(Dated: 13 August 2024)

The electrical properties and performance characteristics of niobium dioxide (NbO₂)-based memristive devices are examined at cryogenic temperatures. Substoichiometric Nb₂O₅ was deposited via magnetron sputtering and patterned in microscale (2×2 - 15×15 μm²) cross-bar Au/Ru/NbO_x/Pt devices and electroformed at 3-5 V to make NbO₂ filaments. At cryogenic temperatures, the threshold voltage (V_{th}) increased by more than a factor of 3. The hold voltage (V_h) was significantly lower than the threshold voltage for fast voltage sweeps (200 ms per measurement). If the sample is allowed to cool between voltage measurements, the hold voltage increases, but never reaches the threshold voltage, indicating the presence of non-volatile Nb₂O₅ in the filament. The devices have an activation energy of $E_a \approx 1.4$ eV, lower than other NbO₂ devices reported. Our works shows that even nominally “bad” memristive devices can be improved by reducing the leakage current and increases the sample resistance at cryogenic temperatures.

I. INTRODUCTION

As the demand for computational power increases, the energy efficiency and scaling limitations of conventional CMOS-based circuits have become increasingly apparent. The rapidly developing field of neuromorphic computing seeks to overcome these limitations by emulating the functions of the human brain.¹ The goal of neuromorphic computing is to revolutionize memory storage and computational paradigms by offering non-volatile storage and analog computing capabilities within the same architecture. In order to realize the goals of neuromorphic circuits, materials must be found that can mimic both the synaptic and neuronal behaviors in nerve cells.²⁻⁷

Crystalline niobium dioxide has emerged as a material of significant interest in neuromorphic circuits, for example, as a scalable neuristor,⁷ as selectors in non-volatile RAM,⁸ or as oscillator neuron devices.⁹ NbO₂ has a structural phase transition at approximately 800°C that is marked by a sharp insulator-metal transition (IMT), dramatically changing the resistance of the material.¹⁰⁻¹³ Reliable threshold switching about the IMT enables the precise control of the device's resistance state, a prerequisite for the reliable operation of neuromorphic circuits.¹⁴

The preferred oxidation state of niobium oxide is Nb₂O₅, which makes deposition of crystalline NbO₂ challenging. While many studies successfully deposit NbO₂ films (sometimes crystalline^{15,16} though more often amorphous or poly-crystalline¹⁷⁻¹⁹), most researchers deposit Nb₂O₅²⁰⁻²² or a mixture of NbO, Nb₂O₅, and NbO₂ (usually referred to as NbO_x)^{8,23-26}, or intentionally layer NbO₂ and Nb₂O₅^{14,27-29} or layer NbO and NbO_x³⁰. In some reports, the exact composition of the NbO_x films is unclear.^{9,31,32}

If the initially deposited film is not NbO₂, researchers must create NbO₂ from the as-deposited film. The most straightforward method is post-deposition annealing,^{13,17,19,26,30,33} with a wide range of annealing temperatures, pressures, and ambient gases. The more common method is to create an electroformed NbO₂ filament by applying a large voltage across the film between the bottom and the top electrode.^{9,15,18,20-22,24,26-28,31} These electroformed devices are usually a crystalline NbO₂ filament of $r \approx 150$ nm²⁸ surrounded by amorphous NbO₂ and Nb₂O₅⁹. Some researchers combine annealing and electroforming,²⁹ and some are unclear how they form NbO₂.³²

Finally, memristive NbO₂ devices typically come in one of two forms. The most com-

mon is a simple cross-bar geometry, where the NbO_x layer is sandwiched between two metal electrodes. In the cross-bar geometry, the typical device sizes range from 2×2 to $40 \times 40 \mu\text{m}^2$.^{9,14,16,20–22,24,26–28,30–32,34,35} These devices nearly always require the stochastic electroforming step, and the electroformed NbO_2 filaments are nearly always much smaller than the device size.²⁸ Some devices of this type rely on a percolation path through the crystalline NbO_2 .²⁹ Less common is a nanoscale-sized bottom electrode (20×20 to $200 \times 200 \text{ nm}^2$) photolithographically patterned as a small metal via through an insulating layer, covered with a blanket niobium oxide film and a large top electrode.^{8,17,23,26,29} These films greatly constrain the device size to be about the size of an electroformed filament or smaller.

