

# SURFACE ELEVATION ERRORS IN FINITE ELEMENT STOKES MODELS FOR GLACIER EVOLUTION

ED BUELER\*

**Abstract.** The primary data which determine the evolution of glaciation are the bedrock elevation and the surface mass balance. From this data, which we assume is defined over a fixed land region, the glacier’s geometry solves a free-boundary problem which balances the surface velocity from the Stokes flow with the surface mass balance. A surface elevation function for this problem is admissible if it is above the bedrock topography, equivalently if the ice thickness is nonnegative. For an implicit time step, this free-boundary problem can be posed in weak form as a variational inequality. After some preparatory theory for the glaciological Stokes problem, we conjecture that the continuous-space, implicit time step problem for the surface elevation is well-posed. This conjecture is supported both by physical arguments and numerical evidence. We then prove a general theorem which bounds the error made by a finite element approximation of a nonlinear variational inequality in a Banach space. The bound is a sum of error terms of different types which are special to variational inequalities. In the case of the implicit-step glacier problem these terms are of three types: errors from discretizing the bed elevation, errors from numerically solving for the Stokes velocity, and finally an expected quasi-optimal finite element error in the surface elevation itself.

**Key words.** error bounds, finite element methods, glaciers, ice flow, variational inequalities

**1. Introduction.** Glacier and ice sheet simulations model the ice as a free-surface layer of very-viscous, incompressible, and non-Newtonian fluid [22, 40]. For simplicity we will only consider simulations of land-based glaciers, without floating portions, and we note that an “ice sheet” is simply a continent-scale glacier.

The two essential input data into such simulations are the bedrock elevation, which is assumed here to be independent of time, and the time-dependent surface mass balance rate (SMB; the climatic mass balance rate [13]). By definition, the SMB is the balance between accumulating snow and the loss of melt water, through runoff, at the upper surface of the glacier [13]. Note that elevations are measured here in meters, and SMB is measured in ice-equivalent units of meters per second.

Thus a glacier simulation takes, as inputs, the bedrock topography, a (generally) time-dependent climate, and an initial geometry. The simulation produces the glacier’s evolving geometry and flow velocity; these are the output fields of primary scientific value. Additional complications are common in comprehensive models [40, 41]. For example, the internal energy [3] or temperature of the ice may be tracked, and/or there may be models of liquid water within the ice matrix or at ice surfaces. However, for simplicity and concreteness we only consider conservation of mass and momentum, but not of energy, and liquid water will play no role. Furthermore we will assume zero velocity, i.e. a non-sliding and non-penetrating condition, at the base of the ice. On the other hand, we will not make the shallowness assumptions which are common in comprehensive ice sheet models.

One may parameterize the glacier’s geometry using either the (upper) surface elevation or the ice thickness. At a time and map-plane location where a glacier exists the surface elevation must exceed the bedrock elevation, equivalently the ice thickness must be positive. The computed flow velocity is only defined at those locations and times where ice is present, namely on an evolving 3D domain between the bedrock and surface elevations. In other words, the surface elevation and thickness functions must satisfy inequalities to be admissible.

Our notation is sketched in Figure 1. Let  $\Omega \subset \mathbb{R}^2$  be a fixed portion of land, with

---

map-plane coordinates  $x = (x_1, x_2) \in \Omega$ . All time-dependent quantities are assumed to be defined on  $t \in [0, T]$  for some  $T > 0$ . On  $\Omega$  assume that we are given, as data, a real and continuous bed elevation function  $b(x)$ , and a real, signed, and continuous SMB function  $a(t, x)$ . In areas of  $\Omega$  where  $a > 0$  (accumulation; downward arrows in Figure 1), a glacier will exist. If  $a < 0$  (upward arrows) then either a glacier exists with an ablating surface, because of flow from accumulation areas, or no glacier exists. Determining which situation applies at given coordinates  $t, x$  requires solving free-boundary problems like those considered in this paper.

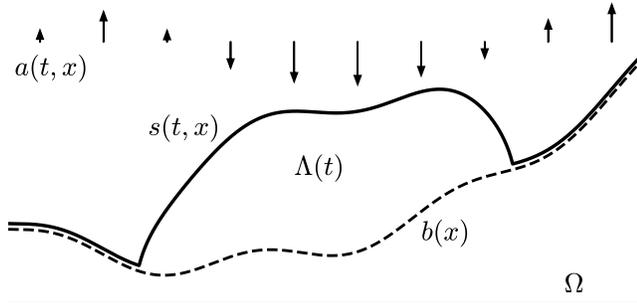

FIG. 1. Glacier notation used in this paper. In fact  $\Omega$  is 2D and  $\Lambda(t)$  is 3D.

Let  $s(t, x)$  be the (solution) ice surface elevation. We will regard this as defined for all  $x \in \Omega$ , but subject to the constraint that the surface  $z = s$  must be at or above the bedrock ( $s \geq b$ ). In regions with no ice  $s = b$  holds. The solution ice velocity  $\mathbf{u}(t, x, z)$  and pressure  $p(t, x, z)$  are then defined only on the open 3D domain

$$(1.1) \quad \Lambda(t) = \{(x, z) : b(x) < z < s(t, x)\} \subset \Omega \times \mathbb{R}.$$

This aspect of glacier modeling deserves emphasis: The time-dependent 3D domain  $\Lambda(t)$ , on which the velocity and pressure are meaningful, is determined by the evolving surface elevation  $s$ , which is itself part of the model solution.

The surface trace of the ice velocity will be of importance; it is reconsidered in a precise Sobolev space context in Section 2. We extend it by zero so that it is defined everywhere in  $\Omega$ :

$$(1.2) \quad \mathbf{u}|_s(t, x) = \begin{cases} \mathbf{u}(t, x, s(t, x)), & s(t, x) > b(t, x) \\ \mathbf{0}, & \text{otherwise.} \end{cases}$$

Compare flux extension by zero in [40]. Also let  $\mathbf{n}_s = \langle -\nabla s, 1 \rangle$  denote an unnormalized and upward surface normal vector. (This is assumed well-defined for current purposes, but compare Section 3.) An infinite-dimensional nonlinear complementarity problem (NCP) [6, 17, 40] applies almost everywhere in  $[0, T] \times \Omega$ :

$$(1.3a) \quad s - b \geq 0$$

$$(1.3b) \quad \frac{\partial s}{\partial t} - \mathbf{u}|_s \cdot \mathbf{n}_s - a \geq 0$$

$$(1.3c) \quad (s - b) \left( \frac{\partial s}{\partial t} - \mathbf{u}|_s \cdot \mathbf{n}_s - a \right) = 0$$

System (1.3) says that either a location is ice free ( $s - b = 0$ ), where the climate

is locally ablating ( $a \leq 0$ ), or that the surface kinematical equation (SKE) holds:

$$(1.4) \quad \frac{\partial s}{\partial t} - \mathbf{u}|_s \cdot \mathbf{n}_s - a = 0.$$

This equation says that the (non-material) surface of the ice moves vertically according to the sum of the SMB and a component of the ice velocity at the surface [40]. Equation (1.4) is a statement of mass conservation at the surface [3], sometimes called the free-surface equation [33] or the kinematic boundary condition<sup>1</sup> [22].

We believe that glaciologists agree with the conditions of NCP (1.3) as a model for glaciers. For example, in numerical ice sheet models the SKE (1.4) is a standard way for surface geometry to evolve [22, 40]. The idea that positive (continuous) SMB at a given location implies the existence of glacier ice there is not controversial. Equivalently, ice-free conditions are understood to exist only where the SMB is negative, because any accumulation (positive SMB) would immediately become glacier ice (by definition).

In the current paper the SMB  $a$  is necessarily assumed to be defined everywhere in  $\Omega$ , regardless of whether a glacier is present or not. This is because a simulated glacier needs to be able to advance into unglaciated locations. In ice-free areas the SMB should have the value which a glacier surface would experience at that time and location. Thus the value can be modeled using precipitation and an energy balance [22], for instance by hypothesizing an ice surface and then computing the balance of snow accumulation minus ablation (using the energy available for melt).

The non-shallow ice dynamics model considered in this paper, which conserves mass and momentum, is the non-sliding (e.g. frozen) base, isothermal, shear-thinning (non-Newtonian), and incompressible Stokes problem [22, 28, 40]. This model is applied over the domain  $\Lambda(t)$  defined in (1.1) above. Let  $\Gamma_s(t) \subset \partial\Lambda(t)$  be the upper surface  $z = s$  and  $\Gamma_b(t) \subset \partial\Lambda(t)$  be the base  $z = b$ . The possibility of cliffs at the ice margin is neglected, so  $\partial\Lambda(t) = \overline{\Gamma_s(t)} \cup \overline{\Gamma_b(t)}$  is assumed to hold at any time. To state the shear-thinning (Glen's) flow law, let  $D\mathbf{u} = (\nabla\mathbf{u} + \nabla\mathbf{u}^\top)/2$  denote the strain rate tensor, with Frobenius norm  $|D\mathbf{u}| = ((D\mathbf{u})_{ij}(D\mathbf{u})_{ij})^{1/2}$  (summation convention). The effective ice (dynamic) viscosity [22] is then given by a regularized formula

$$(1.5) \quad \nu(D\mathbf{u}) = \nu_p (|D\mathbf{u}|^2 + \epsilon)^{(p-2)/2}$$

The exponent  $1 < p \leq 2$ , often written  $p = (1/n) + 1$ , is approximately 4/3 in practice [22]. The coefficient  $\nu_p > 0$  has  $p$ -dependent units, while  $\nu(D\mathbf{u})$  has SI units  $\text{kg m}^{-1} \text{s}^{-1}$ . The values of  $n$  and  $\nu_p$  can be determined from measured properties of ice [21, 22], including temperature, but both are assumed to be constant here. Note that  $p = 2$  yields a Newtonian fluid with constant viscosity, while for  $p < 2$  the  $\epsilon > 0$  regularization implies that  $\nu(D\mathbf{u})$  is bounded above. Assume that the density of ice  $\rho_i$  and the acceleration of gravity  $\mathbf{g}$  are constant. At each time  $t$  the modeled glacier has velocity and pressure solving the following 3D fluid equations:

$$\begin{aligned} (1.6a) \quad & -\nabla \cdot (2\nu(D\mathbf{u}) D\mathbf{u}) + \nabla p = \rho_i \mathbf{g} && \text{within } \Lambda(t) \\ (1.6b) \quad & \nabla \cdot \mathbf{u} = 0 && \text{"} \\ (1.6c) \quad & (2\nu(D\mathbf{u}) D\mathbf{u} - pI) \mathbf{n}_s = \mathbf{0} && \text{on } \Gamma_s(t) \\ (1.6d) \quad & \mathbf{u} = \mathbf{0} && \text{on } \Gamma_b(t) \end{aligned}$$

<sup>1</sup>Note that equation (1.4) is not a boundary condition of any identifiable PDE problem.

