A magnetically levitated mass couples to gravity and can act as an effective gravitational wave detector. We show that a superconducting sphere levitated in a quadrupolar magnetic field, when excited by a gravitational wave, will produce magnetic field fluctuations that can be read out using a flux tunable microwave resonator. With a readout operating at the standard quantum limit, such a system could achieve broadband strain noise sensitivity of $h \lesssim 10^{-19}/\sqrt{\text{Hz}}$ for frequencies of 10 kHz – 1 MHz, opening new corridors for astrophysical probes of new physics.

Gravitational waves have been detected in the Hz–kHz regime with laser interferometers [1], and potentially in the nHz regime with pulsar timing array observations [2]. Beyond these important frequencies ranges, a wide array of potential signals exist across the entire frequency spectrum, including signatures from cosmology, astrophysics, and a variety of speculative physics Beyond the Standard Model. Correspondingly, a number of methods for detecting gravitational waves in the low-frequency nHz–Hz [3–13] and high-frequency \gtrsim kHz [14–22] regimes are in various stages of development.

In this paper, we suggest a broadband method to detect gravitational waves (GWs) in the 10 kHz–10 MHz regime. This regime is particularly motivated by a number of potential signals, including primordial GW backgrounds from Standard Model sources [23–27], astrophysical signatures of physics Beyond the Standard Model [28–30], and GWs sourced from mergers of neutron stars [31] and light primordial black holes [32–34].

The detector concept and predicted reach are shown in Fig. 1. A quadrupolar magnetic field is used to levitate a superconducting test mass. An incoming gravitational wave causes a pickup coil to move relative to the sphere, leading to a time-dependent magnetic flux through the coil. Subsequently, this flux drives a current; continuous measurement of this current leads to continuous measurement of the sphere position. A similar architecture has been suggested as a sensor for dark matter searches [35]. In contrast to the SQUID readout employed in this proposal, here we suggest a flux tunable microwave resonator (FTMR) readout, such as a radio frequency quantum up-converter [36–41], allowing for broadband sensitivity at high frequencies.

The essence of our proposal is similar to GW detection with a laser interferometer, where an optical field is used to continuously monitor the distance of a nearly freely-falling test mass with respect to a reference. In modern incarnations of these detectors, the dominant noise source in the detection band comes from the quan-

tum noise in the optical readout, roughly at the level of the Standard Quantum Limit (SQL) [42, 43]. Because the coupling of a single photon to the test mass motion is weak, reaching the SQL at higher frequencies in an optical system quickly becomes prohibited by the need for stronger lasers. In contrast, as we emphasize below, magnetic systems can achieve orders-of-magnitude larger couplings to the individual microwave photons in a superconducting readout circuit. This could enable operation of a detector at the SQL at frequencies well above the audio band.

I. DETECTOR CONCEPT

We begin by discussing the essential physics of the levitating sphere and the interaction of the system with gravitational waves, before characterizing the readout system. Consider a superconducting sphere of radius R and density ρ placed in a quadrupolar magnetic field. In the presence of the magnetic field, current loops will form on the surface of the sphere to expel magnetic field lines inside the bulk. This system exhibits a stable equilibrium at the center of the quadrupolar magnetic field. For a quadrupolar magnetic field with $\partial B_z/\partial z = b_z$ centered on the origin $\mathbf{B}_0 = \frac{b_z}{2}(x\hat{x} + y\hat{y} - 2z\hat{z})$, the sphere is harmonically trapped with angular frequency

$$\omega_0^2 = \frac{3b_z^2}{2\rho}, \quad (1)$$

and is insensitive to the sphere size provided the radius is much larger than the penetration depth of the superconductor [44]. For reference, a lead sphere in a quadrupole field with gradient $b_z = 29$ T/m, corresponding to the blue curve in Fig. 1, has resonant frequency $f_0 = \omega_0/2\pi \approx 47$ Hz.

The trapping magnetic quadrupole field can be produced using current-carrying coils in an anti-Helmholtz configuration. A gradiometric pick-up loop oriented in the xy -plane measures the flux induced by motion of the levitated sphere, while being insensitive to motion of the trapping coils due to the approximate invariance of the

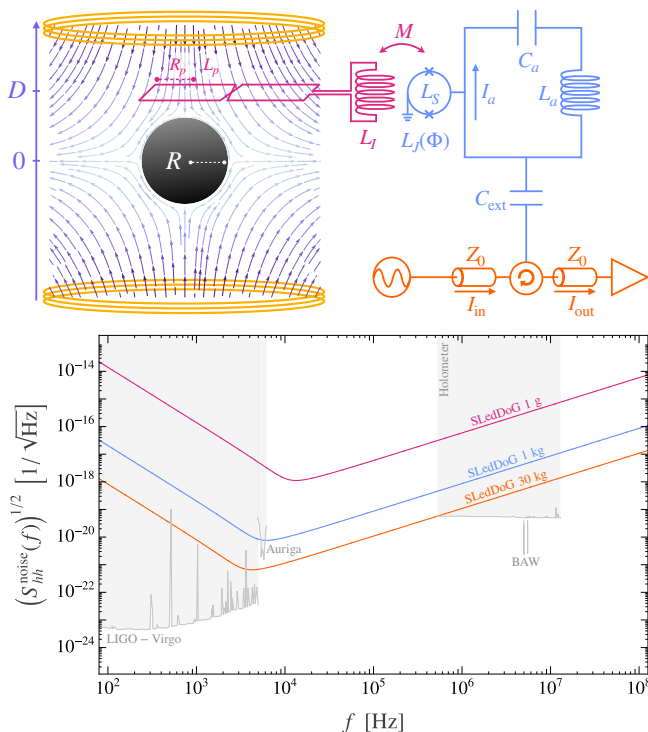

Figure 1. Top: basic SLedDoG detector concept. Bottom: predicted strain sensitivity. Solid curves show the sensitivity for 1 g, 1-kg, and 30-kg setups corresponding to sphere radii of 2.7 mm, 2.7 cm, and 8.6 cm respectively. The sensitivity is optimized at the maximum achievable SQL frequency ω_* for each setup (see App. B). We take $\kappa = 2\omega_*$, $\beta = 1.6$, $\lambda_\Phi = 0.1$, $T = 10$ mK, $\rho = \rho_{\text{Pb}}$, $B_c = 1$ T, $D = R$, $\bar{n} = 100$, and $d\omega_a/d\Phi = 2\pi \times 1$ GHz. The shaded regions depict the strain sensitivities of existing experiments.

z -component of the trapping field under xy -translations, as discussed in App. A.

Now consider a gravitational wave incident on this system, with wavelength much longer than the size of the system. We will describe the signal in the so-called “proper detector frame” [45, 46], in which the metric is locally flat at the origin, taken to be the center of the quadrupole field. In this frame, the elements of the experimental apparatus feel a force due to the GW

$$F_i^{\text{GW}}(\mathbf{x}) = \frac{m}{2} x^j \ddot{h}_{ij}^{TT} \quad (2)$$

that depends on the position \mathbf{x} and mass m , as well as the metric h , evaluated in transverse-traceless gauge [47]. We take m to be the mass of the sphere, assuming that the pickup is attached to a heavy apparatus. The GW force (2) induces a change in the relative distance ξ between the sphere and the pickup loop; with our parameters, the distance between the trap center and sphere is negligible. In the limit that the GW frequency is large enough that the motion of ξ is approximately free, ξ obeys

$$\ddot{\xi} \approx \frac{\ddot{h}_{zz}}{2} D. \quad (3)$$

This change in displacement causes a change in the flux through the pick-up loop, which we read out as discussed below.