Given the wide range of NbO_x films and devices, it is not surprising that there is a wide range of switching behaviors in NbO_2 memristors. Many published reports have found threshold switching behavior with on and off-state resistances (or currents) that can change by an order of magnitude (and often more).^{9,14,16,20–22,24,26–32,34–36} On occasion, researchers have reported NbO_2 films that display non-ohmic behavior but without an abrupt switch from high to low resistance state.^{25,26,29} Controlling the behavior of NbO_2 to achieve repeatable and reliable memristive devices is a key goal of researchers in this field.

We have deposited films of sub-stoichiometric Nb_2O_5 via physical vapor deposition and created devices in the common cross-bar geometry, with device sizes ranging from 2×2 - $15 \times 15 \mu\text{m}^2$. We electroformed an NbO_2 filament which gave poor memristive behavior at room temperature.²⁶ In this work, we examined the behavior of the NbO_2 filaments at cryogenic temperatures. In all cases, the threshold voltage increased and the resistive ratio between the off and on states also increased (high and low resistance states), improving the memristive device characteristics.

II. EXPERIMENT

All NbO_2 films were deposited at the University at Albany College of Nanotechnology, Science & Engineering in a Kurt J. Lesker PVD75 system via reactive magnetron sputtering using targets purchased from Kurt J. Lesker. The deposition occurred in an oxygen poor environment at 25°C at 3% O_2 flow in Ar atmosphere at 3 mTorr with a target power density of 6 W/cm^2 . This process yields sub-stoichiometric amorphous Nb_2O_5 after the deposition which can be crystallized into the metastable allotrope NbO_2 .

X-ray photoelectron spectroscopy (XPS) was measured with a Kratos Axis Ultra DLD, which has a monochromatic Al- $k\alpha$ X-ray source, and hemispherical analyzer. Survey spectra were measured with a pass energy of 100 eV, and high resolution spectra were measured with a pass energy of 20 eV. XPS data were analyzed with the CasaXPS software package.

Atomic force microscopy images were taken with a Park System AFM in tapping mode. The measurements were performed in air. We used the open-source software package Gwyddion to analyze our data.

The cross-bar device structures were fabricated at the Cornell NanoScale Science and Technology Facility with 50 nm-thick Pt bottom electrodes ranging in width from 2 μm to 15 μm on SiO_2 . Blanket NbO_x deposition occurred on top of the bottom electrode, and then capped with a top electrode of a 10 nm adhesion layer of Ru followed by 50 nm of either Au or Pt. Device patterning used standard liftoff photolithography and RIE for cleaning and to etch through the NbO_x layer to reach the bottom electrode. The schematic of the cross devices is shown as an inset in Fig. 1. The NbO_x films in the cross-bar devices were not thermally annealed after deposition.

The electric behavior of the devices were measured using a Keithley 2400 Source Measure Unit in voltage control mode with a compliance current of 1 mA. IV curves were initially swept from -1 to 1 V, with some sweeps reaching voltages as high as ± 5 V to create the electroformed NbO_2 filaments. The devices were cooled to low temperatures in a Janis closed-cycle cryostat. The temperature was monitored using a Lakeshore 336 temperature controller.

III. RESULTS AND DISCUSSION

A. Sample growth and characterization

The as-grown materials were characterized with XPS, XRD, and AFM. Characterization was measured on blanket film depositions using similar deposition conditions as on the device substrates.

XPS survey scans indicate the presence of Nb, O, and adventitious C contamination. High resolution scans for binding energies corresponding to the niobium 3d doublet can be found in Figure 1, with large peaks at around 207.7 eV and 210.4 eV, which correspond to the