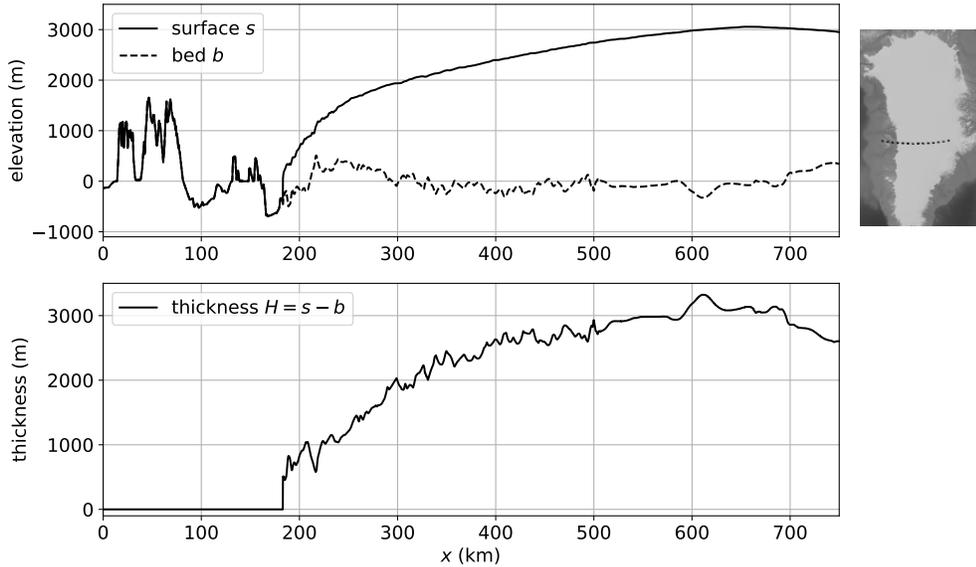

FIG. 2. A cross-section of the Greenland ice sheet at  $70^\circ N$  latitude (see inset). While the ice surface  $s$  is relatively smooth because of ice flow (top), the bedrock elevation  $b$  is much rougher. The corresponding ice thickness  $H = s - b$  (bottom), though a valid geometry parameterization, inherits the low regularity of  $b$ . (Data from [35] and A. Aschwanden, personal communication.)

Boundary condition (1.6c) says that the sub-aerial upper surface is stress free; this must not be confused with the SKE (1.4).

In summary at this point, we assume that a glacier simulation is an evolving free-surface flow, subject to a signed climate that can add or remove ice, coupled to a nonlinear Stokes problem which must be solved within an evolving, 3D icy domain. The initial/boundary value problem consisting of (1.1)–(1.6) requires data  $b(x)$ ,  $a(t, x)$  plus an initial surface elevation  $s(0, x)$ . The solution variables are  $s(t, x)$ ,  $\mathbf{u}(t, x, z)$ , and  $p(t, x, z)$ , with  $s$  defined everywhere over  $[0, T] \times \Omega$ , but subject to  $s \geq b$ , and with  $\mathbf{u}, p$  defined on  $\Lambda(t)$  for each  $t$  (equation (1.1)). The surface elevation  $s$  and surface velocity trace  $\mathbf{u}|_s$  are linked by the kinematical NCP (1.3).

Note that the NCP (1.3) is the only place where a time derivative appears in the model statement; the SKE (1.4) is a consequence of this NCP. Because the flow is very viscous [1], the Stokes sub-model (1.5)–(1.6) acts as an instantaneous “algebraic” constraint on the evolution statement in (1.3). The coupled, infinite-dimensional problem of determining the evolving geometry of a glacier, namely system (1.1)–(1.6), is therefore simultaneously a differential algebraic equation system [2, 33] and an NCP.

While essentially equivalent in the continuum problem, formulations using thickness functions to parameterize geometry have different character from those using surface elevation, as here, when the bedrock is realistically rough. Surface elevation  $s$  will be preferred because of the flow-caused smoothing effect illustrated in Figure 2. That is, we observe that for land-based glaciers  $s(t, x)$  is smoother in  $x$  than the thickness  $H(t, x) = s(t, x) - b(x)$  because the latter “inherits” the lower regularity of the (typically) eroded and faulted bedrock topography  $b(x)$ .

Glacier simulations are commonly formulated using a finite element (FE) method for the Stokes sub-problem [25, 27, 36], or for a shallow approximation thereof. How-

ever, to the author's knowledge all existing non-shallow (Stokes) evolution models use an explicit time-stepping scheme for the geometry, for example as in [27] or [33], with the one exception of the exploratory model in reference [42].

This work considers implicit time steps for the theoretical reasons addressed in Section 4. For a time step  $\Delta t > 0$ , the solution  $s \approx s(t_n, x)$ , from applying the backward Euler scheme to NCP (1.3), satisfies the conditions of a similar NCP:

$$\begin{aligned} (1.7a) \quad & s - b \geq 0 \\ (1.7b) \quad & s - \Delta t \mathbf{u}|_s \cdot \mathbf{n}_s - \ell^n \geq 0 \\ (1.7c) \quad & (s - b)(s - \Delta t \mathbf{u}|_s \cdot \mathbf{n}_s - \ell^n) = 0 \end{aligned}$$

For clarity we have collected-together a source term  $\ell^n(x) = s^{n-1}(x) + \int_{t_{n-1}}^{t_n} a(t, x) dt$ , which is assumed known. The essential approach of this paper starts in Section 3, where we re-write NCP (1.7) as a weak form variational inequality (VI) problem. Based on conjectured well-posedness for that problem (Section 4), our main results are in Sections 6 and 7. We prove new estimates on the numerical error which arises from solving the surface elevation VI problem by FE approximation.

Observe that the backward Euler scheme chosen for problem (1.7) is merely the simplest A-stable scheme which can be applied to the continuous time problem (1.3). Extension to higher-order A-stable and/or stiff decay [2] schemes is obviously of interest, but we do not pursue them because the problem (1.7) already contains all the important features. For finite-dimensional differential algebraic equation problems, such implicit schemes are the standard choices [2], given the stiffness exhibited by such systems. In the infinite-dimensional case here, where the SKE (1.4) is constrained at any time by the ‘‘algebraic’’ Stokes problem (1.5)–(1.6), implicit schemes are in fact the natural choice.

One can also make a case for implicit time-stepping based on simulation performance, that is, by comparing to the conditionally-stable explicit alternatives [7]. However, this assumes that NCP (1.7) can be solved efficiently, and that the implicit scheme turns out to have unconditional stability. In fact, neither efficiency nor stability are addressed in the current paper.

This paper is organized as follows. Section 2 recalls the theory of the Glen-law Stokes problem on a fixed domain, and we add an apparently-new bound on the surface trace of the velocity solution (Corollary 2.6). In Section 3 we reformulate the coupled NCP problem (1.5)–(1.7) as a VI weak form. The key coupling term is the surface motion term  $\mathbf{u}|_s \cdot \mathbf{n}_s$  in SKE (1.4), for which we provide a quantitative bound over a Sobolev space of surface elevation functions (Lemma 3.2). However, this bound is subject to Conjecture A, which hypothesizes that the surface velocity trace is Lipschitz continuous with respect to surface elevation. Well-posedness for each implicit step VI problem is considered in Section 4, based upon Conjecture B hypothesizing the coercivity of the same surface motion term. Certain physical and modeling ideas are discussed in Section 4, as context needed to understand Conjecture B, followed in Section 5 by some numerical evidence for the validity of this Conjecture. At this point we have in hand a mathematically-precise time-discretized model, though with only conjectural well-posedness (Theorem 4.1). This continuum model is apparently stated here for the first time. Turning to FE approximations, in Section 6 we prove an abstract FE error estimate, Theorem 6.3 and its Corollaries, for general VI problems involving nonlinear operators on Banach spaces. This new estimate, which makes coercivity and Lipschitz assumptions on the operator, extends the classical bilinear case by Falk [18]. In Section 7 we apply the abstract estimate to the glacier problem,

yielding our final result which is Theorem 7.2. The physical significance of each term in this error estimate, and how associated FE method choices are made, is addressed at the end.

We will use only these few abbreviations: FE (finite element), NCP (nonlinear complementarity problem), PDE (partial differential equation), SIA (shallow ice approximation), SKE (surface kinematical equation), SMB (surface mass balance), and VI (variational inequality).

**2. The surface velocity from a glacier Stokes problem.** In this Section we consider the weak form of the non-sliding, isothermal, and Glen-law Stokes sub-model (1.5)–(1.6). This sub-model, which is applied on a 3D domain  $\Lambda = \Lambda(t)$ , defined by (1.1) at a particular time  $t$ , computes the surface velocity field  $\mathbf{u}|_s$  which appears in NCP (1.3). We will return to that the larger model in Section 3.

We assume that the ice base  $\Gamma_b \subset \partial\Lambda$ , on which a Dirichlet condition  $\mathbf{u} = \mathbf{0}$  holds, has positive measure, and that the remaining Neumann boundary  $\Gamma_s = \partial\Lambda \setminus \overline{\Gamma_b}$  is sufficiently-smooth so that a zero normal stress condition can be applied.

Suitable function spaces for Stokes problem (1.5)–(1.6) are then well-known. Let  $1 < p \leq 2$ . Denote the Sobolev space [16] of real-valued functions with  $p$ th-power integrable first derivatives by  $W^{1,p}(\Lambda)$ , and let

$$(2.1) \quad \mathcal{V} = W_b^{1,p}(\Lambda; \mathbb{R}^3)$$

be the corresponding space of vector-valued functions with trace zero along  $\Gamma_b$ . Let  $[H] \geq 1$  m be a representative *vertical* glacier dimension. We define the norm on  $\mathcal{V}$  by

$$(2.2) \quad \|\mathbf{v}\|_{\mathcal{V}} = \left( \int_{\Lambda} |\mathbf{v}|^p dx dz + [H]^p \int_{\Lambda} |\nabla \mathbf{v}|^p dx dz \right)^{1/p}.$$

Here  $dx dz = dx_1 dx_2 dz$  is the 3D volume element, which will generally be suppressed in integrals. Note that  $|\mathbf{v}|$  denotes the Euclidean norm, while  $|\nabla \mathbf{v}| = ((\nabla \mathbf{v})_{ij} (\nabla \mathbf{v})_{ij})^{1/2}$  is the Frobenius norm of  $\nabla \mathbf{v} \in \mathbb{R}^{3 \times 3}$ . Remark 1.2.1 in [5] explains the length scaling in (2.2), such that  $\|\mathbf{v}\|_{\mathcal{V}}$  has consistent units.

Let  $\mathcal{Q} = L^{p'}(\Lambda)$  where  $p' = p/(p-1) \approx 4$  is the conjugate exponent. Define

$$(2.3) \quad \mathcal{M} = \mathcal{V} \times \mathcal{Q}$$

as the mixed space of admissible velocity and pressure pairs. For  $(\mathbf{u}, p) \in \mathcal{M}$  define

$$(2.4) \quad F_{\Lambda}(\mathbf{u}, p)[\mathbf{v}, q] = \int_{\Lambda} 2\nu(D\mathbf{u})D\mathbf{u} : D\mathbf{v} - p\nabla \cdot \mathbf{v} - (\nabla \cdot \mathbf{u})q - \rho_i \mathbf{g} \cdot \mathbf{v},$$

where  $A : B = a_{ij}b_{ij}$  (summation convention). The (mixed) weak form of the Stokes sub-model seeks the solution  $(\mathbf{u}, p)$  satisfying

$$(2.5) \quad F_{\Lambda}(\mathbf{u}, p)[\mathbf{v}, q] = 0 \quad \text{for all } (\mathbf{v}, q) \in \mathcal{M}.$$

Jouvet and Rappaz [28] have proven that problem (2.5) is well-posed if the Neumann portion of  $\partial\Lambda$  is  $C^1$ . Their proof uses the equivalence of (2.5) and the minimization of a convex and coercive functional over the divergence-free subspace  $\mathcal{V}_{\text{div}} = \{\mathbf{v} \in \mathcal{V} : \nabla \cdot \mathbf{v} = 0\}$ . Our regularization in Glen law (1.5) differs from that in [28], but the necessary modifications are addressed in [25]. Note that if the weak solution is sufficiently regular then the strong form (1.6) is also satisfied.