In addition to causing relative motion between the sphere and the pick-up loop, the GW also moves the primary coils, and distorts the shape of the elements of the experimental apparatus. In the frame with the origin at the trap center, the two primary coils always feel equal and opposite forces in the z -direction. For simplicity, in the rest of the paper we focus on $+$ -polarised GWs incident along the xy -plane and relegate a complete discussion of the other GW-induced strains to App. A. For such a GW, the GW signal comes from changes in ξ , and the phenomena from other GW configurations affect the signal by only an $\mathcal{O}(1)$ amount compared to this expectation.

Proposals to use levitated superconductors as dark matter detectors and gravity gradiometers use SQUIDS to read out changes in the magnetic field [35, 41, 48–50]. However, at frequencies higher than ~ 10 kHz, it becomes difficult to strongly couple the SQUID to the displacement of the sphere, leading to large imprecision noise. We instead propose employing a flux tunable microwave resonator (FMTR, [36, 37]) which we will show can strongly couple to the displacement of the sphere at high frequencies. The FMTR, pictured in Fig. 1, is a driven microwave resonator inductively coupled to displacement of the sphere via a pickup circuit — a transformer which transfers flux from a pickup coil to the SQUID via an input coil, in which both the pickup and the input coil have inductances L_p . We assume any parasitic inductance in the pickup circuit is much smaller than L_p . The microwave resonator is an LC circuit with capacitance $C \equiv C_a + C_{\text{ext}}$ and inductance $L(\Phi) \equiv L_a + L_s + L_J(\Phi)$ dependent on the flux threading the SQUID, which in turn depends on the displacement of the sphere. In a typical Josephson system, $L_J(\Phi)$ is periodic; we will here be interested in the regime of small fluxes, where we can linearize $L_J \approx L_J(0) + (dL_J/d\Phi)\Phi$. In this regime the resonator’s frequency is also a function of the threading flux, which can be approximated as $\omega_a(\Phi) \approx \omega_a + (d\omega_a/d\Phi)\Phi$.

The microwave resonator dynamics and the mechanical motion of the sphere both amount to simple harmonic oscillators in these approximations. Let a^\dagger be the creation operator for a microwave resonator photon. The Hamiltonian $H_{\text{LC}} = \omega_a(\Phi)a^\dagger a$ then has frequency depending on the magnetic flux threading the resonator, as discussed above. For small mechanical displacements ξ , this flux is

$$\Phi = \beta \lambda_\Phi R^2 b_z \xi \equiv \eta \xi, \quad (4)$$

where $\lambda_\Phi \approx M/2L_p$ characterizes the transduction between flux through the pickup loop Φ_p and the readout circuit Φ in terms of the mutual inductance of the input coil and the SQUID, β is a dimensionless parameter dependent on the geometry of the pickup loop [51, 52], and R is the radius of the sphere. After linearizing around $\xi = 0$, the Hamiltonian H_{sys} for the sphere and resonator

can be written as

$$H_{\text{sys}} = \omega_a a^\dagger a + \omega_0 b^\dagger b - G_0 a^\dagger a (b + b^\dagger). \quad (5)$$

Here $\xi = \xi_0(b + b^\dagger)$, and we have defined the zero point fluctuation scale and single-photon coupling

$$\xi_0 = \frac{1}{\sqrt{2m\omega_0}}, \quad G_0 = \eta \xi_0 \frac{d\omega_a}{d\Phi}. \quad (6)$$

The resonator is driven by a source of microwave photons with frequency ω_d . The drive photons pick up a phase shift as they circulate the resonator and then exit, where their phase can be measured, again in analogy with the laser photons in an interferometer. Moreover, the drive effectively enhances the single-photon coupling G_0 . To model both of these effects, we employ the standard input-output formalism [43]. The output current is related to the input current through the usual I/O relation

$$q_{\text{out}} = q_{\text{in}} - \sqrt{\kappa}q, \quad (7)$$

where κ is the loss rate of the microwave resonator. Linearizing around the drive, the Heisenberg equations of motion for the system become

$$\begin{aligned} \dot{\xi} &= \frac{p}{m} \\ \dot{p} &= -m\omega_0^2 \xi - \frac{G}{\phi_0^2 \xi_0} \phi - \gamma p + F_{\text{in}} \\ \dot{\phi} &= \frac{q}{C} - \kappa \phi + \sqrt{\kappa} \phi_{\text{in}} \\ \dot{q} &= -C\omega_a^2 \phi - \frac{2G}{\phi_0^2 \xi_0} \xi - \kappa q + \sqrt{\kappa} q_{\text{in}}, \end{aligned} \quad (8)$$

Here, κ is the loss rate in the LC circuit, $G = G_0 \sqrt{\bar{n}}$ is the single-photon coupling enhanced by the presence of $\bar{n} \gg 1$ circulating photons in the microwave resonator. In practice, \bar{n} is limited by the requirement that the inductance $L_J(\Phi)$ be linear in Φ . A system with a large G is strongly coupled, such that small fluctuations in the position of the sphere will lead to large fluctuations of the output modes.

The equations of motion are easily solved in frequency domain. This gives the output current, our basic observable:

$$\begin{aligned} q_{\text{out}} &= e^{i\phi_c} q_{\text{in}} + 2 \left(\frac{G}{\phi_0 \xi_0} \right)^2 \kappa \chi_c^2 \chi_m \phi_{\text{in}} \\ &+ 2 \left(\frac{G}{\phi_0 \xi_0} \right) \sqrt{\kappa} \chi_c \chi_m m \nu^2 D h_{\text{in}}. \end{aligned} \quad (9)$$

Here, h_{in} is the gravitational wave signal [which gives a force $F_{\text{in}} = mD\nu^2 h_{\text{in}}/2$, see Eq. (2)], and the LC circuit (“cavity”) and mechanical motion susceptibilities are

$$\chi_c(\nu) = \frac{1}{i\nu - \kappa/2}, \quad \chi_m(\nu) = \frac{1}{m[(\omega_0^2 - \nu^2) - i\gamma\nu]}. \quad (10)$$

The phase $e^{i\phi_c} = \chi_c/\chi_c^*$. The second line of Eq. (9) shows the gravitational wave is encoded into the measured output on the microwave line. The first line shows

the two noise sources added by the readout itself: the shot noise, encoded by the q_{in} field, and the back-action noise, encoded by the ϕ_{in} field. In the next section, we analyze the relative size of these terms and quantify their added noise.

II. NOISE AND SENSITIVITY

We assume that our detector is limited by irreducible technical noise from the surrounding thermal bath, as well as the quantum measurement noise added from the readout system. In practice, operating in a $T \sim 10$ mK fridge, the microwave LC circuit has $\omega_a \gg T$. This means that the readout circuit is dominated by its quantum vacuum noise. With a reasonably high- Q mechanical system, the thermal noise on the mechanics is not important in this regime, as we show quantitatively at the end of this section; see also Fig. 2.

The strain noise power spectrum of the detector can be computed using the solution (9) and the Weiner-Khinchin theorem, following standard techniques [43]. For completeness we also provide a detailed derivation in App. B. The result takes the form $S_{hh} = S_{hh}^T + S_{hh}^{\text{SN}} + S_{hh}^{\text{BA}}$, where the first term represents thermal noise acting directly on the sphere, and the last two terms are the quantum readout noise, called shot noise and back-action respectively.