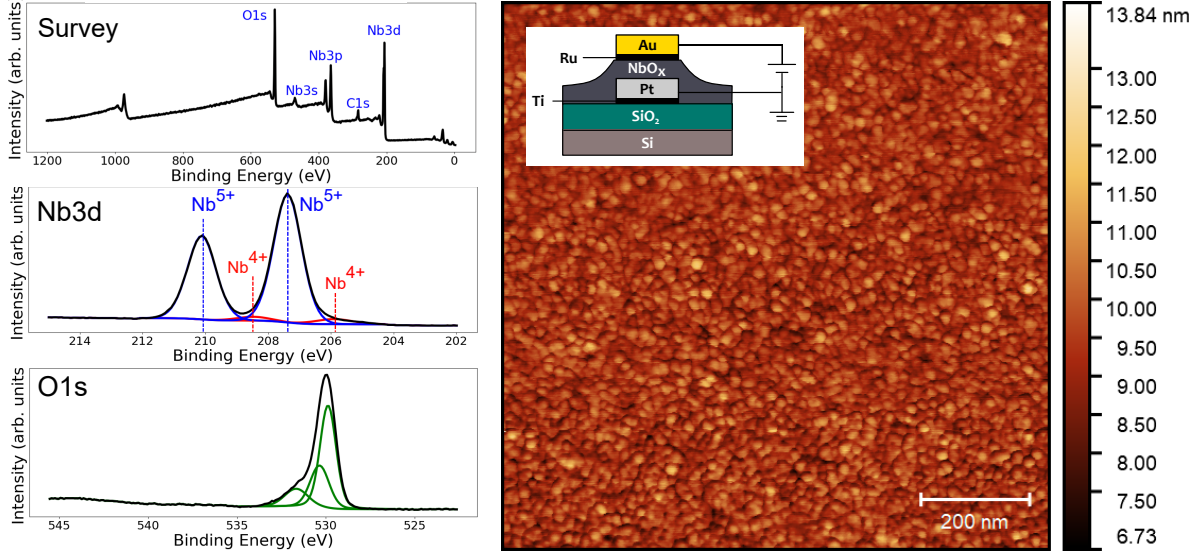

FIG. 1. Sample characterization of the NbO_2 films. The left shows the XPS results, indicating that the as-grown sample is mostly Nb_2O_5 . The right shows a representative AFM topography of a blanket as-deposited Nb_2O_5 film, with RMS roughness of around 0.33 nm. The inset on the AFM topography shows the device schematic.

doublet for Nb_2O_5 (+5 oxidation state). A second, vanishingly small, doublet corresponding to the +4 oxidation state of NbO_2 occurs roughly ~ 2.2 eV lower than the doublet for the +5 oxidation state. Typically, when NbO_2 is exposed to atmospheric conditions, it will form a thin surface oxide of Nb_2O_5 due to the interaction with atmospheric oxygen.^{12,13,37,38} However, for NbO_2 bulk films, the surface oxide is typically limited to the top 1.5 nm to 2.5 nm, and XPS is expected to show strong NbO_2 doublet peaks which corresponds to the underlying NbO_2 film²³. The lack of a significant secondary doublet implies that the as-grown film is almost exclusively Nb_2O_5 .

The AFM images look qualitatively similar between all samples. A representative image can be found in Figure 1, with RMS roughness for the sample at 0.33 nm. XRD measurements indicate that the as-grown films are amorphous, with crystalline NbO_2 developing upon annealing at 600 to 900 $^\circ\text{C}$ ²⁶. The films in this study were not annealed.

FIG. 2. Representative I-V curves of an electroformed NbO₂ filament measured on a $15 \times 15 \mu\text{m}^2$ cross-bar device. As the surrounding temperature decreases, the resistance, V_{th} and $R_{\text{on/off}}$ increases. The input power was turned off after each measurement, allowing the sample to cool.

B. Cryogenic measurements of NbO₂ filaments

We present our results on cryogenic measurements on a typical electroformed NbO₂ filament in Fig. 2. At room temperature, this device shows a gradual change in resistance to the compliance current (1 mA) and makes a poor memristive device, as reported previously.²⁶ As the temperature decreases, the device resistance, the threshold voltage, V_{th} , and the resistance off/on ratio, $R_{\text{off/on}}$, all increase significantly. This increase in device resistivity is understood as not only the increase in resistance of the crystalline NbO₂ filament, but also the suppression of the leakage current, that is, the current that flows through the amorphous matrix surrounding the NbO₂ filament.⁹ As the current that flows through the amorphous material decreases, the signal becomes dominated by the crystalline NbO₂ filament, allowing the sharp change in resistance due to the structural IMT phase change to become apparent at about 200 K.