**THEOREM 2.1** (Theorem 3.10 in [28] and Appendix A of [25]). *Suppose  $\Lambda$  is bounded,  $\partial\Lambda$  is Lipschitz,  $\Gamma_s$  is  $C^1$ , and  $\Gamma_b$  has positive measure. Let  $1 < p \leq 2$  and  $\epsilon > 0$  in (1.5). Then there exists a unique pair  $(\mathbf{u}, p) \in \mathcal{M}$  solving (2.5), and  $\mathbf{u} \in \mathcal{V}_{\text{div}}$ .*

Our primary purpose, resumed in the next Section, is to study the glacier geometry NCP (1.3), and its weak form. For that analysis we now bound the surface trace  $\mathbf{u}|_s$  in terms of certain geometric properties of  $\Lambda$ . This uses several inequalities.

**LEMMA 2.2** (Poincaré's inequality; (7.44) in [19]). *Under the assumptions of Theorem 2.1, there exists a dimensionless constant  $c_p(\Lambda) > 0$  so that*

$$(2.6) \quad \int_{\Lambda} |\mathbf{v}|^p \leq c_p(\Lambda) [H]^p \int_{\Lambda} |\nabla \mathbf{v}|^p \quad \text{for all } \mathbf{v} \in \mathcal{V},$$

and thus  $\|\mathbf{v}\|_{\mathcal{V}}^p \leq (c_p(\Lambda) + 1) [H]^p \int_{\Lambda} |\nabla \mathbf{v}|^p$ .

**LEMMA 2.3** (Korn's inequality; to prove set  $F(x)$  to the identity in Corollary 4.1 of [38]). *Under the same assumptions, there exists a dimensionless constant  $k_p(\Lambda) > 0$  so that*

$$(2.7) \quad \int_{\Lambda} |\nabla \mathbf{v}|^p \leq k_p(\Lambda) \int_{\Lambda} |D\mathbf{v}|^p \quad \text{for all } \mathbf{v} \in \mathcal{V}.$$

The main idea of the following *a priori* bound is that velocity solution is controlled by geometric properties of the domain  $\Lambda$ , including the constants in the above inequalities, along with certain physical constants. We will denote the ice volume by  $|\Lambda|$ .

**LEMMA 2.4.** *Suppose  $\mathbf{u} \in \mathcal{V}$  is the solution from Theorem 2.1. Then there is  $C > 0$  depending on  $p$ ,  $\rho_i |\mathbf{g}|$ ,  $\nu_p$ ,  $\epsilon$ ,  $[H]$ ,  $|\Lambda|$ ,  $c_p(\Lambda)$ , and  $k_p(\Lambda)$  so that*

$$(2.8) \quad \|\mathbf{u}\|_{\mathcal{V}} \leq C.$$

*Proof.* From (2.5) and  $\mathbf{u} \in \mathcal{V}_{\text{div}}$  it follows that

$$(2.9) \quad 0 = F_{\Lambda}(\mathbf{u}, p)[\mathbf{u}, p] = \int_{\Lambda} 2\nu(D\mathbf{u})D\mathbf{u} : D\mathbf{u} - \rho_i \mathbf{g} \cdot \mathbf{u}.$$

Apply Korn's inequality, the facts that  $p > 0$  and  $(p-2)/2 \leq 0$ , and equation (1.5):

$$(2.10) \quad \begin{aligned} \int_{\Lambda} |\nabla \mathbf{u}|^p &\leq k_p(\Lambda) \int_{\Lambda} |D\mathbf{u}|^p \leq k_p(\Lambda) \int_{\Lambda} (|D\mathbf{u}|^2 + \epsilon)^{(p-2)/2} (D\mathbf{u} : D\mathbf{u} + \epsilon) \\ &= k_p(\Lambda) \left[ \epsilon^{p/2} |\Lambda| + (2\nu_p)^{-1} \int_{\Lambda} 2\nu(D\mathbf{u})D\mathbf{u} : D\mathbf{u} \right]. \end{aligned}$$

By equation (2.9) and Hölder's inequality we thus have

$$(2.11) \quad \begin{aligned} \int_{\Lambda} |\nabla \mathbf{u}|^p &\leq k_p(\Lambda) \left[ \epsilon^{p/2} |\Lambda| + (2\nu_p)^{-1} \int_{\Lambda} \rho_i \mathbf{g} \cdot \mathbf{u} \right] \\ &\leq k_p(\Lambda) \left[ \epsilon^{p/2} |\Lambda| + (2\nu_p)^{-1} \rho_i |\mathbf{g}| |\Lambda|^{1/p'} \|\mathbf{u}\|_{\mathcal{V}} \right]. \end{aligned}$$

By Lemma 2.2,

$$(2.12) \quad \|\mathbf{u}\|_{\mathcal{V}}^p \leq (c_p(\Lambda) + 1) [H]^p k_p(\Lambda) \left[ \epsilon^{p/2} |\Lambda| + (2\nu_p)^{-1} \rho_i |\mathbf{g}| |\Lambda|^{1/p'} \|\mathbf{u}\|_{\mathcal{V}} \right].$$

Let  $z = \|\mathbf{u}\|_{\mathcal{V}}$ . We have proved that

$$(2.13) \quad z^p \leq c_0 + c_1 z$$

for  $p > 1$  and some constants  $c_i > 0$ . Note that  $g(y) = y^p - c_1 y - c_0$  is smooth with  $g(0) = -c_0 < 0$  and  $g(y) \rightarrow +\infty$  as  $y \rightarrow +\infty$ , so there exists a right-most root  $\tilde{y} > 0$  with  $\tilde{y} = f(p, c_0, c_1)$ . Since  $g(z) \leq 0$  we have  $z \leq \tilde{y}$ . This proves (2.8) with  $C = \tilde{y}$ .  $\square$

LEMMA 2.5 (Trace inequality). *Under the assumptions of Theorem 2.1, there exists a dimensionless constant  $\gamma_p(\Lambda) > 0$  so that for all  $\mathbf{v} \in \mathcal{V}$ ,*

$$(2.14) \quad \int_{\Gamma_s} |\mathbf{v}|^p dS \leq \frac{\gamma_p(\Lambda)}{[H]} \|\mathbf{v}\|_{\mathcal{V}}^p$$

where  $\mathbf{v}$  on the left is the trace on  $\Gamma_s$ , and  $dS$  denotes the area element over  $\partial\Lambda$ .

*Proof.* Theorem 5.5.1 in [16] defines a trace operator  $T : \mathcal{V} \rightarrow L^p(\partial\Lambda)$ , and a constant  $c > 0$ , dependent only on  $p$  and  $\Lambda$ , so that

$$(2.15) \quad \int_{\partial\Lambda} |T\mathbf{v}|^p dS \leq c \int_{\Lambda} |\mathbf{v}|^p + |\nabla\mathbf{v}|^p \leq c \int_{\Lambda} |\mathbf{v}|^p + [H]^p |\nabla\mathbf{v}|^p$$

for  $\mathbf{v} \in \mathcal{V}$ . However, because  $\mathbf{v} = \mathbf{0}$  along  $\Gamma_b$ ,  $\int_{\Gamma_s} |T\mathbf{v}|^p dS = \int_{\partial\Lambda} |T\mathbf{v}|^p dS$ . The result follows if we define  $\gamma_p(\Lambda) = [H]c$ .  $\square$

Combining Lemmata 2.4 and 2.5 yields the following bound. In later uses of this result, recall that  $\Lambda$  and  $\Gamma_s$  are determined by  $s$  and  $b$ , i.e. as in definition (1.1).

COROLLARY 2.6 (Surface velocity bound). *Suppose  $\mathbf{u} \in \mathcal{V}$  is the Stokes velocity solution from Theorem 2.1. The norm of its trace over  $\Gamma_s$  is controlled, a priori, by  $[H]$ ,  $C$  in (2.8), and  $\gamma_p(\Lambda)$  in (2.14):*

$$(2.16) \quad \int_{\Gamma_s} |\mathbf{u}|^p dS \leq \frac{\gamma_p(\Lambda)}{[H]} C^p.$$

**3. The weak-form implicit time-step model.** Now we return to the implicit time-stepping scheme for updating the surface elevation in a model based on Stokes dynamics, namely NCP (1.7). Recall how this problem is derived. Let  $\{t_n\}$  be any increasing sequence of times in  $[0, T]$ , with  $t_0 = 0$ . Let  $\Delta t = t_n - t_{n-1}$  denote the generic step length. Let  $a^n(x)$  be the (temporal) average of the data  $a(t, x)$  over  $[t_{n-1}, t_n]$ . Suppose that  $s(x) = s^n(x) \approx s(t_n, x)$  approximates the surface elevation at time  $t_n$ . Using a backward Euler implicit step [2], SKE (1.4) becomes

$$(3.1) \quad \frac{s - s^{n-1}}{\Delta t} - \mathbf{u}|_s \cdot \mathbf{n}_s - a^n = 0.$$

(The unknown  $s = s^n$  appears both in the surface velocity  $\mathbf{u}|_s$  and slope  $\mathbf{n}_s$ .) For cleaner appearance, clear the denominator in (3.1) and define

$$(3.2) \quad \ell^n(x) = s^{n-1}(x) + \Delta t a^n(x) = s^{n-1}(x) + \int_{t_{n-1}}^{t_n} a(t, x) dt.$$

However, as noted in the Introduction,  $s = s^n$  in (3.1) actually solves a problem of free-boundary type, which is NCP (1.7). In particular, complementarity equation (1.7c) says that, at the solution time and almost everywhere over  $\Omega$ , either there is

no ice ( $s = b$ ) or equation (3.1) holds. Of course,  $s$  does not solve (3.1) over the bare ground part of  $\Omega \subset \mathbb{R}^2$  where  $s = b$ .