The total quantum readout noise can be minimized at a single frequency of choice. The shot noise term is due to vacuum fluctuations in the phase of the microwave drive, while the back-action is from the random inductive force acting on the mechanical system due to the microwave drive fluctuations. Explicitly,

$$\begin{aligned} S_{hh}^{\text{SN}}(\nu) &= \frac{\xi_0^2}{G^2 \kappa m^2 D^2 \nu^4 |\chi_c|^2 |\chi_m|^2} \\ S_{hh}^{\text{BA}}(\nu) &= \frac{G^2 \kappa}{\xi_0^2 m^2 D^2 \nu^4} |\chi_c(\nu)|^2, \end{aligned} \quad (11)$$

where the approximation holds for high frequencies. From these expressions, we see that variation of the (drive-enhanced) coupling G trades between the shot and back-action noise. In principle, we can always select a target frequency ω_* and tune the drive strength so that $G = G_*(\omega_*)$ minimizes the sum of these two quantum noise contributions. The resulting noise level is called the Standard Quantum Limit (SQL) at frequency ω_* . The required coupling strength is

$$\begin{aligned} G_* &= \frac{\xi_0}{\sqrt{\kappa} |\chi_m(\omega_*)| |\chi_c(\omega_*)|} \\ &\approx 20 \text{ MHz} \times \left(\frac{\omega_*/2\pi}{100 \text{ kHz}} \right)^{3/2} \left(\frac{100 \text{ Hz}}{\omega_0/2\pi} \right)^{1/2}, \end{aligned} \quad (12)$$

where we are taking the high-frequency limit $\omega_* \gtrsim \kappa \gg \omega_0, \gamma$. Note that the required coupling is independent of the test mass m . A central question for us is how close a realistic system can get to achieving this requirement.

As discussed in the introduction, magnetic systems like ours allow for relatively large values of the single-photon coupling (6), and can potentially enable SQL-level measurements at frequencies higher than those achievable with optical readout. To study this quantitatively, we first discuss some basic operational restrictions. The magnetic field gradient b_z is limited by the critical field of the superconducting sphere as $b_z \leq \frac{4}{5}B_c/R$ [44]. We will saturate this inequality and assume that the sphere is lead coated with TiN to maximize its density. Thin TiN films have been shown to achieve critical fields up to $B_c \sim 5$ T [53]. Under this assumption, the achievable single-photon couplings are of order

$$G_0 = \xi_0 \lambda_\Phi \beta B_c R \frac{d\omega_a}{d\Phi} \quad (13)$$

$$\approx 0.2 \text{ MHz} \times \left(\frac{B_c}{1 \text{ T}}\right)^{1/2} \left(\frac{\lambda_\Phi}{0.1}\right) \left(\frac{\beta}{1}\right),$$

where we take the circuit's frequency response to an input flux $d\omega_a/d\Phi \approx 2\pi \times 1 \text{ GHz}$ [37]. Comparing Eqs. (12) and (13), and recalling that the drive-enhanced coupling is $G = \sqrt{\bar{n}}G_0$, the basic conclusion is that SQL-level noise is achievable in this parameter regime, with very moderate amounts of circulating power in the circuit $\bar{n} \lesssim 10^2$.

Achieving the SQL at larger mass or higher frequency becomes more difficult. The limit at higher frequency comes from the $G_* \sim \omega_*^{3/2}$ scaling in Eq. (12). The scaling with sensor size is more subtle. We can parameterize $m = 4\pi\rho R^3/3$ and $\omega_0^2 = 24B_c^2/25\rho R^2$, using Eq. (1) and assuming $b_z = 4B_c/5R$ as discussed above. In terms of the sphere size R , we have $G_* \sim \omega_0^{-1/2} \sim R^{1/2}$, while $G_0 \sim (m\omega_0)^{-1/2}R^1 \sim R^0$, independent of R . Thus larger spheres require stronger driven couplings, or equivalently, larger circulating power \bar{n} in the circuit. Beyond $\bar{n} \approx 10^2$, the circuits tend to become non-linear.

In Fig. 2, we show all the contributions to the noise budget assuming that the SQL is achieved at $\omega_* \approx \kappa/2 \approx 2\pi \times 100 \text{ kHz}$. Tuning the loss rate in this way minimises the coupling required to reach the SQL at this frequency. We see that the shot noise and backaction cross at the appropriate frequency, and the thermal noise, modeled using the standard formula [54, 55],

$$S_{hh}^T(\nu) = \frac{2\gamma T}{mD^2\nu^4}, \quad (14)$$

is subdominant at the relevant frequencies. The same noise budget was used to produce the basic sensitivity projections in Fig. 1.

III. OUTLOOK

The sensitivity curves shown in Fig. 1 suggest that levitated superconducting test masses, read out with a flux tunable microwave circuit, could be capable of broad-band detection of gravitational waves in the 10 kHz–10

Figure 2. Noise PSDs referred to the GW strain for a 1 kg SLEDDoG setup. Solid lines show the noise profiles for a setup reaching the SQL at $\omega_* = \kappa/2 \approx 2\pi \times 23 \text{ kHz}$. The dashed line shows SQL, where $S_{hh}^{\text{SN}} = S_{hh}^{\text{BA}}$. We note that at $T = 10 \text{ mK}$, the mechanical modes of the sphere will be thermally occupied leading to peaks in the thermal noise PSD near mechanical resonances for $f \gtrsim 10 \text{ kHz}$. Due to the ω^{-4} scaling of the thermal noise PSD, we expect this effect to be subdominant and neglect it in our treatment. The bottom panel shows the coupling $G(\nu)$ required to reach the SQL at frequency ν for a 1 kg setup (solid) and the estimated achievable coupling G derived in App. C (dashed).

MHz band. Above this frequency range, our noise estimates are on less clear footing, because internal mechanical modes in the system will come into play. However, within the main band of interest, our proposal would open a wide swath of observable GW frequencies. Moreover, the core technology is being actively pursued to perform searches for a variety of dark matter candidates [35] and tests of low-energy quantum gravity [56]. The key advantage of these magnetic systems is the possibility of strong single-photon couplings, enabling operation at or even below the SQL at frequencies well above the kHz scale, impossible with standard optical readout methods. Our results further reinforce the need to develop such systems as future quantum-limited detectors of high-frequency signals.

IV. ACKNOWLEDGEMENTS

We thank Daniel Belkin, John Groh, Roni Harnik, Yoni Kahn, Noah Kurinsky, Nick Rodd, Philip Schmidt, Jan Schütte-Engel, Jacob Taylor, and Martin Zemlicka for helpful discussions. Appendix A: Complete Signal Calculation

The signal considered around Eq. (3) only takes into account the relative motion of the pickup loop and the sphere under the influence of a GW. However, at the frequencies we consider here ($> \text{kHz}$), the entire setup is effectively in free fall. This result can be seen by noting that the setup is made of solid materials with sound speeds $v_s \sim 10^3 \text{ m/s}$ and has a length scale of 1 m yielding a resonant frequency $\omega_c \sim \text{kHz}$. In practice, we must therefore consider the motion of the anti-Helmholtz (AHC) coils that source the quadrupolar field, the motion of the sphere, and the motion of the pickup loop. We will show that the gradiometric (figure-8) pickup circuit setup nullifies any change in primary magnetic field due to the motion of the primary coils. The dominant effect is due to the change in field sourced by the superconducting sphere.

A passing gravitational wave affects the following:

- The distance to the loop D , and thus the sphere–loop separation ξ , affecting the flux through the loop. This is the dominant signal we consider, and is discussed in the main body of the text.
- The path of the loop \mathcal{C}_ℓ , upon which the flux depends, which we show to be subleading to the previous effect; this is discussed in Sec. A 1 b.
- Distortion of the primary coils, including their shape and separation from the trap center. As we show, in the gradiometric loop configuration which we employ, this does not directly induce a change in flux through the loop, since the magnetic field is still approximately translation-invariant. However, both of these effects can change the magnetic field gradient along the coaxial direction at the centre of the quadrupole trap, which in turn changes the magnetic field that the sphere produces. This field is not translation-invariant, and so produces a measurable change through the pick-up loop. This effect can be of the same order as the first effect, but there exist configurations in which it vanishes, as shown in Sec. A 2.
- The shape of the sphere, which changes the field it induces. We show in Sec. A 3 that this effect is subdominant.

1. Forces due to a gravitational wave

In this section, we derive results on how a gravitational wave affects the primary coils, pick-up loop, and levitated particle.

