6-0)[–53\]](#page-6-1), band alignments and charge transfer [\[54,](#page-6-2) [55\]](#page-6-3). Although domain walls have been attracting more and more attentions in two-dimensional systems [\[56–](#page-6-4)[58\]](#page-6-5), the DMI control of domain wall dynamics remains less touched.

In this Letter, the DMI torques and domain wall dynamics of $CrI₃-In₂Se₃$ vdW heterostructures are studied. Our first-principles calculations indicate the interfacial DMI in CrI_3 monolayer can be induced in these heterostructures and the full reversal of DMI vector can be achieved in the $In_2Se_3/CrI_3/In_2Se_3$ sandwich-like heterostructure, which can generate DMI torques to drive the motion of domain walls. Furthermore, the existing of interfacial DMI can enlarge the critical field of Walker breakdown in magnetic field-driven domain wall motion. Such magnetoelectric vdW heterostructures shed lights on the low energy-consuming domain wall nanoelectronic applications.

CrI³ monolayer is a well-recognized two-dimensional ferromagnetic sheet with a magnetic easy axis perpendicular to its plane [\[59\]](#page-6-6). The effective spin Hamiltonian for CrI3's honeycomb lattice can be written as:

$$
H = -J \sum_{\langle i,j \rangle} \mathbf{S}_i \cdot \mathbf{S}_j - \sum_{\langle i,j \rangle} \mathbf{D}_{ij} \cdot (\mathbf{S}_i \times \mathbf{S}_j) - A \sum_i (S_i^z)^2,
$$
\n(1)

where **S** is the normalized spin vector, i/j are site indexs, and <> denotes nearest-neighbors. As depicted in Fig. $1(a)$. The first term is the ferromagnetic exchange $(J > 0)$, and the second term describes the interfacial DMI with the coefficient vector D. Due to the inversion symmetry, $D = 0$ for isolated CrI₃ monolayer. However, the symmetry can be broken from the original D_{3d} to C_{3v} for CrI³ monolayer on substrate, producing nonzero DMI

vectors satisfy $\mathbf{D}_{\mu} = \mathbf{e}_z \times \mathbf{e}_{\mu}$ ($\mu = 1, 2, 3$) as depicted in Fig. $1(a)$. The last term is the magnetocrystalline anisotropy with the easy axis along the z-axis $(A > 0)$.

Due to the presence of DMI, the magnetic domain walls should belong to the Neel-type with specific chirality (i.e. clockwise (CW) or counter-clockwise (CCW)) to reduce the energy cost from DMI, as sketched in Fig. [1\(](#page-0-2)b). In such a honeycomb lattice, although domain walls are possibly propagating along the zig-zag or armchair directions, i.e. the shadow stripes in Fig. [1\(](#page-0-2)a), they can be proved being equivalent in the magnetic dynamics [\[60\]](#page-6-7). Then in the continuous limit, the model Hamiltonian for N'eel-type domain walls propagating along the x -axis can be expressed as:

$$
H = \int \left[\frac{J}{2}(\nabla \mathbf{S})^2 - D\mathbf{e}_y \cdot (\mathbf{S} \times \nabla \mathbf{S}) - \frac{4A}{3}(S^z)^2\right] dx, \tag{2}
$$

where D is the amplitude of DMI vector. Therefore, the domain wall can be described as $S^x = \operatorname{sech}(x/\Delta)$ with the characteristic width $\Delta = \sqrt{3J/8A}$ [\[61\]](#page-6-8). It's worthy to note that the effective width of domain walls in the honeycomb lattice should be $\pi \Delta a_0$ (a₀ is the Cr-Cr distance as defined in Fig. $1(a)$).