The strong form NCP (1.7) has a weak-form variational inequality (VI; [16, 30]) version which is better-suited to both well-posedness theory and finite element (FE) analysis. Let us regard the precise Banach space  $\mathcal{X}$  of surface elevations as unknown (for now). The admissible surface elevations come from a convex and closed subset

$$(3.3) \quad \mathcal{K} = \{r \in \mathcal{X} : r|_{\partial\Omega} = b|_{\partial\Omega} \text{ and } r \geq b\}.$$

(The fixed (Dirichlet) boundary condition is included into the definition of  $\mathcal{K}$ .) The VI is then derived as follows via the argument from [6]. Suppose that  $s \in \mathcal{K}$  is a sufficiently-regular solution of NCP (1.7). Let  $\Omega_I$  be the (measurable) subset of  $\Omega$  on which constraint (1.7a) is inactive, where glacier ice is present:  $\Omega_I = \{x : s(x) > b(x)\}$ . From (1.7c), integration over  $\Omega_I$  shows that

$$(3.4) \quad \int_{\Omega_I} (s - \Delta t \mathbf{u}|_s \cdot \mathbf{n}_s - \ell^n) (r - s) = 0$$

for any  $r \in \mathcal{K}$ . On the other hand, suppose  $\Omega_A = \{x \in \Omega : s(x) = b(x)\}$  is the active (ice-free) region for constraint (1.7a). Observe that (1.7b) says that  $b - \ell^n = s - \Delta t \mathbf{u}|_s \cdot \mathbf{n}_s - \ell^n \geq 0$  on  $\Omega_A$ .<sup>2</sup> Note that  $r - s = r - b \geq 0$  on  $\Omega_A$  if  $r \in \mathcal{K}$ . Therefore integration yields an inequality:

$$(3.5) \quad \int_{\Omega_A} (s - \Delta t \mathbf{u}|_s \cdot \mathbf{n}_s - \ell^n) (r - s) = \int_{\Omega_A} (b - \ell^n) (r - b) \geq 0.$$

Almost everywhere, either land is glacier covered (within  $\Omega_I$ ) or ice-free ( $\Omega_A$ ), so addition of (3.4) and (3.5) gives the following VI for  $s \in \mathcal{K}$ :

$$(3.6) \quad \int_{\Omega} (s - \Delta t \mathbf{u}|_s \cdot \mathbf{n}_s) (r - s) \geq \int_{\Omega} \ell^n (r - s) \quad \text{for all } r \in \mathcal{K}.$$

This integral inequality is known to be true of  $s \in \mathcal{K}$  in advance of knowledge about the ice-covered part of  $\Omega$ .

Now, well-posedness of the weak-form Stokes problem (2.5) over a 3D domain  $\Lambda$ , plus the surface trace bound in Corollary 2.6, allows us to create a well-defined map from an admissible surface elevation  $s$  to the corresponding surface velocity solution  $\mathbf{u}|_s$ . The map is defined via definition (1.1) of  $\Lambda = \Lambda(t)$ , followed by the solution of (2.5) over  $\Lambda$ , evaluation of the trace of  $\mathbf{u}$  along  $\Gamma_s$  (Corollary 2.6), and then definition (1.2) (which includes extension by zero). For this map to be well-defined,  $s$  must be admissible ( $s \in \mathcal{K}$ ) and sufficiently regular so that these steps are justified. We call

$$(3.7) \quad \Phi(s) = -\mathbf{u}|_s \cdot \mathbf{n}_s$$

the *surface motion map*. It maps the scalar surface elevation  $s$  to the dynamical term in the SKE (3.1). Constructing a bound for  $\Phi$  will help to identify a Banach space  $\mathcal{X}$  in which to seek admissible solutions  $s$ .

As before, let  $\Omega \subset \mathbb{R}^2$  be a bounded domain. Let  $[L] > 0$  be a representative *horizontal* scale; compare (2.2). For any  $r \geq 1$  and  $q \in W^{1,r}(\Omega)$  we define

$$(3.8) \quad \|q\|_{W^{1,r}} = \left( \int_{\Omega} |q|^r dx + [L]^r \int_{\Omega} |\nabla q|^r dx \right)^{1/r}.$$

<sup>2</sup>Note the role of extension by zero (1.2) here.

LEMMA 3.1 (Preliminary bound on  $\Phi(s)$ ). *Suppose  $2 \leq r \leq \infty$ , and assume  $s \in W^{1,r}(\Omega)$  is admissible ( $s \geq b$ ). With  $\Lambda$  defined by (1.1), assume that the hypotheses of Theorem 2.1 and Corollary 2.6 apply, which also shows that  $\Phi(s)$  is a well-defined measurable function. Then there is a constant  $C > 0$  independent of  $q$  so that*

$$(3.9) \quad \left| \int_{\Omega} \Phi(s)q \, dx \right| = \left| \int_{\Omega} \mathbf{u}|_s \cdot \mathbf{n}_s q \, dx \right| \leq C \|q\|_{W^{1,r}} \quad \text{for all } q \in W^{1,r}(\Omega).$$

*Proof.* Observe that  $dS = |\mathbf{n}_s| \, dx = \sqrt{1 + |\nabla s|^2} \, dx$  is the surface area element for  $\Gamma_s \subset \partial\Lambda$ . Let  $p' = p/(p-1)$  be the conjugate exponent to  $1 < p \leq 2$ . Apply the triangle inequality, and Hölder's inequality twice:

$$(3.10) \quad \begin{aligned} \left| \int_{\Omega} \Phi(s)q \, dx \right| &\leq \int_{\Omega} |\mathbf{u}|_s |\mathbf{n}_s| |q| \, dx = \int_{\Omega} |\mathbf{u}|_s |\mathbf{n}_s|^{1/p} |\mathbf{n}_s|^{1/p'} |q| \, dx \\ &\leq \left( \int_{\Omega} |\mathbf{u}|_s^p |\mathbf{n}_s| \, dx \right)^{1/p} \left( \int_{\Omega} |\mathbf{n}_s| |q|^{p'} \, dx \right)^{1/p'} \\ &\leq \left( \int_{\Gamma_s} |\mathbf{u}|^p \, dS \right)^{1/p} \left( \int_{\Omega} |\mathbf{n}_s|^r \, dx \right)^{1/(p'r)} \left( \int_{\Omega} |q|^{p'r'} \, dx \right)^{1/(p'r')}. \end{aligned}$$

If  $C_1$  is the *a priori* bound from (2.16) then

$$(3.11) \quad \left| \int_{\Omega} \Phi(s)q \, dx \right| \leq C_1^{1/p} \left( \int_{\Omega} (1 + |\nabla s|^2)^{r/2} \, dx \right)^{1/(p'r)} \|q\|_{L^{p'r'}}.$$

Note that if  $\alpha \geq 0$  then  $(1 + \alpha)^{r/2} \leq 2^{(r-2)/2} (1 + \alpha^{r/2})$ , so

$$(3.12) \quad \begin{aligned} \left| \int_{\Omega} \Phi(s)q \, dx \right| &\leq C_1^{1/p} \left( 2^{(r-2)/2} \int_{\Omega} 1 + |\nabla s|^r \, dx \right)^{1/(p'r)} \|q\|_{L^{p'r'}} \\ &\leq C_2 (|\Omega| + [L]^{-r} \|s\|_{W^{1,r}}^r)^{1/(p'r)} \|q\|_{L^{p'r'}}. \end{aligned}$$

Since  $2 \leq p' \leq p'r' < \infty$ , by Sobolev's inequality<sup>3</sup> we also have  $\|q\|_{L^{p'r'}} \leq C_3 \|q\|_{W^{1,r}}$ , which yields (3.9).  $\square$

The key assumption in Lemma 3.1 is that  $s \in W^{1,r}(\Omega)$  implies that the domain  $\Lambda$  is nice enough so that Corollary 2.6 gives a finite bound. The key conclusion is that  $\Phi(s) \in (W^{1,r}(\Omega))'$ , the dual space. This conclusion will be critical in analyzing the weak form of NCP (1.7).

Now we conjecture that for some<sup>4</sup>  $r > 2$ , the  $L^{r'}$ -norm of the surface trace  $\mathbf{u}|_s$  is Lipschitz as a function of  $s \in W^{1,r}(\Omega)$ . Note that we do not assume that  $\mathbf{u}|_s$  is continuous, only that it is a measurable function defined over all of  $\Omega$ .

CONJECTURE A. *There exists  $2 < r \leq \infty$  with the following two properties: (i) If  $s \in W^{1,r}(\Omega)$  is admissible ( $s \geq b$  and  $s = b$  on  $\partial\Omega$ ) then the conclusion of Theorem 2.1 applies, giving a well-defined surface velocity  $\mathbf{u}|_s$ . (ii) If also  $r \in W^{1,r}(\Omega)$  is admissible, yielding different values  $\mathbf{u}|_r$ , then there exists  $C_A > 0$ , independent of  $s$  and  $r$ , such that*

$$(3.13) \quad \|\mathbf{u}|_r - \mathbf{u}|_s\|_{L^{r'}} \leq C_A \|r - s\|_{W^{1,r}}.$$

<sup>3</sup>For example, apply Theorem 8.8 from [32] using  $n = 2$ ,  $k = m = 1$ ,  $p = r$ , and  $q = p'r'$ .

<sup>4</sup>The reason for requiring  $r > 2$  will be seen in Lemma 3.2. It would seem to be a technical requirement, as Section 7 demonstrates well-behaved numerical results using the more convenient exponent  $r = 2$ .

From now on we will assume Conjecture A holds for some  $2 < r \leq \infty$ . We define

$$(3.14) \quad \mathcal{X} = W^{1,r}(\Omega).$$

Since  $r > 2$  we have  $\mathcal{X} \hookrightarrow C(\bar{\Omega})$ . Definition (3.3) describes the closed and convex admissible subset  $\mathcal{K} \subset \mathcal{X}$ . If  $s \in \mathcal{K}$  then, by Conjecture A,  $\mathbf{u}|_s \cdot \mathbf{n}_s$  is a measurable, real-valued function on  $\Omega$ . From now on we will write  $\Phi(s)$  as a linear functional on  $q \in \mathcal{X}$ :

$$(3.15) \quad \Phi(s)[q] = - \int_{\Omega} \mathbf{u}|_s \cdot \mathbf{n}_s q \, dx.$$

Lemma 3.1 has shown that  $\Phi$  maps from  $\mathcal{K}$  to the (topological) dual space  $\mathcal{X}'$ . Note that  $\Phi(s)[q]$  is nonlinear in  $s$ . The next Lemma simply proves that  $\Phi$  is Lipschitz-continuous if we assume Conjecture A.

**LEMMA 3.2.** *Suppose that Conjecture A holds. Fix  $b \in \mathcal{X}$  and use definition (3.3) to define  $\mathcal{K}$ . The map  $\Phi : \mathcal{K} \rightarrow \mathcal{X}'$  is Lipschitz on bounded subsets of  $\mathcal{K}$ , that is, for each  $R > 0$  there is  $C(R) > 0$  so that if  $r, s \in B_R \cap \mathcal{K} = \{t \in \mathcal{K} : \|t\|_{\mathcal{X}} \leq R\}$  and  $q \in \mathcal{X}$  then*

$$(3.16) \quad \left| \Phi(r)[q] - \Phi(s)[q] \right| \leq C(R) \|r - s\|_{\mathcal{X}} \|q\|_{\mathcal{X}}$$

*Proof.* Suppose  $s, r \in \mathcal{K}$ . Add and subtract  $\mathbf{u}|_s \cdot \mathbf{n}_r$ , and apply triangle inequalities, including  $|\mathbf{n}_r| = (1 + |\nabla r|^2)^{1/2} \leq 1 + |\nabla r|$ , as follows:

$$(3.17) \quad \begin{aligned} |\Phi(r)[q] - \Phi(s)[q]| &\leq \int_{\Omega} |\mathbf{u}|_r - \mathbf{u}|_s| |\mathbf{n}_r| |q| \, dx + \int_{\Omega} |\mathbf{u}|_s| |\mathbf{n}_r - \mathbf{n}_s| |q| \, dx \\ &\leq \int_{\Omega} |\mathbf{u}|_r - \mathbf{u}|_s| |q| \, dx + \int_{\Omega} |\mathbf{u}|_r - \mathbf{u}|_s| |\nabla r| |q| \, dx \\ &\quad + \int_{\Omega} |\mathbf{u}|_s| |\nabla r - \nabla s| |q| \, dx \end{aligned}$$