In the proper detector frame, Newtonian forces act on every element of the experimental apparatus due to a passing gravitational wave [46]. The components of the force-density f_i acting on an object of density ρ at location \mathbf{x} are $f_i = \frac{1}{2}\rho h_{ij}^{\text{TT}} x^j$, where h_{ij}^{TT} are the components of the metric perturbation in TT-gauge. From here on, we omit the superscript TT on the metric perturbation h .

For a gravitational wave travelling in the \hat{z} direction, the components of a monochromatic metric perturbation h' of energy ω_g are

$$h'(t, z) = \begin{pmatrix} h_+ & h_\times & 0 \\ h_\times & -h_+ & 0 \\ 0 & 0 & 0 \end{pmatrix} \cos(\omega_g(t - z)), \quad (\text{A1})$$

which depends on the amplitude of the two polarisations h_+ and h_\times .

Given the cylindrical symmetry of our system, we may consider a gravitational wave to lie in the (x, z) -plane, without loss of generality. We obtain such a gravitational wave, propagating with a polar angle θ_h from the x -axis, by rotating Eq. (A1) $h(\theta_h) = \mathcal{R}(\theta_h) \cdot h' \cdot \mathcal{R}^\top(\theta_h)$, with

$$\mathcal{R}(\theta_h) = \begin{pmatrix} \cos \theta_h & 0 & \sin \theta_h \\ 0 & 1 & 0 \\ -\sin \theta_h & 0 & \cos \theta_h \end{pmatrix}. \quad (\text{A2})$$

The force density due to such a gravitational wave may be decomposed into its two polarisation components \mathbf{f}_+ and \mathbf{f}_\times , with

$$\mathbf{f}_+(\mathbf{x}) = h_+ \begin{pmatrix} x \cos^2 \theta_h - \frac{z}{2} \sin 2\theta_h \\ -y \\ z \sin^2 \theta_h - \frac{x}{2} \sin 2\theta_h \end{pmatrix} \cos \omega_g t, \quad (\text{A3})$$

and

$$\mathbf{f}_\times(\mathbf{x}) = h_\times \begin{pmatrix} y \cos \theta_h \\ x \cos \theta_h - z \sin \theta_h \\ -y \sin \theta_h \end{pmatrix} \cos \omega_g t, \quad (\text{A4})$$

where we have assumed that ω is much smaller than the inverse size of the experiment.

a. Force on primary coils

The primary coils comprising the anti-Helmholtz system, in the absence of a gravitational wave, are two circular wires of radius R_C at heights $z = \pm a$; a parametric description $\mathbf{c}_\pm(\lambda)$ of these two undisturbed coils is

$$\mathbf{c}_\pm(\lambda) = \begin{pmatrix} R_C \cos \lambda \\ R_C \sin \lambda \\ \pm a \end{pmatrix}, \quad (\text{A5})$$

where $\lambda \in [0, 2\pi)$.

Under the effect of a $+$ -polarised GW, we approximate the primary coils as a set of test masses, such that they are distorted by the force Eq. (A3) a

$$\mathbf{c}_\pm(\lambda) \rightarrow \begin{pmatrix} R_C \cos \lambda (1 + h_+ \cos^2 \theta_h) \mp \frac{h_+ a}{2} \sin 2\theta_h \\ R_C \sin \lambda (1 - h_+) \\ \pm a + h_+ (\pm a \sin^2 \theta_h - \frac{R_C}{2} \cos \lambda \sin 2\theta_h) \end{pmatrix}, \quad (\text{A6})$$

where we have absorbed the time-dependence of the GW into h_+ . This equation describes an elliptical coil that is subject to five effects: i) the length along the x -axis is changed to $R_C(1 + h_+ \cos^2 \theta_h)$; (ii) the length along the y -axis is changed to $R_C(1 - h_+)$, (iii) the coil is x -translated by $\mp \frac{h_+ a}{2} \sin 2\theta_h$; (iv) the coil is z -translated by $\pm a h_+ \sin^2 \theta_h$; and (v) the coil is rotated through the y -axis by an angle $\phi_h \approx -\frac{h_+}{2} \sin 2\theta_h$.

Similarly, for a \times -polarised wave, the coils are distorted by Eq. (A4) resulting in

$$\mathbf{c}_\pm(\lambda) \rightarrow \begin{pmatrix} R_C (\cos \lambda + h_\times \sin \lambda \cos \theta_h) \\ R_C (\sin \lambda + h_\times \cos \lambda \cos \theta_h) \mp a h_\times \sin \theta_h \\ \pm a - h_\times R_C \sin \lambda \sin \theta_h, \end{pmatrix} \quad (\text{A7})$$

which again describes an ellipse, but now i) with axis lengths $R_C(1 \pm h_\times \cos \theta_h)$; (ii) y -translated by $\mp a h_\times \sin \theta_h$; and (iii) tilted around the x -axis by $\phi_h \approx -h_\times \sin \theta_h$.

b. Force on pick-up loop

The pick-up loop is comprised of a two circular lengths of wire in a figure-8 shape. As such, this loop will be distorted in an analogous manner to Eqs. (A6) and (A7), with the replacement $R_C \rightarrow R_\ell$ and $a \rightarrow D$.

We neglect distortions of the pick-up loop, since, as shown in Fig. 3, the field is concentrated at the center of the loop, implying the flux is insensitive to small changes in the loop boundary.

In a gradiometric configuration, one measures the difference between fluxes through the two loops of the figure-8 coil. Thus any change in magnetic field that is translation-invariant in the plane of the loop will not cause a signal. Since both the pick-up loop and the primary coils are rotated by a GW by the same angle, and the quadrupolar field generated by elliptical coils is still translation-invariant in directions perpendicular to the primary coil's axis, the distortion of the primary coils does not induce any change in flux through the gradiometric pick-up loop.

2. Magnetic fields sourced by Anti-Helmoltz Coils

The quadrupolar trap is sourced by the magnetic field of two on axis solenoids with current running in opposite directions. We will assume that without a GW, the solenoids are fixed at $a_\pm \hat{z}$. We will refer to quantities relating to the solenoid at $a_+ \hat{z}$ with the subscript $+$ and those relating to the solenoid at $a_- \hat{z}$ with the subscript $-$. We'll

start by solving for the magnetic field sourced by a generic current loop of radius R_ℓ and height a positioned in the xy plane. The magnetic field can be written in integral form as

$$\mathbf{B}(r, \theta, z) = \frac{IR_\ell}{4\pi} \int_0^{2\pi} \frac{d\theta_\ell \hat{\boldsymbol{\theta}} \times (\mathbf{r}_\ell - \mathbf{r})}{|\mathbf{r}_\ell - \mathbf{r}|^3} \quad (\text{A8})$$

In cylindrical coordinates, the separation vector between a point on the loop (subscripts ℓ) and a point in space is

$$\mathbf{r}_\ell - \mathbf{r} = (r \cos(\theta_\ell - \theta) - R_\ell) \hat{r} + r \sin(\theta - \theta_\ell) \hat{\theta} + (z - a) \hat{z} \quad (\text{A9})$$

Therefore, the magnetic field is

$$\mathbf{B}(r, \theta, z) = \frac{\mu_0 IR_\ell}{4\pi} \int_0^{2\pi} d\theta_\ell \frac{-(r \cos(\theta - \theta_\ell) - R_\ell) \hat{z} + (z - a) \hat{r}}{(r^2 + R_\ell^2 - 2R_\ell r \cos(\theta - \theta_\ell) + (z - a)^2)^{3/2}} \quad (\text{A10})$$

We consider a system in which the radii of both the sphere and the pickup loop as well as the loop-sphere displacement are small compared to the radius and the z position of the primary coils. In this case, we can expand the integrand and solve for the magnetic field along the z -axis – this is the only component of the field that affects the sphere-induced field as well as the flux through pick-up loops in the $x - y$ plane.

$$B_z^{\text{1coil}}(z) = \frac{\mu_0 IR_\ell^2}{2} \frac{a^2 + R_\ell^2 + 3az}{(a^2 + R_\ell^2)^{5/2}} \quad (\text{A11})$$

The total field at a point z due to an AHC is

$$B_z^{\text{AHC}}(z) = \mu_0 IR_\ell^2 \frac{3az}{(a^2 + R_\ell^2)^{5/2}} = b_z z \quad (\text{A12})$$

where we have defined the magnetic field gradient near the center of the trap as

$$b_z \equiv \mu_0 IR_\ell^2 \frac{3a}{(a^2 + R_\ell^2)^{5/2}}. \quad (\text{A13})$$

Note that Eq. (A12) is translation-invariant along both the x and y axes, and so the flux due to the primary coils through a gradiometric pick-up loop vanishes.