For excellent device performance, memristive devices should have a large V_{th} and a large $R_{\text{off/on}}$. The change in the threshold voltage as a function of temperature is presented in Fig. 3. This increase in threshold voltage has been seen in other work,^{9,24,32} though in the increase in V_{th} in our devices is roughly a factor of 2 larger than has been reported in the literature previously, indicating that cryogenic temperatures have improved our device

performance beyond that reported previously. This indicates that sub-stoichiometric Nb_2O_5 creates devices that have a more pronounced sensitivity to temperature changes.

In addition to high threshold voltages, a large separation between the hold and threshold voltages is required for memristive device performance. Fig. 3 also presents our results on the hold voltage. We expect the device to remain in the low-resistance “on” state for voltages lower than the threshold voltage as the device remains above the IMT temperature (about 800°C). We find the hold voltage to be dependent on the rate of the voltage bias ramp. A 200 ms integration time per measurement gives a $\Delta V = |V_{\text{th}} - V_{\text{h}}| \approx 0.2V$ at or above 200 K, similar to or slightly smaller than the differences reported on previous cryogenic measurements.^{9,24,32} The hold voltage stays constant as temperature decreases, leading to an increase in ΔV to nearly 0.6 V at 50 K, as shown in Fig. 3.

However, longer integration times or pauses between measurements can allow the sample to cool down, which will cause the device to go through the IMT at higher hold voltages. In Fig. 3, we also present data where the voltage source was turned off for 1 s between measurements, allowing the device to cool between measurements. We show that ΔV decreases significantly, but that despite expectations, $\Delta V \neq 0$, indicating a non-volatile material embedded in series with the filament. While NbO_2 can mimic the volatile neuronal behavior of nerve cells, the as-grown material, Nb_2O_5 , is attractive because it can mimic the non-volatile synaptic functions of nerve cells.^{22,39,40} Numerical models of the IMT in NbO_2 filaments often require the incorporation of Nb_2O_5 regions to fully describe the behavior of the filaments.^{24,35,41} Our results support the inclusion of such non-volatile Nb_2O_5 layers, as evidenced by the separation between the threshold and hold voltages, even when the device is allowed to cool down.

C. Threshold Power

The IMT in NbO_2 is a thermally-driven transition at $\approx 800^\circ\text{C}$, and this high temperature is achieved by simple Joule heating in the sample. In cross-bar filament devices, the device area can change, but the filament cross-sectional area stays constant.²⁶ This means that the power necessary to heat the material to the phase transition, P_{th} , also stays constant for various device sizes.²⁰ Because the thermal conductivity of our material stack (gold and platinum) varies by less than 10% between 50 and 300 K, we expect the power needed to

FIG. 3. The threshold voltage V_{th} at positive and negative bias as a function of temperature. As the temperature decreases, the V_{th} increases. With a short integration time (200 ms) between measurements, the hold voltage V_h is significantly lower than the threshold voltage V_{th} and $\Delta V = |V_{th} - V_h|$ is large. Turning off the drive voltage between measurements reduces ΔV , but the hold voltage never reaches the threshold voltage, indicating the presence of non-volatile Nb_2O_5 in the filament.

induce a thermal transition should also stay constant in our devices, even as the temperature decreases or the sample resistance increases. Our measurements of P_{th} are presented in Fig. 4 and show that once the leakage current is suppressed and the IMT becomes obvious in the IV curves at around 200 K, the threshold power becomes constant, as expected for the thermally driven transition.

D. Resistance Measurements

Careful study of the resistance in these devices can give a better understanding of the underlying state of NbO_2 . For low electric fields, the electrical resistivity (or conductivity) is expected to vary as:^{8,19,27}

$$\rho = \rho_0 e^{E_a/k_B T}, \quad (1)$$

where ρ_0 is a constant and E_a is the activation energy. Arrhenius plots in NbO_2 memristive devices show linear behavior and activation energies between 0.15 and 0.24 eV (when measured from 300 K to 400 K),^{8,22} and measurements on thin film NbO_2 give an Arrhenius plot