Because  $r > 2$ , Sobolev's inequality gives  $\|q\|_{L^\infty} \leq c_\infty \|q\|_{\mathcal{X}}$  for some  $c_\infty > 0$ . By applying Hölder's inequality to each integral we have

$$(3.18) \quad \int_{\Omega} |\mathbf{u}|_r - \mathbf{u}|_s| |q| \, dx \leq \|\mathbf{u}|_r - \mathbf{u}|_s\|_{L^{r'}} \|q\|_{L^r},$$

$$(3.19) \quad \begin{aligned} \int_{\Omega} |\mathbf{u}|_r - \mathbf{u}|_s| |\nabla r| |q| \, dx &\leq \left( \int_{\Omega} |\mathbf{u}|_r - \mathbf{u}|_s|^{r'} |q|^{r'} \, dx \right)^{1/r'} \|\nabla r\|_{L^r} \\ &\leq [L]^{-1} \|\mathbf{u}|_r - \mathbf{u}|_s\|_{L^{r'}} \|r\|_{\mathcal{X}} \|q\|_{L^\infty}, \end{aligned}$$

$$(3.20) \quad \begin{aligned} \int_{\Omega} |\mathbf{u}|_s| |\nabla r - \nabla s| |q| \, dx &\leq \left( \int_{\Omega} |\mathbf{u}|_s|^{r'} |q|^{r'} \, dx \right)^{1/r'} \|\nabla r - \nabla s\|_{L^r} \\ &\leq [L]^{-1} \|\mathbf{u}|_s - \mathbf{0}\|_{L^{r'}} \|r - s\|_{\mathcal{X}} \|q\|_{L^\infty}. \end{aligned}$$

Note that  $\mathbf{u}|_b = \mathbf{0}$ ; there is no glacier whatsoever. Now apply Conjecture A to (3.18), (3.19), and (3.20):

$$(3.21) \quad |\Phi(r)[q] - \Phi(s)[q]| \leq C_A (1 + c_\infty [L]^{-1} (\|r\|_{\mathcal{X}} + \|s - b\|_{\mathcal{X}})) \|r - s\|_{\mathcal{X}} \|q\|_{\mathcal{X}}.$$

Assume  $s, r, b \in B_R \cap \mathcal{K}$ . Then, by the triangle inequality, (3.16) follows with  $C(R) = C_A (1 + 3c_\infty [L]^{-1} R)$ .  $\square$

We now possess sufficient tools to define an operator which puts the backward Euler time step VI (3.6) into a mathematically-precise weak form. If  $s \in \mathcal{K}$  and  $q \in \mathcal{X}'$  then we define  $F_{\Delta t} : \mathcal{K} \rightarrow \mathcal{X}'$ :

$$(3.22) \quad F_{\Delta t}(s)[q] = \Delta t \Phi(s)[q] + \int_{\Omega} sq = \int_{\Omega} (s - \Delta t \mathbf{u}|_s \cdot \mathbf{n}_s) q.$$

It is easy to show that if Conjecture A holds then by Lemma 3.2 this operator is also well-defined and Lipschitz on bounded subsets. We assume that the source term  $\ell^n$ , defined in (3.2), is in  $\mathcal{X}'$ , which is to say we assume that  $a^n \in \mathcal{X}'$ . Then we will seek  $s = s^n \in \mathcal{K}$  so that

$$(3.23) \quad \boxed{F_{\Delta t}(s)[r - s] \geq \ell^n[r - s] \quad \text{for all } r \in \mathcal{K}.}$$

This VI, which merely rewrites (3.6), is the final weak form of the implicit time-step problem. The reader should keep in mind its strong-form NCP (1.7) as well.

Recalling the specific Lipschitz statement (3.16), suppose we know that  $|\Phi(r)[q] - \Phi(s)[q]| \leq C(R)(\|r - s\|_{\mathcal{X}})^{\omega} \|q\|_{\mathcal{X}}$  for some exponent  $\omega > 0$ . This would provide sufficient continuity for the well-posedness theorem in Section 4. However, the finite element error theorem in Section 6 needs (3.16) with  $\omega = 1$ .

If the horizontal components of the surface velocity are differentiable then one might revise operator definition (3.22) as follows. Write  $\mathbf{u} = (u, v, w)$  in cartesian coordinates, and define  $\mathbf{U} = (u, v)$ . Assuming  $\mathbf{U}|_s = \mathbf{0}$  along  $\partial\Omega$ , e.g. supposing the glacier is strictly inside the open domain  $\Omega$ , integrate (3.22) by parts to give

$$(3.24) \quad F_{\Delta t}(s)[q] = \int_{\Omega} (s - \Delta t w|_s) q - \Delta t \nabla \cdot (\mathbf{U}|_s q).$$

However, this form seems not to represent a good regularity trade-off between  $\mathbf{u}|_s$  and  $s$ . We have proven in Section 2 that  $\mathbf{u}|_s$  is an  $L^p$  function over  $\Gamma_s$  (Corollary 2.6), but we have no proof that it is more regular than that. On the other hand, we are indeed hypothesizing that  $\nabla s$  is a well-defined function in  $L^r$ , because  $s \in \mathcal{X} = W^{1,r}(\Omega)$ . Thus we will keep definition (3.22) even though (3.24) looks more like the divergence-form operators typically written for thickness-based models, e.g. [6, 26].

**4. Theoretical considerations for the surface elevation VI problem.** The numerical error bounds proven later in Sections 6 and 7 need to compare a surface elevation computed by the finite element (FE) method with the unique solution of the continuum problem, the VI (3.23). This problem must be well-posed for this comparison (norm difference) to make sense. Despite the theoretical progress made in Sections 2 and 3, no results known to the author prove such well-posedness, nor for any similar glacier geometry evolution problem based on Stokes dynamics, so we will instead conjecture well-posedness in Subsection 4.4 below. We build up to this Conjecture B using comparative cases and physical reasoning.

**4.1. The explicit time-step problem lacks regularity.** First consider a glacier that does not flow. Time-step problem (3.23) then reduces to determining the geometry according only to the SMB and the prior geometry, a problem which turns out to be well-posed over  $L^2(\Omega)$ . To see this precisely, let  $F_{\Delta t}^0(s)[q] = \int_{\Omega} sq$ , which sets  $\mathbf{u}|_s = \mathbf{0}$  in (3.22). Assuming that definition (3.2) yields  $\ell^n \in L^2(\Omega)$ , there exists a unique solution  $s \in \mathcal{K}_{L^2} = \{r \in L^2(\Omega) : r \geq b\}$  of the no-flow VI problem

$$(4.1) \quad F_{\Delta t}^0(s)[r - s] \geq \ell^n[r - s] \quad \text{for all } r \in \mathcal{K}_{L^2}.$$

The solution is by truncation [30, section II.3]:

$$(4.2) \quad s = \max\{b, \ell^n\} = \max\{b, s^{n-1} + \Delta t a^n\} \quad (\text{no flow}).$$

Thus, in the absence of flow, the new surface is raised or lowered according to the (pointwise) integral of the SMB rate, restricted so that it will not go below the bed.

The explicit time-step VI problem has the same mathematical character as the no-flow problem. Suppose  $s^{n-1}$  is admissible and sufficiently regular so that  $\mathbf{n}_{s^{n-1}}$  is well-defined, and so that the weak-form Stokes problem (2.5) is well-posed over the domain  $\Lambda_{s^{n-1}}$ . The explicit operator

$$(4.3) \quad F_{\Delta t}^e(s)[q] = \int_{\Omega} (s - \Delta t \mathbf{u}|_{s^{n-1}} \cdot \mathbf{n}_{s^{n-1}}) q$$

then arises by applying forward Euler to SKE (1.4); compare definition (3.22). The explicit VI problem corresponding to (3.23), namely

$$(4.4) \quad F_{\Delta t}^e(s)[r - s] \geq \ell^n[r - s],$$

is again well-posed in  $L^2(\Omega)$ , and solved for  $s \in \mathcal{K}_{L^2}$  by truncation:

$$(4.5) \quad s = \max\{b, s^{n-1} + \Delta t \mathbf{u}|_{s^{n-1}} \cdot \mathbf{n}_{s^{n-1}} + \Delta t a^n\} \quad (\text{explicit step}).$$

Now observe that formula (4.5) leaves no regularity for the next step. The derivatives in  $\mathbf{n}_{s^{n-1}}$ , the trace evaluation  $\mathbf{u}|_{s^{n-1}}$ , and the truncation itself all (generally) reduce regularity of the  $s$  solving (4.5) relative to  $s^{n-1}$ . It would seem from what we know about well-posed Stokes problems that the function  $s$  defined by (4.5) is not regular enough, i.e. not sufficiently differentiable in space, so as to serve as the surface elevation at the start of the next time step. That is, it is not clear that  $s$  from (4.5) defines a sufficiently-smooth domain  $\Lambda$  so that the (weak) Stokes problem (2.5) is well-posed.

Re-stating this situation generously is worthwhile because explicit time-stepping simulations using Stokes dynamics are in fact common in glacier science: There is no *known* mathematical reason why such explicit schemes should converge under temporal refinement. This is because the continuum limit of the time-discretized solution, resulting from taking multiple explicit time steps and applying truncation (4.5), is not even conjecturally clear. Convergence and stability being intimately related, this situation aligns with the very incomplete current understanding of which explicit refinement paths are conditionally stable [7, 11, 33, and references therein]. If it were shown that the parabolic VI problem [20] corresponding to strong form conditions (1.1)–(1.6) were well-posed then convergence of both implicit and explicit schemes would become generally clearer.

The regularity of the surface elevation solution might be improved by use of semi-implicit Euler time-stepping [33], which uses  $s$  in the surface normal in (4.3):  $\mathbf{n}_{s^{n-1}} \rightarrow \mathbf{n}_s$ . However, [33] demonstrate that this change, by itself, has small effect on stability, and it is not clear why it would suffice to address the regularity and well-posedness concerns.

**4.2. The problem is not of advection type.** It is common in the literature to regard the SKE (1.4) as an advection, based on its appearance,<sup>5</sup> but this is far from

<sup>5</sup>Often written  $\frac{\partial s}{\partial t} + u \frac{\partial s}{\partial x} + v \frac{\partial s}{\partial y} = a + w$ , where  $(u, v, w)$  denotes the surface velocity [22, 40].

the whole truth. Mathematically, it is not an advection because the surface velocity is not determined externally, but instead through coupled stress balance equations over the domain determined by the SKE solution. The surface elevation solution  $s$  supplies the “advecting” velocity  $\mathbf{u}|_s$ . Physically, glacier geometry solves a gravity-driven, free-surface, and viscous flow problem, so ice flows predominantly downhill. The surface therefore typically responds to local surface perturbations with negative feedback; the flow response to a raised surface bump tends to remove the bump, and likewise for an indentation. This response is diffusive, not advective, at least in the large. Such diffusive response explains the relatively smooth large-scale appearance of actual surface elevations (Figure 2).

In the shallow ice approximation (SIA) this diffusive character is made precise. For the non-sliding and isothermal SIA model [22, 26] in particular, SKE (1.4) is seen to be the following nonlinear diffusion:

$$(4.6) \quad \frac{\partial s}{\partial t} - \Gamma(s-b)^{n+1} |\nabla s|^{n+1} - \nabla \cdot \left( \frac{n+1}{n+2} \Gamma(s-b)^{n+1} |\nabla s|^{n-1} \nabla s \right) - a = 0$$

Here  $n \approx 3$  is Glen’s exponent [22] and  $\Gamma > 0$  is a constant equivalent to  $\nu_p$  in (1.5). The divergence term in (4.6), which arises from the vertical velocity term in the SKE, acts as negative feedback.