Since the gradient of the magnetic field does vary with the major/minor axes of the ellipse as well as with the separation a of the primary coils, the field that the sphere produces is affected by the motion of the primary coils, which induces a change in flux through the gradiometric loop since it is not translation-invariant.

a. Distortions

For a set of elliptical anti-Helmholtz coils whose axes have length $R_p(1 + h_x)$ and $R_p(1 + h_y)$, and whose co-axial distance to the trap-centre is $a(1 + h_z)$, the z -component of the magnetic field is

$$B_z = \frac{3IaR_p^2}{(a^2 + R_p^2)^{7/2}} \left[a^2(1 + h_x + h_y - 4h_z) + R_p^2 \left(1 - \frac{3}{2}(h_x + h_y) + h_z \right) \right] z \quad (\text{A14})$$

to linear order in $h_{x,y,z}$. We note that for a purely $+$ -polarised GW travelling along the equator with $\theta_h = \pi/2$, $h_x = 0$, $h_y = -h_+$ and $h_z = h_+$, and so B_z is constant to linear order in h for $a = R_p/\sqrt{2}$. In this configuration, the GW-induced strain of the primary coils may be ignored.

3. Strain on sphere

The sphere itself feels a strain under the influence of a GW. This strain distorts the shape of the sphere, which in turn affects the magnetic field produced by the currents circulating along its surface. In the quasistatic limit, the induced magnetic field \mathbf{B}_{ind} satisfies both $\nabla \cdot \mathbf{B}_{\text{ind}} = \nabla \times \mathbf{B}_{\text{ind}} = 0$, and so admits the expansion [35]

$$\mathbf{B}_{\text{ind}}(r, \theta, \phi) = \sum_{l=0}^{\infty} \sum_{m=-l}^l a_{lm} r^{-l-2} \left[-(l+1) \mathbf{Y}_{lm} + \boldsymbol{\Psi}_{lm} \right], \quad (\text{A15})$$

Figure 3. The z -component magnetic field induced by the sphere, evaluated at the height of the pick-up loop, in units of $b_z R$. The pick-up loop is shown in dotted black.

where the basis vectors are given in terms of the real scalar spherical harmonics $Y_{lm}(\theta, \phi)$ as

$$\mathbf{Y}_{lm} = Y_{lm} \hat{r}, \quad \mathbf{\Psi}_{lm} = r \nabla Y_{lm}. \quad (\text{A16})$$

The total magnetic field \mathbf{B}_{tot} must satisfy the continuity condition

$$\hat{n} \cdot (\mathbf{B}_0 + \mathbf{B}_{\text{ind}})|_{\Sigma} = 0, \quad (\text{A17})$$

where \hat{n} is the unit normal to the superconducting element's surface Σ , and \mathbf{B}_0 is the trap magnetic field. This continuity condition specifies the value of the coefficients a_{lm} of Eq. (A15), given a particular trap field.

The field due to the sphere, when unperturbed by a GW, satisfies $\hat{r} \cdot \mathbf{B}_{\text{tot}}(\mathbf{r}_0) = 0$, for all $\mathbf{r}_0 \in \Sigma_0$, where Σ_0 is surface of the unperturbed sphere. If the sphere is at the centre of a *quadrupolar* trap, we have

$$\mathbf{B}_0 = \sqrt{\frac{\pi}{5}} b_z r (2\mathbf{Y}_{20} + \mathbf{\Psi}_{20}), \quad (\text{A18})$$

where b_z is given by Eq. (A13). The continuity condition $B_{\text{tot},r}(R, \theta, \phi) = 0$ implies that the unperturbed coefficients $a_{lm} = a_{lm}^{(0)}$ are

$$a_{20}^{(0)} = \frac{2}{3} \sqrt{\pi/5} b_z R^5, \quad (\text{A19})$$

where R is the sphere's radius, with the coefficients vanishing. The z -component of this induced field is plotted in Fig. 3, where we have set $z = R$.

Under small perturbation due to a GW, the continuity condition implies

$$\hat{n} \cdot \mathbf{B}_{\text{tot}} \approx \hat{r} \cdot \mathbf{B}_{\text{tot}}(\mathbf{r}_0) + \hat{\delta} \cdot \mathbf{B}_{\text{tot}}(\mathbf{r}_0) + \hat{r}_i \cdot \Delta_j \nabla_j B_{\text{tot},i}(\mathbf{r}_0) + \mathcal{O}(h^2) = 0, \quad (\text{A20})$$

where $\hat{\delta} \equiv \hat{n} - \hat{r}$ is the deviation of the perturbed normal vector, and $\mathbf{\Delta}(\theta, \phi) \equiv \mathbf{r} - \mathbf{r}_0$ is the change in position of the sphere's surface, both of which are $\mathcal{O}(h)$. We also expand the induced magnetic field in terms of its unperturbed value $\mathbf{B}_{\text{ind}}^{(0)}$ and the $\mathcal{O}(h)$ corrections $\mathbf{B}_{\text{ind}}^{(1)}$; Eq. (A20) then implies

$$\hat{r} \cdot \mathbf{B}_{\text{ind}}^{(1)} = -\hat{\delta} \cdot \left(\mathbf{B}_0(\mathbf{r}_0) + \mathbf{B}_{\text{ind}}^{(0)}(\mathbf{r}_0) \right) - \mathbf{\Delta} \cdot \nabla \left(B_{0,r}(\mathbf{r}_0) + B_{\text{ind},r}^{(0)}(\mathbf{r}_0) \right), \quad (\text{A21})$$

which must be solved to find the coefficients $a_{lm}^{(1)}$ of the corrections to the induced field.

Assuming that the frequency ω_g of a GW incident on the sphere is much larger than the mechanical resonance of the sphere, the distortion of the sphere due to the GW can be decomposed into a time dependent amplitude and dimensionless spatial mode profiles \mathbf{S}_{nlm} :

$$\Delta(\mathbf{x}, t) = h\eta_{nlm}^g e^{-i\omega_g t} R \mathbf{S}_{nlm}(\mathbf{x}) . \quad (\text{A22})$$

The amplitude of the mechanical perturbation depends on the GW strain, the sphere radius, and the GW coupling to the mechanical mode η_{nlm}^g defined as [20]

$$\eta_{nlm}^g = \frac{1}{2VR} \hat{h}_{ij}^{\text{TT}} \int_V dV x^j S_{nlm}^i(\mathbf{x}) , \quad (\text{A23})$$

where \hat{h}^{TT} is the TT metric perturbation normalized by the strain. The spatial profiles, normalized such that $\int_V dV |\mathbf{S}(\mathbf{x})|^2 = V$, can be expanded in terms of vector spherical harmonics such that each mode causes a distortion [20, 46]

$$\Delta_{nlm}(\mathbf{x}) = h\eta_{nlm}^g R (A_{nl}(R) \mathbf{Y}_{lm} + B_{nl}(R) \mathbf{\Psi}_{lm}) , \quad (\text{A24})$$

where the coefficients A_{nl}, B_{nl} depend on the mechanical properties of the sphere.