To obtain the effective coefficients from real heterostructures, the first-principles calculations based on density functional theory (DFT) are performed, and technical details of calculations can be found in Supplemen-tary Materials (SM) [\[60\]](#page-6-7). Both CrI₃ and $In₂Se₃$ monolayers are hexagonal lattices, as shown in Fig. [2\(](#page-1-0)a-b), and their lattice constants are well-matched by following the their lattice constants are well-matched by following the $(1\times1)/(\sqrt{3}\times\sqrt{3})$ stacking mode with less than 0.5% mismatch. The $\text{CrI}_3/\text{In}_2\text{Se}_3$ bilayer and $\text{In}_2\text{Se}_3/\text{CrI}_3/\text{In}_2\text{Se}_3$ trilayer are considered. Here, the energetically most favorable stacking modes are displayed in Fig. [2\(](#page-1-0)c-f), while other stacking modes are discussed in SM [\[60\]](#page-6-7). The $\rm CrI_3/In_2Se_3$ bilayer is polar despite the polarization direction of In_2Se_3 . The $In_2Se_3/CrI_3/In_2Se_3$ trilayer can

FIG. 3. (a) Charge redistribution between the upper I and lower I surfaces in CrI_3/\downarrow . The charge density is plotted near the Fermi level with range of [−0.3, 0] eV with isosurface level as 0.005 $e/\text{\AA}^3$. (b) Noncollinear Cr-spin orders in honeycomb lattice of CrI₃ layer, where out-of-plane (blue arrows) and inplane (red arrows) spins are in arrangements with different chiralities CW or CCW. (c, d) The exchange coefficient J , magnetocrystalline anisotropy A, and strength of DMI vector \mathbf{D} in CrI₃ monolayer (ML) and CrI₃-In₂Se₃ heterostructures, where \uparrow or \downarrow denotes the polarization of In₂Se₃ layer.

be polar or nonpolar, depending on the combination of polarizations of two In_2Se_3 layers, as shown in Fig. [2\(](#page-1-0)e-f). For bilayer heterostructures CrI₃/ \uparrow and CrI₃/ \downarrow (here \uparrow or \downarrow denotes the polarization direction in In₂Se₃ layer), the energy is calculated as the function of interlayer distance L. As shown in Fig. [2\(](#page-1-0)g), their optimal distances L_{\uparrow} and L_{\downarrow} are only slightly different. Similar conclusion is also applicable to the trilayer heterostructures, in which the optimal L's slightly depend on the polarization of In_2Se_3 layers.

As aforementioned, the DMI can be induced by the proximity effects at interfaces. Microscopically, DMI can originate from multiple factors, including the lattice distortion, orbital hybridization, electrostatic field, and charge transfer. Here, although the lattice distortions between Cr-I-Cr bonds are rather tiny after optimization, the charge density is significantly different between the upper I and lower I surfaces, due to the electrostatic field from In_2Se_3 , as shown in Fig. [3\(](#page-2-0)a). To calculate the DMI vector, two noncollinear magnetic orders with identical exchange energy but opposite chiralities as depicted in Fig. [3\(](#page-2-0)b), are calculated with SOC. The energy difference between these two states is only contributed by the DMI according to $D = (E_{\text{CCW}} - E_{\text{CW}})/4$.

All calculated coefficients including J, D, and A are summarized in Fig. [3\(](#page-2-0)c-d). On one hand, comparing with monolayer $CrI₃$, the ferromagnetic exchange J is strengthened by 15%-28% in these heterostructures, while the magnetocrystalline anisotropy A is reduced by

FIG. 4. DMI torque-driven domain wall motion. (a-b) Snapshots of S texture with an isolated domain wall, before and after the polarization flipping. The chirality of domain wall is reversed from CW (at 0 ns) to CCW (at 0.8 ns). (c) The time-dependent domain wall position d with different damping coefficients. (d) The average velocities (solid circles) for the DMI torque driven-domain wall motion as a function of α , which can be well fitted using the formula $v_m(\alpha^2+1)^{-1}$.

0-26%. Thus the ferromagnetism of $CrI₃$ should remain robust. On the other hand, nonzero D's appear only in those polar heterostructures. For bilayers, the amplitude of DMI's are estimated as 0.16 meV and 0.3 meV for CrI_3/\uparrow and CrI_3/\downarrow respectively. Interestingly, the sign of DMI does not change upon the ferroelectric switching, implying that the single interface itself contributes to 0.23 meV while the reversable DMI contributes to 0.07 meV. For trilayer, the DMI is completely reversed from 0.08 meV in \uparrow /CrI₃/ \uparrow to -0.08 meV in \downarrow /CrI₃/ \downarrow , while it is zero in \uparrow /CrI₃/ \downarrow or \downarrow /CrI₃/ \uparrow as expected from the inversion symmetry.