Well-posedness results are partially known for SIA models, though usually parameterized using the ice thickness. For  $H = s - b \geq 0$  in steady SIA models, existence is known with  $H^{2q/(q-1)} \in W^{1,q}(\Omega)$ , where  $q = n + 1$  [26]. (However, note that the set of functions whose given power is in a certain Sobolev space is not generally even a vector space.) In time-dependent cases both existence and uniqueness is known when the bedrock is flat [10, 37].

The strong regularity and smoothness exhibited by solutions to (4.6) probably does not persist for solutions to a Stokes-based SKE (1.4). The surface response in a Stokes model is known to have a significantly different small-wavelength limit [36], even though longer wavelengths are handled correctly by the SIA.

In addition to not being an advection, VI problem (3.23) is also not of optimization type. Again this is directly clear in SIA model (4.6), where the problem has porous medium character, that is, the diffusivity scales with a power of the ice thickness. To illustrate the essential idea, it can be shown that the simplest elliptic, quasilinear, and steady porous medium equation  $(u(x)u'(x))' = f(x)$  does not have the symmetry of an optimization problem, that is, there is no objective function of which this equation is the first-order condition. Similarly, the flow of ice under Stokes dynamics scales in some manner with the ice thickness. (Said another way, thin ice which is frozen to the bed has low velocity regardless of surface slope.) While this sketch is not a proof that a particular symmetry does not exist, there is no reason to believe (3.23), or any similar glacier problem, is actually an inequality-constrained minimization problem.

**4.3. Margin shape, and the surface elevation space.** Within a Stokes-based theory the shape that should be predicted for a glacier’s grounded margin is not so clear (Figure 3). This situation makes it difficult to determine a Sobolev space in which VI problem (3.23) might be well-posed. The SIA theory suggests root-type (fractional-power) shapes for the marginal surface elevation, with different shapes for advance and retreat, but with unbounded gradients in all known cases [9, 26]. By contrast, a “wedge” margin shape with a bounded gradient has been hypothesized [14, for example], which would allow  $s \in W^{1,r}(\Omega)$ .

Reality is of course more complicated. In the vicinity of an ice margin, especially

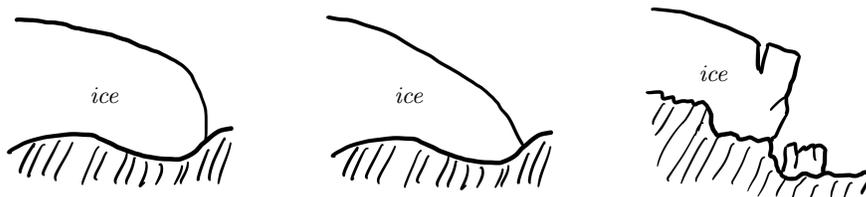

FIG. 3. In which Sobolev space should we seek the surface elevation function? This question relates to the expected shapes of ice margins. The shallow ice theory yields fractional power shapes (left), but other models suggest a “wedge” shape (center). Actual glacier margins often have overhangs, crevasses, and cliffs (right).

on steep bedrock features, real glacier ice can generate overhangs which violate the assumption of a single-valued surface elevation function. Similarly, real bedrock can overhang. Fractures, crevasses, and cliffs are commonly found in glacier margins, but modeling such features requires a departure from the viscous fluid paradigm considered here.

Because margins are small features compared to the overall scale of glaciers and ice sheets, most modeling literature ignores overhangs and assumes instead that surface and bed elevation functions are well-defined; see [25, 27, 33, 42] among many examples. Extending Stokes-based viscous models by allowing fractures, for example by supplementing momentum conservation with an additional advected damage variable [39] so that ice-cliff calving can occur via a stress-failure criterion, might one day suggest a preferred margin regularity assumption for a viscous-only theory like the one here.

**4.4. Conjectural well-posedness for the continuum problem.** Subsections 4.1–4.3 have deployed various imperfect arguments to explain why the backward Euler VI problem (3.23) could be well-posed, or at least why other approaches are less promising. We now state a mathematically-precise conjectural framework for well-posedness of this problem based upon the idea that the surface motion map  $\Phi(s) = -\mathbf{u}|_s \cdot \mathbf{n}_s$  assigns different results to inputs which differ in Sobolev norm, and indeed that it does so in a positive manner.

**CONJECTURE B.** For  $r > 2$  such that Conjecture A holds, let  $\mathcal{X} = W^{1,r}(\Omega)$ . Fix  $b \in \mathcal{X}$  and let  $\mathcal{K} = \{r \in \mathcal{X} : r|_{\partial\Omega} = b|_{\partial\Omega} \text{ and } r \geq b\}$ . Recall that  $\Phi : \mathcal{K} \rightarrow \mathcal{X}'$  is then well-defined by Lemma 3.2. Then there are constants  $\alpha > 0$  and  $q > 1$  so that

$$(4.7) \quad (\Phi(r) - \Phi(s)) [r - s] \geq \alpha \|r - s\|_{\mathcal{X}}^q \quad \text{for all } r, s \in \mathcal{K}.$$

Inequality (4.7) is called *q-coercivity* of  $\Phi$  over  $\mathcal{K}$ . In the abstract context of Section 6, if an operator is both continuous and *q-coercive*, over a closed and convex subset of a Banach space, then the corresponding VI problem is well-posed. This is what we prove next, namely that Conjectures A and B are sufficient for well-posedness of implicit time step VI problem (3.23).

**THEOREM 4.1.** Assume Conjectures A and B, and fix  $b \in \mathcal{X}$  to define  $\mathcal{K}$ . Suppose that  $s^{n-1} \in \mathcal{K}$  and that the SMB function  $a(t, x)$  is in  $C([0, T]; L^{r'}(\Omega))$ . Then  $F_{\Delta t}$  defined by (3.22) is both continuous and *q-coercive*, and thus there exists a unique surface elevation  $s \in \mathcal{K}$  satisfying VI problem (3.23).

*Proof.* Let  $R > 0$ . By Lemma 3.2 there is  $C(R) > 0$  so that if  $r, s \in B_R \cap \mathcal{K}$  then  $|\Phi(r)[q] - \Phi(s)[q]| \leq C(R) \|r - s\|_{\mathcal{X}} \|q\|_{\mathcal{X}}$ . Then by definition (3.22), Hölder’s

inequality, and Sobolev's inequality we have

$$(4.8) \quad \begin{aligned} |F_{\Delta t}(r)[q] - F_{\Delta t}(s)[q]| &\leq \int_{\Omega} |r - s||q| + \Delta t |\Phi(r)[q] - \Phi(s)[q]| \\ &\leq C \|r - s\|_{\mathcal{X}} \|q\|_{\mathcal{X}} \end{aligned}$$

for some  $C > 0$  which depends on  $R$  and  $\Delta t$ . Thus  $F_{\Delta t}$  is (Lipschitz) continuous on bounded subsets of  $\mathcal{K}$ . If Conjecture B holds then

$$(4.9) \quad \begin{aligned} (F_{\Delta t}(r) - F_{\Delta t}(s)) [r - s] &= \int_{\Omega} (r - s)^2 + \Delta t (\Phi(r) - \Phi(s)) [r - s] \\ &\geq \alpha \Delta t \|r - s\|_{\mathcal{X}}^q, \end{aligned}$$

so  $F_{\Delta t}$  is  $q$ -coercive over  $\mathcal{K}$  with constant  $\alpha \Delta t > 0$ . From definition (3.2), the hypothesis on  $a$ , and Hölder's inequality,

$$(4.10) \quad |\ell^n[q]| \leq \left( \|s^{n-1}\|_{L^{r'}} + \Delta t \max_{t \in [t_{n-1}, t_n]} \|a(t, \cdot)\|_{L^{r'}} \right) \|q\|_{L^r}$$

for all  $q \in \mathcal{X}$ . Because  $\|s^{n-1}\|_{L^{r'}} < \infty$  by Sobolev's inequality, and  $\|q\|_{L^r} \leq \|q\|_{\mathcal{X}}$ , it follows that  $\ell^n \in \mathcal{X}'$ . Because  $F_{\Delta t}$  is  $q$ -coercive it is also coercive and strictly-monotone (Definition 6.1). Now Corollary III.1.8 of [30] shows unique existence of a solution to (3.23).  $\square$

Note that if the surface motion map has coercivity constant  $\alpha > 0$  (Conjecture B) then  $F_{\Delta t}$  has constant  $\alpha \Delta t$ .

Theorem 4.1 addresses only the well-posedness of a single time-step problem over  $[t_{n-1}, t_n]$ . Its conclusion is not sufficient to show well-posedness of the time-dependent problem parabolic VI problem over  $[0, T]$  corresponding to NCP (1.3). If this problem were known to be well-posed then one might analyze whether implicit steps converge in the  $\Delta t \rightarrow 0$  limit.

The computation of  $\mathbf{u}|_s$  and  $\Phi(s) = -\mathbf{u}|_s \cdot \mathbf{n}_s$ , or equivalent expressions, would seem to be necessary in any evolving-geometry Stokes framework. These expressions are addressed in Conjectures A and B, and it would seem that any modeling practitioner who uses Stokes dynamics would expect such expressions to be well-behaved in some manner. However, the Conjectures may be difficult to prove despite some progress in Sections 2 and 3. Greater progress has been made in the SIA case [10, 26, 37], which could be helpful.

**5. Numerical exploration of coercivity.** We may explore the validity of Conjecture B by sampling from numerical simulations. The experiments here,<sup>6</sup> performed using Python and the Firedrake FE library [24], are not intended to demonstrate implicit time-stepping, but only to generate admissible surface elevation pairs  $r, s \in \mathcal{K}$  to use as samples. For a given sample pair we evaluated the 2-coercivity ratio

$$(5.1) \quad \rho(r, s) = \frac{(\Phi(r) - \Phi(s)) [r - s]}{\|r - s\|_{\mathcal{X}}^2}.$$

If, for all pairs in some  $\mathcal{K}$ , the set of ratios  $\{\rho(r, s)\}$  were bounded below by a positive constant  $\alpha > 0$ , then this would confirm the  $q = 2$  coercivity inequality (4.7) for that

<sup>6</sup>Source code is at the public repository [github.com/bueler/glacier-fe-estimate](https://github.com/bueler/glacier-fe-estimate), in the `py/` directory. The codes call the library at [github.com/bueler/stokes-extrude](https://github.com/bueler/stokes-extrude).

$\mathcal{K}$ . Of course, a numerical experiment allows only finite sampling, and furthermore a finite spatial discretization must be used.

The domain for our experiments is the 1D interval  $\Omega = (-L, L)$ ,  $L = 100$  km, with  $\mathcal{X} = W_b^{1,2}(\Omega)$ . The interval  $\Omega$  was uniformly-meshed into equal intervals. The  $P_1$  piecewise-linear FE space  $\mathcal{X}_h \subset \mathcal{X}$  was used for the bed  $b$  and the surface  $s$ , giving polygonal domains  $\Lambda$  defined by  $b, s$ ; see equation (1.1). Three bed profiles (Figure 4) were considered, *flat* with  $b = 0$ , *smooth* with a superposition of several wavelengths down to 10 km, and *rough* with an additional 4 km wavelength mode. These beds generate corresponding constraint sets  $\mathcal{K}_i \subset \mathcal{X}$ ,  $i = 1, 2, 3$ .