The unit normal vector given in terms of the sphere's deformed radius $R_h(\mathbf{r}) := |\mathbf{r}_0 - \Delta(\mathbf{r})|$ can be determined from Eq. (A24) as

$$\begin{aligned} \hat{n} &= \frac{\nabla R_h(\mathbf{r})}{|\nabla R_h(\mathbf{r})|} \\ &\approx \hat{r} - h\eta_{nlm}^g A_{nl} \mathbf{\Psi}_{lm}, \end{aligned} \quad (\text{A25})$$

which is normal to the perturbed surface at the same (θ, ϕ) as the unperturbed sphere. Therefore the $\mathcal{O}(h)$ corrections to the induced field must satisfy, by Eq. (A21),

$$\sum_{l'm'} a_{l'm'} \frac{(l'+1)}{r^{l'+2}} Y_{l'm'} = h\eta_{nlm}^g \frac{A_{nl} a_{20}^{(0)}}{R^4} (\mathbf{\Psi}_{lm} \cdot \mathbf{\Psi}_{20} - 12 \mathbf{Y}_{lm} \cdot \mathbf{Y}_{20}) + \sqrt{\frac{\pi}{5}} h\eta_{nlm}^g A_{nl} b_z R (\mathbf{\Psi}_{lm} \cdot \mathbf{\Psi}_{20} - 2 \mathbf{Y}_{lm} \cdot \mathbf{Y}_{20}) . \quad (\text{A26})$$

Now we make use of the facts that spherical harmonics are orthogonal when integrated over the sphere

$$\int d\Omega Y_{lm} Y_{l'm'} = \delta_{ll'} \delta_{mm'} , \quad (\text{A27})$$

and further satisfy the condition

$$\begin{aligned} C_{m_1 m_2 m_3}^{l_1 l_2 l_3} &:= \int d\Omega Y_{l_1 m_1} Y_{l_2 m_2} Y_{l_3 m_3} \\ &= \sqrt{\frac{(2l_1+1)(2l_2+1)(2l_3+1)}{4\pi}} \begin{pmatrix} l_1 & l_2 & l_3 \\ m_1 & m_2 & m_3 \end{pmatrix} \begin{pmatrix} l_1 & l_2 & l_3 \\ 0 & 0 & 0 \end{pmatrix} , \\ D_{m_1 m_2 m_3}^{l_1 l_2 l_3} &:= \int d\Omega Y_{l_1 m_1} (\nabla_\Omega Y_{l_2 m_2}) \cdot \nabla_\Omega (Y_{l_3 m_3}) \\ &= \frac{l_2(l_2+1) + l_3(l_3+1) - l_1(l_1+1)}{2} \int d\Omega Y_{l_1 m_1} Y_{l_2 m_2} Y_{l_3 m_3} , \end{aligned} \quad (\text{A28})$$

where $\begin{pmatrix} l_1 & l_2 & l_3 \\ m_1 & m_2 & m_3 \end{pmatrix}$ is the Wigner 3- j symbol, and ∇_Ω is the surface gradient. Using these expressions, we may integrate Eq. (A26) over the sphere, weighted by a spherical harmonic, to find

$$\begin{aligned} a_{l'm'}^{(1)} &= -h\eta_{nlm}^g \frac{A_{nl} R^{l'+2}}{l'+1} \left[\frac{a_{20}^{(0)}}{R^4} (12C_{m'm_0}^{l'l_2} - D_{m'm_0}^{l'l_2}) + \sqrt{\frac{\pi}{5}} b_z R (2C_{m'm_0}^{l'l_2} - D_{m'm_0}^{l'l_2}) \right] \\ &= -h\eta_{nlm}^g \frac{A_{nl} R^{l'+2}}{l'+1} \frac{a_{20}^{(0)}}{R^4} \left(15C_{m'm_0}^{l'l_2} - \frac{5}{2} D_{m'm_0}^{l'l_2} \right) , \end{aligned} \quad (\text{A29})$$

where we have made use of Eq. (A19) in the second line.

For the quadrupolar $l = 2$ mechanical deformations induced by a GW, the Wigner 3- j symbols appearing in Eq. (A29) vanish unless $l = 0, 2, 4$, implying that $\mathcal{O}(h)$ corrections are induced to the monopole, quadrupole and octupole moments. Furthermore, the GW-mechanical couplings η_{nlm}^g are $\mathcal{O}(1)$ only for $n = 0$ and $l = 2$. For a +-polarized GW propagating in the xy plane, $\eta_{022}^g = 0.52$ and $\eta_{020}^g = -0.30$ with all other $n = 0$ couplings equal to zero; we also find $A_{02} = 0.96$. For such a wave, the change in flux $\delta\Phi^{(1)}$ is then given by integrating the perturbed magnetic field, given by Eqs. (A15) and (A29), over the gradiometric loop configuration sketched in Fig. 3, and is

$$\frac{\delta\Phi^{(1)}}{\Phi^{(0)}} = -0.54he^{-i\omega_g t}; \quad (\text{A30})$$

we neglect this effect in the main text as it is smaller than the signal of Eq. (C3) coming from variation in the sphere-loop separation.

Appendix B: System Hamiltonian and input-output formalism

In this appendix, we begin by deriving the full Hamiltonian of the sphere coupled to the readout circuit. We then show how to employ the standard input-output formalism from quantum optics [43] to calculate the signal and noise power spectral densities. Throughout, we follow closely Ref. [36], generalizing where necessary.

We begin by deriving the Hamiltonian for the sphere, the readout circuit, and their coupling. Independently, each of the two systems is simply a harmonic oscillator. We write

$$H_{\text{sphere}} = \frac{p^2}{2m} + \frac{1}{2}m\omega_0^2\xi^2, \quad H_{\text{LC}} = \frac{q^2}{2C} + \frac{\phi^2}{2(L_a + L_J(\Phi))} = \frac{q^2}{2C} + \frac{1}{2}C\tilde{\omega}_a^2\phi^2, \quad (\text{B1})$$

where we have restricted the motion of the sphere to the z axis, Φ is the magnetic flux through the readout circuit, $\tilde{\omega}_a = \tilde{\omega}_a(\Phi) = 1/\sqrt{L(\Phi)C}$ is the (flux-dependent) frequency of the circuit in terms of the total (flux-dependent) inductance $\tilde{L} = \tilde{L}(\Phi) = L_a + L_J(\Phi)$, q is the charge on the capacitor and ϕ is the phase. These are conjugate variables which behave analogously to the position and momentum z and p for the mechanical system. The inductance L_J is assumed to be nonlinear, which can be achieved for example using a Josephson interferometer for which L_J is periodic in Φ .