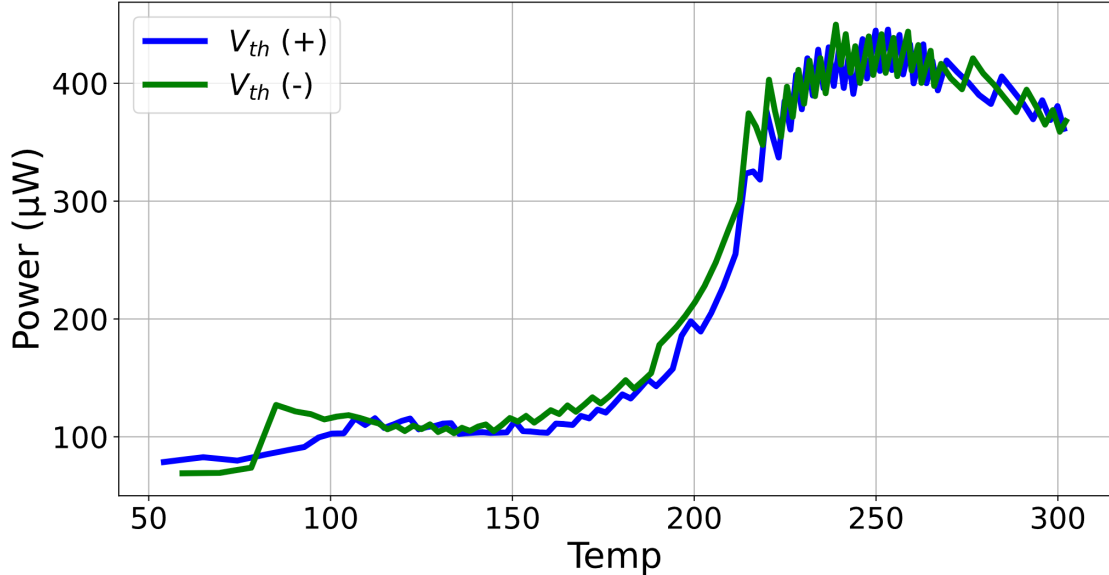

FIG. 4. The threshold power P_{th} at positive and negative bias as a function of temperature. As the temperature decreases, the P_{th} varies until the leakage current is suppressed, at around 200 K. After that, the power is constant, as expected for the thermally-driven IMT in NbO_2 .

that varies smoothly from $E_a = 0.25$ eV at cryogenic temperatures (≈ 200 K) to $E_a = 0.44$ eV near the IMT temperature.¹⁹

To measure the material resistance at low electric fields, researchers typically choose a voltage far from the threshold voltage, usually between at or near 0.5 V,^{22,29} in order to ensure that the material is ohmic in nature.⁸ Ohmic behavior is necessary to separate the intrinsic behavior of the NbO_2 filament from the effects of Joule heating in the sample. We analyzed dI/dV for our samples, and found that our sample was non-ohmic over the entire range of temperatures and voltages measured, even at the lowest measured voltages (0.03 V). Above ≈ 200 K, the measured resistances at the two lowest voltages (0.03 V and 0.06 V) differed by less than 1%, indicating minimal effects due to Joule heating. Below 200 K, the percent change in V/I between the lowest measured voltages increased smoothly to more than 20% at 80 K, indicating strong Joule heating in the sample even at very low bias voltages (0.03 V).

Our measurements of the device resistance are presented in an Arrhenius plot in Fig. 5. We presented V/I at the lowest measured resistance, 0.03 V, as well as a conventional choice, 0.4 V. Above 200 K, the Arrhenius curve is linear for 0.03 V, and we find an activation energy of $E_a = 0.14$ eV. This activation energy is lower than the $E_a \approx 0.2$ eV reported for NbO_2