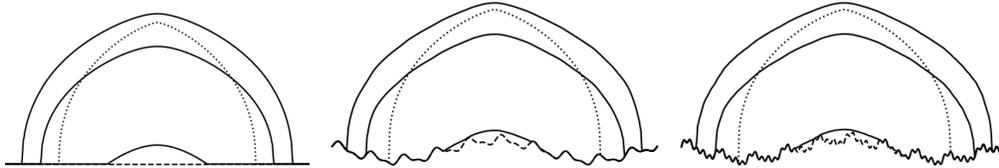

FIG. 4. Three bed cases (*flat*, *smooth*, *rough*) define constraint sets  $\mathcal{K}_i \subset \mathcal{X}$  in the numerical experiment. For each  $\mathcal{K}_i$ , three time-dependent runs of  $T = 200$  years, starting from the same initial state (dotted), but using different constant values of the SMB (see text), generated a large number of admissible states. Example states at  $t = 170$  years are shown (solid). Ratios (5.1) were computed for 1000 sample pairs  $r, s$  from each set  $\mathcal{K}_i$ .

For each constraint set  $\mathcal{K}_i$ , three constant SMB values were considered (units  $\text{ms}^{-1}$ ):  $a = \{-2.5, 0.0, 1.0\} \times 10^{-7}$ . For each SMB value a time-dependent run of duration  $T = 200$  years started from the same initial surface elevation profile.<sup>7</sup> The positive SMB value was sufficient to advance the ice margins nearly to the domain boundary at  $|x| = L$  by the final time  $T$ , while the negative SMB value caused the glacier to disappear entirely by that time.

In these simulations each time-step VI (3.23) was semi-implicit. That is, definition (3.22) was modified to use the prior surface velocity  $\mathbf{u}|_{s^{n-1}}$ . The numerical VI solution was by a reduced-space Newton method with line search [4]. The ‘‘FSSA’’ stabilization technique from [33] was applied, which generates a modified Stokes weak form compared to (2.5); see equation (23) in [33]. The Stokes problem (2.5), with viscosity regularization  $\epsilon = 10^{-19} \text{ s}^{-2}$  in (1.5), was solved on each domain  $\Lambda$  using a vertically-extruded mesh of quadrilaterals (Figure 7), mixed FE method for the  $Q_2 \times Q_1$  (Taylor-Hood) stable pair [15], and a Newton solver, with direct solution of the linear step equations. The resulting time-dependent numerical method is only conditionally stable, but adequate for our purpose of generating sample surfaces.

The basic result of these experiments is shown in Figure 5. These are sample ratio  $\rho(r, s)$  histograms from the highest spatial resolution, namely  $\Delta x = 500$  m and 40 elements in each extruded column. More than 87% of all the ratios were positive, and of these the medians for the three  $\mathcal{K}_i$  were in the range  $[4.5, 5.2] \times 10^{-13}$ . For the remaining negative ratios, the medians were in the range  $[-4.1, -2.8] \times 10^{-14}$ , much smaller in magnitude.

Figure 5 does *not* represent compelling evidence of 2-coercivity by definition (6.3), but it does not exclude it. In fact, the details of the discretization of the ice margin strongly influence the negative ratios. Noting that ratio evaluation uses integral (3.15),

<sup>7</sup>A Halfar profile [23] with characteristic time  $t_0 = 29$  years was used as the initial state. In the case of a flat bed and  $a = 0$  the exact time-dependent solution under SIA dynamics is known by Halfar’s result [23]. The final ( $T = 200$  a) surface elevation, from using Stokes dynamics in the actual experiment, agrees closely with the SIA exact solution; compare comments in [33].

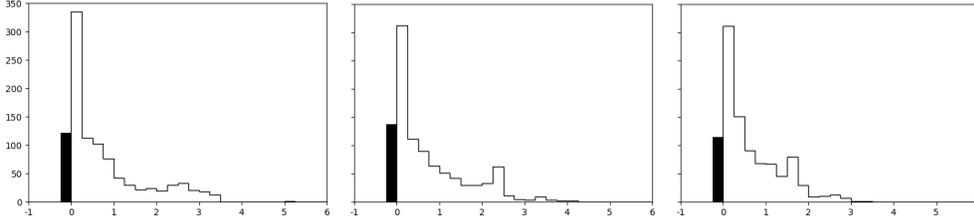

FIG. 5. Histograms of ratios  $\rho(r, s)$  for 1000 sample pairs from each of the three sets  $\mathcal{K}_i$  (Figure 4). The horizontal axis has  $\rho(r, s) \in [-1, 6] \times 10^{-12}$ , and the common vertical axis is for counts between 0 and 350. About 10% of these ratios are negative (solid).

if that integrand is reset to zero where the ice is thinner than 100 m then the negative values disappear (not shown). Even without such thresholding, at lower horizontal resolution ( $\Delta x = 2000$  m) the median magnitude of negative ratios was roughly twice as large (not shown). The disappearance of negative ratios under grid refinement should not be excluded. Margin approximation improvements, such as adaptive/local mesh refinement, will probably improve the numerical evidence for coercivity.

It is theoretically possible that the operator  $\Phi$  is monotone, inequality (6.2), but not  $q$ -coercive for any  $q$ . In that case a revised well-posedness argument can be attempted, for example by adding a small coercive form as in section III.2 of [30]. However, if a continuum pair  $r, s$  with a negative ratio were actually to be found in some  $\mathcal{K}$ , i.e. with an exact continuum ratio  $\rho(r, s) < 0$  from (5.1), then the coercivity-based well-posedness framework of this paper would fail.

Regarding Conjecture A, Lipschitz continuity for the surface velocity trace, the ratio  $\|\mathbf{u}|_r - \mathbf{u}|_s\|_{L^2} / \|r - s\|_{W^{1,2}}$  for the same sample pairs was also evaluated. Over all three sets  $\mathcal{K}_i$ , at the highest resolution, the maximum ratio was  $3.5 \times 10^{-9}$ , providing a lower bound for  $C_A$ . Again, numerical experiments obviously cannot prove the Conjecture.

**6. Abstract error estimate for a finite element approximation.** In this Section we consider the FE approximation of an abstract VI problem. We will return to glaciological problem (3.23) in Section 7.

Let  $\mathcal{X}$  be a real reflexive Banach space with norm  $\|\cdot\|$  and topological dual (Banach) space  $\mathcal{X}'$ . Denote the dual pairing of  $\ell \in \mathcal{X}'$  and  $v \in \mathcal{X}$  by  $\ell[v]$ , and define  $\|\ell\|_{\mathcal{X}'} = \sup_{\|v\|=1} |\ell[v]|$ . Let  $\mathcal{K} \subset \mathcal{X}$  be a nonempty, closed, and convex subset, called the constraint set, whose elements are called admissible. For a continuous, but generally nonlinear, operator  $f : \mathcal{K} \rightarrow \mathcal{X}'$ , and a source functional  $\ell \in \mathcal{X}'$ , the VI problem is to find  $u \in \mathcal{K}$  such that

$$(6.1) \quad f(u)[v - u] \geq \ell[v - u] \quad \text{for all } v \in \mathcal{K}.$$

VI problem (3.23) is in this form. The best known example of (6.1) is the obstacle problem for the Laplacian operator—see [12, 16, 30] for theory and FE analysis. A key observation is that  $f(u) - \ell \in \mathcal{X}'$  is generally nonzero when  $u$  solves (6.1), though if  $u$  is in the interior of  $\mathcal{K}$  then  $f(u) = \ell$ . Under sufficient regularity assumptions an NCP like (1.3) or (1.7) follows from (6.1).

DEFINITION 6.1. *An operator  $f : \mathcal{K} \rightarrow \mathcal{X}'$  is said to be monotone if*

$$(6.2) \quad (f(v) - f(w))[v - w] \geq 0 \quad \text{for all } v, w \in \mathcal{K}$$

and strictly monotone if equality in (6.2) implies  $v = w$  [34], [30, Chapter III]. It is coercive if there is  $w \in \mathcal{K}$  so that  $(f(v) - f(w))[v - w]/\|v - w\| \rightarrow +\infty$  for  $v \in \mathcal{K}$  as  $\|v\| \rightarrow +\infty$ . It is  $q$ -coercive [6], for some  $q > 1$ , if there exists  $\alpha > 0$  such that

$$(6.3) \quad (f(v) - f(w))[v - w] \geq \alpha \|v - w\|^q \quad \text{for all } v, w \in \mathcal{K}.$$

If  $f : \mathcal{K} \rightarrow \mathcal{X}'$  is monotone and coercive, and also continuous on finite-dimensional subspaces, then VI (6.1) has a solution [30, Corollary III.1.8]. If  $f$  is strictly monotone then the solution is unique. The definition of  $q$ -coercive was already given in Conjecture B. If  $f$  is  $q$ -coercive then it is coercive and strictly monotone, so  $q$ -coercivity and continuity yield well-posedness for (6.1). Note that Definitions 6.1 and 6.2 do not require  $f$  to be defined on all of  $\mathcal{X}$ , but only on  $\mathcal{K}$ .

The following definition appeared in Lemma 3.2. If it holds then  $f$  is continuous.

**DEFINITION 6.2.** For  $R > 0$  let  $B_R = \{v \in \mathcal{X} : \|v\| \leq R\}$ . We say  $f : \mathcal{K} \rightarrow \mathcal{X}'$  is Lipschitz on bounded subsets of  $\mathcal{K}$  if for every  $R > 0$  there is  $C(R) > 0$  so that if  $v, w \in B_R \cap \mathcal{K}$  and  $z \in \mathcal{X}$  then  $|(f(v) - f(w))[z]| \leq C(R)\|v - w\|\|z\|$ , equivalently

$$(6.4) \quad \|f(v) - f(w)\|_{\mathcal{X}'} \leq C(R)\|v - w\| \quad \text{for all } v, w \in B_R \cap \mathcal{K}.$$

An FE method for (6.1) becomes a finite-dimensional VI problem. Suppose  $\mathcal{X}_h \subset \mathcal{X}$  is a finite-dimensional subspace, typically some space of continuous, piecewise-polynomial functions defined on a mesh. The FE constraint set  $\mathcal{K}_h \subset \mathcal{X}_h$  is assumed to be closed and convex, but generally  $\mathcal{K}_h \not\subseteq \mathcal{K}$ . Let  $f_h : \mathcal{K}_h \rightarrow \mathcal{X}'$ , and note that generally  $f_h \neq f$  because of quadrature and other approximations. (Looking ahead, both  $\mathcal{K}_h \not\subseteq \mathcal{K}$  and  $f_h \neq f$  occur naturally in the glacier geometry problem; see Section 7.) The FE VI problem is

$$(6.5) \quad f_h(u_h)[v_h - u_h] \geq \ell[v_h - u_h] \quad \text{for all } v_h \in \mathcal{K}_h.$$

We will assume that (6.5) has a solution  $u_h \in \mathcal{K}_h$ .

The following abstract error estimation theorem extends the well-known result by Falk [18]. See also Theorem 5.1.1 in [12], and a version of the estimate wherein  $u$  (but not  $u_h$ ) solves a variational equality [31, Theorem 1]. For the proof we must assume that the domain of  $f$  includes the FE solution, which is achieved here by defining a convex superset of  $\mathcal{K}$  and  $\mathcal{K}_h$ . This technical assumption permits a clean and general estimation theorem, but the choice of  $\mathcal{K}_h$  made in Section 7 means that the convex hull construction is not needed in our glacier application; see Corollary 6.4.