Motion of the sphere relative to the pickup loop (with distance ξ) induces an external flux $\Phi \propto \xi$ through the resonator circuit. For small changes in position, the change in flux is determined by the gradient of the flux with respect to the separation $\partial\Phi_p/\partial z$. We parametrize this gradient as [37]

$$\frac{\partial\Phi_p}{\partial z} = \beta b_z R^2, \quad (\text{B2})$$

where $b_z = \partial(\mathbf{B}_0)_z/\partial z$ is the trap's magnetic field gradient, R is the sphere's radius, and $\beta \sim O(1)$ is a dimensionless geometric coefficient. The magnetic field on the surface of the sphere is approximately $b_z R$, and so this product is constrained to be less than the critical field of the superconducting sphere. The loop flux Φ_p is linearly related to flux through the SQUID $\Phi = \lambda_\Phi \Phi_p$, through a transduction coefficient

$$\lambda_\Phi = \frac{M}{L_I + L_p + L_w} \approx \frac{M}{2L_p} \quad (\text{B3})$$

where $M \leq \sqrt{L_S L_I}$ is the mutual inductance, given in terms of the SQUID and input inductances L_S and L_I , respectively, L_p is the loop inductance, and L_w is any stray inductance in the system. We assume that there is perfect coupling between the input coil and the SQUID, such that $M = \sqrt{L_S L_I}$. The transduction coefficient is maximised for $L_I = L_p$ and $L_w \ll L_I$, which is the approximation in the second step. Integrating $\Phi = \lambda_\Phi \Phi_p$ once and putting this together reproduces Eq. (4), which here is more usefully written as

$$\eta \equiv \frac{\partial\Phi}{\partial\xi} = \beta b_z R^2 \lambda_\Phi \approx \beta b_z \frac{M}{2L_p} R^2. \quad (\text{B4})$$

For small fluxes $\Phi \approx 0$ through the SQUID, in particular those generated by small motions of the sphere, we can expand

$$\tilde{\omega}_a(\Phi) = \omega_a + \Phi \frac{\partial\tilde{\omega}_a(0)}{\partial\Phi}, \quad \frac{\partial\tilde{\omega}_a(0)}{\partial\Phi} = -\frac{1}{2}C\omega_a^3 \frac{\partial L_J(0)}{\partial\Phi}, \quad (\text{B5})$$

where here and in the rest of the paper, $\omega_a = 1/\sqrt{LC}$ is the (flux-independent) LC frequency in terms of the (flux-independent) total inductance at zero flux $L = \tilde{L}(0) = L_a + L_J(0)$. Finally, we can use this expansion to write the total Hamiltonian as two oscillators with a simple coupling:

$$H_{\text{sys}} = \frac{p^2}{2m} + \frac{1}{2}m\omega_0^2\xi^2 + \frac{q^2}{2C} + \frac{1}{2}C\omega_a^2\phi^2 + V_{\text{int}}. \quad (\text{B6})$$

The interaction term comes from expanding

$$\tilde{\omega}_a^2 \approx \omega_a^2 + 2\omega_a \frac{\partial\tilde{\omega}_a}{\partial\xi} \xi \approx \omega_a^2 + 2\omega_a \frac{\partial\tilde{\omega}_a}{\partial\Phi} \frac{\partial\Phi}{\partial\xi} \xi \quad (\text{B7})$$

and using the above results to evaluate the derivatives, yielding

$$V_{\text{int}} = -C\omega_a \frac{\partial\omega_a}{\partial\Phi} \eta \xi \phi^2, \quad (\text{B8})$$

where again η is given in Eq. (B4).

The coupling term in Eq. (B8) represents a nonlinear coupling between the sphere and the LC circuit $\sim \xi\phi^2$. This is similar to the usual optomechanical coupling $\sim xa^\dagger a$ between the position of a suspended mirror and the cavity photon number operator. There is a slight difference since the optomechanical coupling is dispersive (position couples to energy, which is conserved) while the magnetomechanical coupling here is not (position couples to ϕ^2 , which is not conserved). However, when the readout system is driven, the two couplings behave identically, as we will see below.

This system can be quantized following standard methods [57]. Simply, ξ, p, q , and ϕ are promoted to operators. Since the system is a pair of coupled harmonic oscillators we explicitly introduce ladder operators

$$\xi = \xi_0 (b^\dagger + b), \quad p = ip_0 (b^\dagger - b), \quad \phi = \phi_0 (a^\dagger + a), \quad q = iq_0 (a^\dagger - a). \quad (\text{B9})$$

Here the prefactors are the vacuum amplitudes (i.e., the uncertainties in the ground state):

$$\xi_0 = \sqrt{\frac{1}{2m\omega_0}}, \quad p_0 = \sqrt{\frac{m\omega_0}{2}}, \quad \phi_0 = \sqrt{\frac{1}{2C\omega_a}}, \quad q_0 = \sqrt{\frac{C\omega_a}{2}}. \quad (\text{B10})$$

The commutation relations are canonical: $[\xi, p] = [\phi, q] = i$. In terms of the ladder operators we can write the Hamiltonian as

$$H_{\text{sys}} = \omega_a a^\dagger a + \omega_0 b^\dagger b - G_0 (a^\dagger + a)^2 (b^\dagger + b), \quad (\text{B11})$$

where the single-photon coupling is

$$G_0 = C\omega_a \eta \frac{\partial \omega_a}{\partial \phi} \xi_0 \phi_0^2 = \frac{1}{2} \eta \xi_0 \frac{\partial \omega_a}{\partial \Phi}, \quad (\text{B12})$$

and has units of frequency as usual. The Heisenberg equations of motion are thus

$$\dot{\xi} = \frac{p}{m}, \quad \dot{p} = -m\omega_0^2 \xi - \frac{G_0}{\phi_0^2 \xi_0} \phi^2, \quad \dot{\phi} = \frac{q}{C}, \quad \dot{q} = -C\omega_a^2 \phi - \frac{2G_0}{\phi_0^2 \xi_0} \phi \xi. \quad (\text{B13})$$

We see that the motion of the sphere ξ is imprinted on the circuit, and vice versa, the circuit drives the position of the sphere, through the G_0 terms.

Eqs. (B13) describe the sphere and LC circuit in the absence of any noise and without the microwave drive and readout. To incorporate these effects, we use standard input-output techniques [43]. The microwave line is assigned input and output fields $\phi_{\text{in}}, q_{\text{in}}$, with effective coupling rate κ , and we also allow for an external force F_{in} on the mechanical motion of the sphere, which can include both the signal of interest as well as thermal noise. The Heisenberg equations, Eq. (B13), become Heisenberg-Langevin equations,

$$\begin{aligned} \dot{\xi} &= \frac{p}{m}, & \dot{\phi} &= \frac{q}{C} - \frac{\kappa}{2} \phi + \sqrt{\kappa} \phi_{\text{in}} \\ \dot{p} &= -m\omega_0^2 \xi - \frac{G_0}{\phi_0^2 \xi_0} \phi^2 - \gamma p + F_{\text{in}}, & \dot{q} &= -C\omega_a^2 \phi - \frac{2G_0}{\phi_0^2 \xi_0} \phi \xi - \frac{\kappa}{2} q + \sqrt{\kappa} q_{\text{in}}. \end{aligned} \quad (\text{B14})$$

The output fields are related to the input fields by the usual I/O relations

$$\phi_{\text{out}} = \phi_{\text{in}} - \sqrt{\kappa} \phi, \quad q_{\text{out}} = q_{\text{in}} - \sqrt{\kappa} q. \quad (\text{B15})$$

Driving the microwave line at the LC frequency $\phi_{\text{in}} \rightarrow \bar{\phi}_{\text{in}} \cos(\omega_a t) + \phi_{\text{in}}$, where the overlined term is the drive strength and the second term is the vacuum fluctuation around this drive, we can solve for the steady-state solution $\bar{\phi} = \bar{\phi}_{\text{in}} / \sqrt{\kappa}$ to leading order in couplings and perturbations, assuming a sufficiently strong drive $|\bar{\phi}_{\text{in}}| \gg \phi_{\text{in}}$. Moving to the frame co-rotating with the drive (i.e., the LC circuit) and linearizing around the strong drive, we obtain the equations of motion (8) given in the main text, viz.

$$\begin{aligned} \dot{\xi} &= \frac{p}{m}, & \dot{\phi} &= -\frac{\kappa}{2} \phi + \sqrt{\kappa} \phi_{\text{in}} \\ \dot{p} &= -m\omega_0^2 \xi - \frac{G}{\phi_0 \xi_0} \phi - \gamma p + F_{\text{in}}, & \dot{q} &= -\frac{2G}{\phi_0 \xi_0} \xi - \frac{\kappa}{2} q + \sqrt{\kappa} q_{\text{in}}, \end{aligned} \quad (\text{B16})$$

where the drive-enhanced coupling is

$$G \equiv \sqrt{\bar{n}} G_0, \quad \bar{n} \equiv \frac{|\bar{\phi}_{\text{in}}|^2}{\phi_0^2 \kappa} \quad (\text{B17})$$

in terms of the number \bar{n} of microwave quanta circulating in the LC circuit. In this limit the equations of motion are linear and therefore easy to solve with linear response in the frequency domain.