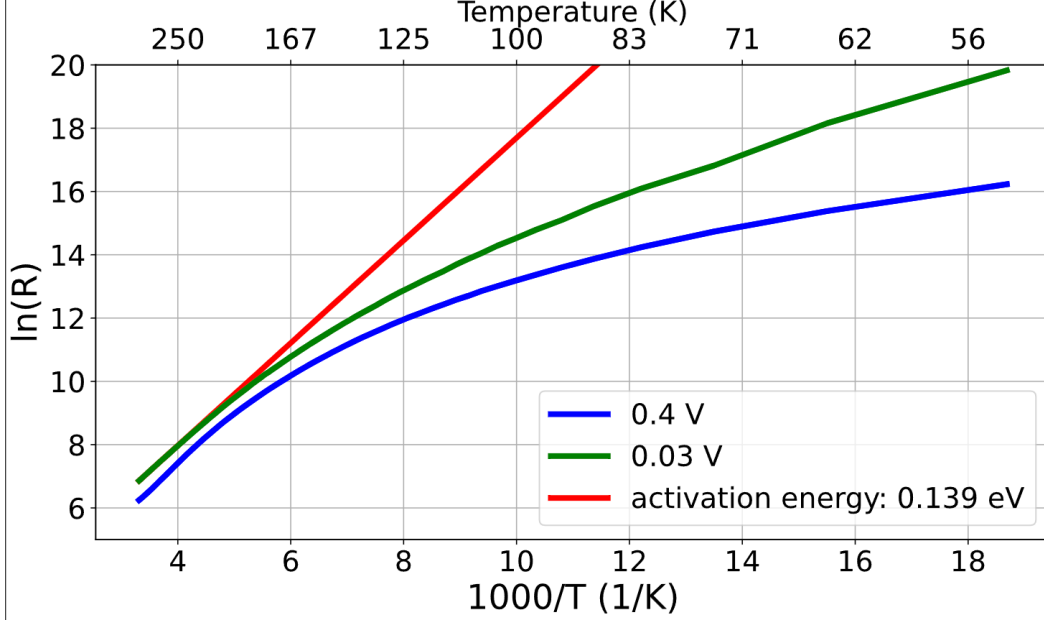

FIG. 5. This graph plots the natural logarithm of resistance against the inverse of temperature, highlighting a smooth curve that can be compared to results from Stoever et al. (2020). Our data indicate that the temperature range of 200K - 300K is reliable for resistance measurements at low voltages, which we utilized to determine the activation energy (E_a) of the NbO_2 .

devices,^{8,22} and significantly lower than $E_a \sim 0.3 - 0.4$ eV reported for thin-film NbO_2 .¹⁹ Below 200 K in Fig. 5, we see a smoothly varying curve for 0.03 V, similar to results in thin-film NbO_2 ,¹⁹ and due to the significant Joule heating, a line fit is not possible.

In order to compare our devices to others reported in the literature, we have also included the measured V/I at 0.4 V in Fig. 5. At 0.4 V, the device has a lower resistance compared to the measurements at 0.03 V, which we expect, as the higher temperature at 0.4 V due to Joule heating leads to higher device temperatures. Above ≈ 225 K, the slope at 0.4 V matches the slope at 0.03 V, meaning the activation energy is similar at $T \gtrsim 225$ K.

The results in our filament devices are correlated: The lower activation energy in the device leads directly to both the lower resistance and the poor switching behavior when compared with other filament devices at room temperature. As a result, we can conclude that as-grown sub-stoichiometric Nb_2O_5 is not a good candidate for NbO_2 devices via electroformation. The low activation energy in this material means that the resistance in these devices must be increased before it can be useful for memristors —this can be accomplished by decreasing the temperature, or by decreasing the device size.²⁶

IV. CONCLUSION

We have studied filamentary devices electroformed from as-deposited sub-stoichiometric Nb_2O_5 . At room temperature, these devices are poor candidates for memristive applications, with low threshold voltages and with an $R_{\text{off/on}}$ ratio near zero.²⁶

Cryogenic measurements of these same devices show a marked increase in resistance due to the suppression of leakage currents. Below 200 K, the filaments display a large increase in the threshold voltage driven by the increase in the device resistance at lower temperatures. Nevertheless, the power required to heat the sample to the IMT temperature stays constant, as expected for this thermally-driven transition. The off/on resistance ratio increases to values between 10 and 50, and the hold voltage is significantly lower than the threshold voltage for rapid voltage sweeps. Thus, at cryogenic temperatures, the device performance improves significantly.

There is a wide variety of NbO_2 and Nb_2O_5 films currently being used by researchers in efforts to optimize the niobium oxide's performance for memristive devices. Some of the widely varying results come from the lack of clarity in growth conditions and lack of clarity in the underlying niobium oxide films used for devices. However, our results indicate that even nominally "bad" films can be used for memristive devices if steps are taken to reduce the leakage current and increase the device resistance: through percolation paths and incomplete annealing,²⁹ through annealing and nanoscale device sizes,²⁶ or through operation at cryogenic temperatures.