To study the spin dynamics of domain walls in the CrI₃ layer, we employed the atomic simulations by solving Landau-Lifshitz-Gilbert (LLG) equation [\[61\]](#page-6-8):

$$
\frac{\partial \mathbf{S}}{\partial t} = \frac{\gamma}{\mu_s} \left(\mathbf{S} \times \frac{\partial H}{\partial \mathbf{S}} \right) + \alpha \left(\mathbf{S} \times \frac{\partial \mathbf{S}}{\partial t} \right),\tag{3}
$$

where $\gamma = g\mu_B/\hbar$ is the gyromagnetic ratio. $\mu_s = 3 \mu_B$ is the atomic magnetic moment for Cr^{3+} . The last term is for Gilbert damping with coefficient α , which is typically determined by electron spin resonance in experiments. A stripy honeycomb lattice $N = 600 \times 4$ is adopted, with periodic boundary conditions along the y-direction and open boundary conditions along the x-direction. The two x-ends are fixed as spin-up and spin-down. The fourth-order Runge-Kutta method is used to solve the LLG equation to obtain the time-dependent evolution of spins.

In the trilayer heterostructure, the DMI vector can be reversed by flipping the polarization, i.e. from $+0.08$ meV to −0.08 meV, which is anticipated to pump the DMI torques for spin dynamics [\[40,](#page-5-10) [45\]](#page-5-14). Here, we study an isolated domain wall at the honeycomb lattice, starting from a sharp boundary between the spin-up domain and spin-down domain. As shown in Fig. [4\(](#page-2-1)a), due to the DMI ($D = 0.08$ meV) in \uparrow /CrI₃/ \uparrow , the final stable state is a CW Néel-type domain wall. After the polarization flipping to $\sqrt{\text{CrI}_3/\downarrow}$, the DMI energy will produce an effective field acting on the domain wall, and thus pumps a DMI torque as:

$$
\Gamma_D = -\frac{2D\gamma}{\mu_s} (\mathbf{S} \cdot \mathbf{e}_y) \nabla \mathbf{S},\tag{4}
$$

which will reverse the chirality of domain wall and induce a transverse motion as well. As shown in Fig. [4\(](#page-2-1)b), with a large damping coefficient $\alpha = 0.2$, the domain wall moves by ~ 15 nm along the x-direction within 0.8 ns, accompanying its chirality reversal to CCW. This dynamic process with a smaller damping coefficient $\alpha = 0.1$ is also calculated for comparison. As shown in Fig. $4(c)$, the transverse motion distance d reaches \sim 30 nm within \sim 1.5 ns. The motion of domain wall converges to stop gradually, thus it is not precise to define the motion time and the final distance d_s . In fact, for the honeycomb lattice, the DMI torque-driven domain wall motion can be well described by:

$$
d = \frac{a_0 \Delta}{\alpha} \arctan[\sinh(\frac{t}{Q})],\tag{5}
$$

where $Q = 8\Delta(\alpha + \alpha^{-1})\mu_s/(3\pi\gamma D)$ denotes the characteristic time and the maximal moving distance is $d_s =$ $a_0\Delta\pi/\alpha$. More details about the derivatives can be found in Supporting Information, and this kind of domain wall motion is similar to the "rolling-downhill" type motion discovered in multiferroic perovskites [\[40\]](#page-5-10). All the simulation results are in perfect agreement with the theory, in which the moving distance is proportional to α^{-1} and independent on the strength of DMI. Here, we can define the effective time for the motion as $\sim 2\pi Q$, thus the average velocity can be calculated by $\bar{v} = 3a_0\pi\gamma D/[16(\alpha^2+1)\mu_s]$. The average velocity \bar{v} increases with decreasing α and its maximal limitation is $v_{\rm m} = 3a_0\pi\gamma D/16\mu_s$ when $\alpha \to 0$, in consistent with the simulation results as shown in Fig. $4(d)$. For the $In_2Se_3/CrI_3/In_2Se_3$ heterostructure, the maximal average velocity is estimated as ~ 20 m/s, which is close to the typical velocity of magnetic field-driven ferromagnetic domain walls below 50 mT [\[35,](#page-5-19) [62–](#page-6-9)[64\]](#page-6-10).