The observable we are interested in is the output charge q_{out} , since q is the variable that gets the information about the mechanical system. From the I/O relation (B15), this means we need the solution for $\phi(\nu)$ in terms of the various input fields. The solution for the mechanical motion $z(\nu)$ is

$$\xi(\nu) = \chi_m(\nu) \left[-\frac{G}{\phi_0 \xi_0} \phi(\nu) + F_{\text{in}}(\nu) \right] \quad (\text{B18})$$

in terms of the response function for the mechanical motion

$$\chi_m(\nu) = \frac{1}{m[(\omega_0^2 - \nu^2) - i\gamma\nu]}. \quad (\text{B19})$$

Using this and the I/O relation, we obtain the solution for $q_{\text{out}}(\nu)$:

$$q_{\text{out}}(\nu) = e^{i\phi_c(\nu)} q_{\text{in}}(\nu) + 2 \left(\frac{G}{\phi_0 \xi_0} \right)^2 \kappa \chi_c^2(\nu) \chi_m(\nu) \phi_{\text{in}}(\nu) - 2 \left(\frac{G}{\phi_0 \xi_0} \right) \sqrt{\kappa} \chi_c(\nu) \chi_m(\nu) F_{\text{in}}(\nu), \quad (\text{B20})$$

where now we use the circuit (“cavity”) response function and phase shift

$$\chi_c(\nu) = \frac{1}{-i\nu + \kappa/2}, \quad e^{i\phi_c(\nu)} = 1 - \kappa \chi_c(\nu) = \frac{-i\nu - \kappa/2}{i\nu + \kappa/2}. \quad (\text{B21})$$

Equation (B20) shows how both any signals of interest and a variety of noise effects are encoded onto the measured output. The signal is part of F_{in} ; for a gravitational wave it is $F_{\text{in}}^{\text{sig}}(\nu) = m\nu^2 Dh(\nu)$, where D is the equilibrium distance between the loop and sphere. Each of the three terms encodes a different noise effect. Thermal noise acting on the sphere motion will also be part of F_{in} and couple in at order G . The term of order G^0 represents shot noise: these are the input fluctuations in q_{in} which transmit through the resonator circuit. The term of order G^2 represents back-action noise: the random drive on the sphere from microwave fluctuations in the circuit, which is then transduced back onto the circuit and eventually shows up in the output. Computing the strain noise from Eq. (B20) is straightforward. To estimate the strain from the charge data stream we divide by the appropriate coefficient, namely

$$h_E(\nu) = \frac{1}{\frac{2G}{\phi_0 \xi_0} \sqrt{\kappa} \chi_c(\nu) \chi_m(\nu) m\nu^2 D} q_{\text{out}}(\nu). \quad (\text{B22})$$

The noise power spectrum referred to this observable is then obtained by the Weiner-Khinchin theorem, which amounts to squaring Eq. (B20) and taking the expectation value:

$$S_{hh} = \frac{1}{\left(\frac{2G}{\phi_0 \xi_0} \right)^2 \kappa |\chi_c|^2 |\chi_m|^2 m^2 \nu^4 D^2} S_{qq} + \left(\frac{G}{\phi_0 \xi_0} \right)^2 \frac{\kappa |\chi_c|^2}{m^2 \nu^4 D^2} S_{\phi\phi} + \frac{1}{m^2 \nu^4 D^2} S_{FF}. \quad (\text{B23})$$

Finally, to work out the SQL, we pick a frequency ω_* at which we want to optimize the total quantum noise. We assume vacuum input noise $S_{qq} = q_0^2/2 = 1/2\phi_0^2$, $S_{\phi\phi} = \phi_0^2/2$. The condition for the optimal coupling $\partial S^{\text{quantum}}(\omega_*)/\partial G^2 = 0$ has solution

$$G_*^2 = \frac{\xi_0^2}{2\kappa |\chi_c(\omega_*)|^2 |\chi_m(\omega_*)|} \quad (\text{B24})$$

and the total noise power, at this frequency, reduces to the usual SQL form:

$$S_{hh}^{\text{quantum}}(\omega_*) \rightarrow \frac{1}{2|\chi_m(\omega_*)| m^2 \omega_*^4 D^2} \approx \frac{1}{2m\omega_*^2 D^2}, \quad (\text{B25})$$

where the approximation is in the “free-particle” limit $\omega_* \gg \omega_0$.

Appendix C: Flux-position coupling

The dimensionless coupling constant β parametrises the sensitivity of the flux through the pick-up loop Φ_p to changes in the position of the loop; it is defined through

$$\frac{\partial \Phi_p}{\partial z} = \beta R^2 b_z. \quad (\text{C1})$$

In this appendix, we give a numerical derivation of its optimal value for a square, gradiometric, pick-up loop coupled to a superconducting sphere at the centre of a quadrupolar field.

For a pick-up loop oriented in the (x, y) plane, the flux only depends on the z -component of the sphere-induced magnetic field, integrated over the loop's surface Σ_p , meaning

$$\frac{\partial \Phi_p}{\partial z} = \int_{\Sigma_p} dA \frac{\partial B_{\text{ind},z}(x, y, D)}{\partial z}, \quad (\text{C2})$$

where $\mathbf{B}_{\text{ind}}(\mathbf{x})$ is given by Eqs. (A15) and (A19).

In Fig. 4, we plot $\frac{\partial B_{\text{ind},z}}{\partial z}$ appearing in Eq. (C2), from which we numerically evaluate the coefficient β in Eq. (C1). We find that at a pick-up loop–sphere separation D equal to R , we achieve a maximum of $\beta \approx 1.6$ for loop of size linear size $\approx 1.1R$.

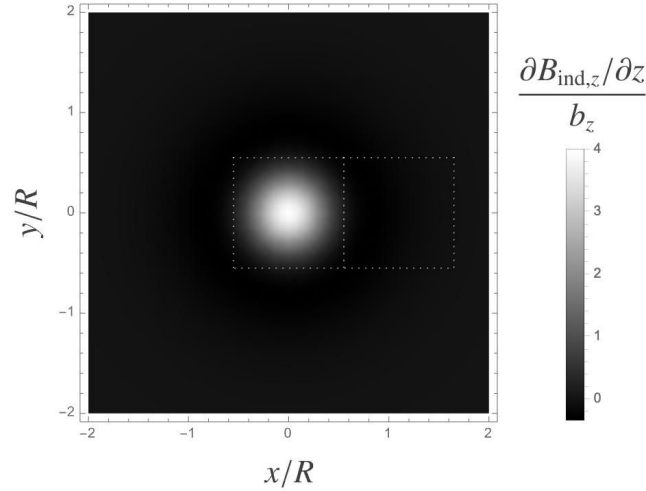

Figure 4. The z -derivative of the magnetic field's z -component, evaluated at the height of the pick-up loop, in units of b_z . The pick-up loop is shown in dotted white.

The change in flux due to a change in sphere–loop separation $\delta\xi = hDe^{-i\omega_g t}$ may be written as $\delta\Phi_p = hD \partial\Phi_p/\partial z$, and so we find

$$\frac{\delta\Phi_p}{\Phi^{(0)}} \approx -2.9he^{-i\omega_g t} \quad (\text{C3})$$

for $\beta = 1.6$, where $\Phi^{(0)}$ is the unperturbed flux through the loop.