For completeness of domain wall motion, we also investigate the magnetic field-driven domain wall motion with different polarizations. Considering a magnetic field h along the z -direction, the Zeeman energy term can be expressed as $H = -h\mu_s \sum_i \mathbf{e}_z \cdot \mathbf{S}_i$, which gives rise to a magnetic field torque as:

$$
\Gamma_h = \gamma h \mathbf{e}_z \times \mathbf{S}.\tag{6}
$$

The snapshots of domain wall dynamics in CrI_3/\downarrow are displayed in Fig. [5\(](#page-3-0)a-b), where the magnetic field torque

FIG. 5. Magnetic field-driven domain wall motion with $\alpha =$ 0.2 . (a-b) Snapshots of the S textures in CrI₃/ \downarrow under different magnetic fields. Under the small field 152 mT, the dynamic process is mainly the steady motion, while it becomes a processional motion under 220 mT. (c) The time-dependent domain wall positions under various magnetic fields. (d) Average velocity of domain wall motion as the functions of magnetic field for monolayer CrI_3 and CrI_3 -In₂Se₃ heterostructures, where dash lines indicate the Walker fields calculated by Eq. [7.](#page-3-1)

together with the Gilbert damping produce a dissipative torque to shift the domain wall and reduce the Zeeman energy. In this process, there is a critical field, called Walker field $h_{\rm W}$ [\[62\]](#page-6-9). Below $h_{\rm W}$, the dynamic process is mainly the steady motion, while it becomes a processional motion above $h_{\rm W}$ (Fig. [5\(](#page-3-0)d)). Here, the timedependent domain wall motions under various magnetic fields are plotted in Fig. [5\(](#page-3-0)c-d), which indicates $h_{\rm W} \sim 152$ mT.

It is known that this h_W orignates from the in-plane magnetic anisotropy. However, for CrI₃ monolayer itself, the fully occupied t_{2g} orbitals at Cr ion together with the D_{3d} point symmetry of honeycomb lattice, preserve the in-plane symmetry and thus the in-plane magnetic anisotropy is almost zero [\[65–](#page-6-11)[67\]](#page-6-12), as confirmed in our calculations. Therefore, the magnetic in-plane anisotropy comes from the interfacial DMI. With the coarse-graining approximation, the Walker field can be derived as:

$$
h_{\rm W} = \frac{3\pi\alpha D}{8\Delta\mu_s},\tag{7}
$$

which agrees with above numerical value very well as shown in Fig. $5(d)$.

Without this interfacial DMI, e.g. in $CrI₃$ monolayer, the domain wall motion can only be the processional motion, which leads to a velocity $v_p = a_0 \alpha \gamma \Delta h / (1 + \alpha^2)$. In heterostructures, below $h_{\rm W}$, the domain wall motion reaches a final steady velocity v_s after a very short speeding duration (~ 0.04 ns). This $v_s = a_0 \gamma \Delta h / \alpha$ is much higher than the $v_{\rm p}$. The numerical results of average velocity \bar{v} are plotted in Fig. [5\(](#page-3-0)d) as a function of magnetic field for different heterostructures. Compared with those $D = 0$ cases (CrI₃ monolayer and non-polar \uparrow /CrI₃/ \downarrow), all polar heterostructures own larger h_W and higher \bar{v} , as expected. In particular, below $h_{\rm W}$, the velocity of domain wall can be up to ~ 140 m/s for CrI₃/ \downarrow , which is considerably large and similar to the gate-voltage effect in those magnetic film experiments [\[64,](#page-6-10) [68\]](#page-6-13).

In conclusion, by employing first-principles calculations and atomic spin dynamics simulations, we have studied the mechanism of interfacial DMI and domain wall dynamics in $CrI₃-In₂Se₃ heterostructures. We have$ demonstrated the DMI torques can be pumped into In2Se3/CrI3/In2Se³ trilayer heterostructures by polarization flipping, which contributes an efficient domain wall motion without either magnetic field or current. Furthermore, the existing and tunable DMI within heterostructures also plays an important role in improving the criti-

cal Walker field for magnetic field-driven domain wall motion, exhibiting the tunable and nonvolatile bias effect. In addition, our results are completely portable to other vdW heterostructures, which can be described by the effective spin model as well. Our results have performed rich manipulations of magnetic domain walls, which can be achieved in magnetoelectric vdW heterostructures.