**THEOREM 6.3.** Define  $\widehat{\mathcal{K}}$  to be the closure in  $\mathcal{X}$  of the convex hull of  $\mathcal{K} \cup \mathcal{K}_h$ , and suppose that  $f : \widehat{\mathcal{K}} \rightarrow \mathcal{X}'$ . For  $q > 1$ , with conjugate exponent  $q' = q/(q-1)$ , assume that  $f$  is  $q$ -coercive over  $\widehat{\mathcal{K}}$  with constant  $\alpha > 0$ , and Lipschitz on bounded sets of  $\widehat{\mathcal{K}}$ . Suppose  $u \in \mathcal{K}$  solves (6.1) and  $u_h \in \mathcal{K}_h$  solves (6.5), and let  $R_h = \max\{\|u\|, \|u_h\|\}$ . Then there is a constant  $c = c(R_h) > 0$ , not otherwise depending on  $u$  or  $u_h$ , so that

$$(6.6) \quad \begin{aligned} \|u - u_h\|^q \leq & \frac{2}{\alpha} \inf_{v \in \mathcal{K}} (f(u) - \ell)[v - u_h] \\ & + \frac{2}{\alpha} \inf_{v_h \in \mathcal{K}_h} (f(u) - \ell)[v_h - u] \\ & + \frac{2}{\alpha} (f(u_h) - f_h(u_h))[u_h] \\ & + c \inf_{v_h \in \mathcal{K}_h} \|v_h - u\|^{q'}. \end{aligned}$$

*Proof.* For arbitrary  $v \in \mathcal{K}$  and  $v_h \in \mathcal{K}_h$ , rewrite (6.1) and (6.5) as follows:

$$(6.7) \quad \begin{aligned} f(u)[u] &\leq f(u)[v] + \ell[u - v], \\ f_h(u_h)[u_h] &\leq f_h(u_h)[v_h] + \ell[u_h - v_h]. \end{aligned}$$

It follows from (6.7) and the q-coercivity of  $f$  that

$$(6.8) \quad \begin{aligned} \alpha \|u - u_h\|^q &\leq (f(u) - f(u_h)) [u - u_h] \\ &= f(u)[u] + f(u_h)[u_h] - f(u)[u_h] - f(u_h)[u] \\ &= f(u)[u] + f_h(u_h)[u_h] \\ &\quad - f(u)[u_h] - f(u_h)[u] + (f(u_h) - f_h(u_h)) [u_h] \\ &\leq f(u)[v] + \ell[u - v] + f(u_h)[v_h] + \ell[u_h - v_h] \\ &\quad - f(u)[u_h] - f(u_h)[u] + (f(u_h) - f_h(u_h)) [u_h] \\ &= f(u)[v - u_h] - \ell[v - u_h] + f(u_h)[v_h - u] - \ell[v_h - u] \\ &\quad + (f(u_h) - f_h(u_h)) [u_h] \\ &= (f(u) - \ell) [v - u_h] + (f(u) - \ell) [v_h - u] \\ &\quad + (f(u) - f(u_h)) [u - v_h] + (f(u_h) - f_h(u_h)) [u_h] \end{aligned}$$

Since  $u, u_h \in B_{R_h}$ , by the Lipschitz assumption over  $\widehat{\mathcal{K}}$  there is  $C(R_h) > 0$  so that

$$(6.9) \quad (f(u) - f(u_h)) [u - v_h] \leq C(R_h) \|u - u_h\| \|u - v_h\|.$$

Noting  $1 < q < \infty$ , now use Young's inequality with  $\epsilon > 0$  [16, Appendix B.2]:

$$(6.10) \quad \begin{aligned} \alpha \|u - u_h\|^q &\leq (f(u) - \ell) [v - u_h] + (f(u) - \ell) [v_h - u] \\ &\quad + C(R_h) (\epsilon \|u - u_h\|^q + \tilde{C}(\epsilon) \|u - v_h\|^{q'}) \\ &\quad + (f(u_h) - f_h(u_h)) [u_h], \end{aligned}$$

where  $\tilde{C}(\epsilon) = (\epsilon q)^{-q'/q} q'^{-1}$ . Choose  $\epsilon > 0$  so that  $C(R_h)\epsilon \leq \alpha/2$ , and subtract:

$$(6.11) \quad \begin{aligned} \frac{\alpha}{2} \|u - u_h\|^q &\leq (f(u) - \ell) [v - u_h] + (f(u) - \ell) [v_h - u] \\ &\quad + C(R_h) \tilde{C}(\epsilon) \|u - v_h\|^{q'} + (f(u_h) - f_h(u_h)) [u_h] \end{aligned}$$

Take infimums to show (6.6). □

Note that Theorem 6.3 does *not* assume any of the following:  $\mathcal{K}_h \subset \mathcal{K}$ ,  $f$  is linear,  $f_h = f$ ,  $f_h$  is continuous, or  $f_h$  is q-coercive. We also do not require that  $u_h$  is the *unique* solution of (6.5); the result holds for any solution.

The next Corollary addresses two important cases where the convex hull operation is not needed. We will see in Section 7 that case *i*) can be imposed in glacier simulations.

**COROLLARY 6.4.** *Suppose that one of the following situations apply:*

- i)  $\mathcal{K}_h \subset \mathcal{K}$ , or*
- ii)  $f$  is defined on all of  $\mathcal{X}$ .*

*Assume  $f$  is q-coercive on, and Lipschitz on bounded subsets of, its domain, namely  $\mathcal{K}$  or  $\mathcal{X}$ , respectively. Otherwise make the assumptions of Theorem 6.3. Then conclusion (6.6) holds. Additionally, in case *i*) the “ $\inf_{v \in \mathcal{K}}$ ” term is zero.*

Consider  $f(u) - \ell \in \mathcal{X}'$ . It might be a measure or a measurable function, and then the first two terms in estimate (6.6) preserve information about its support. (This plays a role in the glacier application of Section 7.) By contrast, the Hilbert space result in [18] computes norms and loses this information. The following Corollary, with easy proof, takes such a norm-based approach. We suppose that  $\mathcal{X}$  continuously and densely embeds into a larger Banach space  $\mathcal{B}$ :

$$(6.12) \quad \mathcal{X} \hookrightarrow \mathcal{B}, \quad \bar{\mathcal{X}} = \mathcal{B}$$

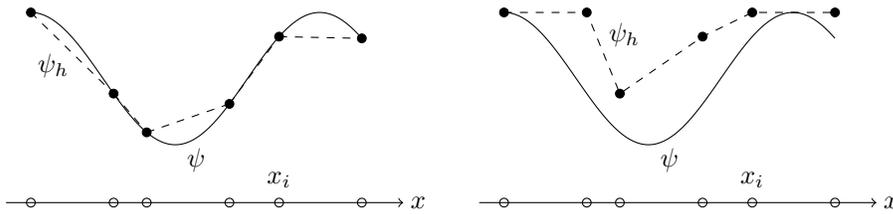

Observe that  $\mathcal{B}' \subset \mathcal{X}'$ . A standard example is  $\mathcal{X} = W^{1,r}(\Omega)$  and  $\mathcal{B} = L^r(\Omega)$ .

**COROLLARY 6.5.** *In addition to the assumptions of Theorem 6.3, suppose (6.12) holds, and that  $\|f(u) - \ell\|_{\mathcal{B}'} < \infty$ . Then*

$$(6.13) \quad \|u - u_h\|^q \leq \frac{2}{\alpha} \|f(u) - \ell\|_{\mathcal{B}'} \left( \inf_{v \in \mathcal{K}} \|v - u_h\|_{\mathcal{B}} + \inf_{v_h \in \mathcal{K}_h} \|v_h - u\|_{\mathcal{B}} \right) \\ + \frac{2}{\alpha} (f(u_h) - f_h(u_h)) [u_h] + \inf_{v_h \in \mathcal{K}_h} c \|v_h - u\|^{q'}$$

The result by Falk [18] combines the above two Corollaries, under the further assumptions that  $f$  is linear and  $f_h = f$ . To say this precisely, suppose  $f(v)[w] = a(v, w)$  is bilinear, uniformly elliptic, and continuous on a Hilbert space  $\mathcal{X}$ . (The definition of uniformly elliptic coincides with definition (6.3) of 2-coercive, and continuity of  $a(v, w)$  implies (6.4).) Suppose that  $\mathcal{X} \hookrightarrow \mathcal{H}$  and  $\bar{\mathcal{X}} = \mathcal{H}$  for some Hilbert space  $\mathcal{H}$ , and that  $\|f(u) - \ell\|_{\mathcal{H}'} < \infty$  so that, up to isomorphism,  $f(u) - \ell \in \mathcal{H}$ . Finally, suppose that  $f(u_h) = f_h(u_h)$ . Then case *ii*) of Corollary 6.4 combines with Corollary 6.5 to yield Theorem 1 in [18].

The  $\inf_{v \in \mathcal{K}}$  term in estimates (6.6) and (6.13) is generally nonzero in obstacle problems where  $\mathcal{K}_h \not\subset \mathcal{K}$ . To see how this case can occur, consider a unilateral obstacle problem where  $\mathcal{K} = \{v \in \mathcal{X} : v \geq \psi\}$ . Suppose  $\psi_h = \pi_h \psi$  is the FE interpolant of  $\psi$ , and define  $\mathcal{K}_h = \{v_h \in \mathcal{X}_h : v_h \geq \psi_h\}$ . While  $\psi_h(x_j) = \psi(x_j)$  for interpolation nodes  $x_j$ , generally  $\psi_h(x) \geq \psi(x)$  will not hold for all  $x \in \Omega$  even if  $\psi$  is arbitrarily smooth, nor will  $\psi_h(x) \leq \psi(x)$  hold (Figure 6, left; see also [12, Figure 5.1.3]).

**FIG. 6.** *Nodal admissibility does not imply admissibility. Left: If  $\psi_h = \pi_h \psi$  is the interpolant of  $\psi$  then generally  $\mathcal{K}_h \subset \mathcal{K}$  will not hold. Right: Generating the FE obstacle by  $\psi_h = R^\oplus \psi \geq \psi$ , using monotone nodal operator (6.14), will cause  $\mathcal{K}_h \subset \mathcal{K}$ .*

For such unilateral problems we may bypass the issue by using a monotone nodal operator (Figure 6, right), defined as follows. Assume  $P_1$  elements and a continuous obstacle  $\psi$ . For a given triangulation  $\mathcal{T}_h$  and node  $x_i$  let

$$(6.14) \quad (R^\oplus \psi)(x_i) = \max_{x \in N_i} \psi(x),$$

where  $N_i$  is the closure of the union of the elements adjacent to  $x_i$ ; compare the multilevel version of  $R^\oplus$  in [8]. Let  $\psi_h$  be the unique  $P_1$  function with nodal values  $(R^\oplus\psi)(x_i)$ . Then  $\psi_h(x) \geq \psi(x)$  for all  $x \in \Omega$ .

When we return to the surface elevation based glacier problem in Section 7 we will use this monotone operator on the bed elevation. Models which solve for ice thickness using  $P_1$  elements do not need this step; here  $\mathcal{K} = \{v \in \mathcal{X} : v \geq 0\}$ , so  $\mathcal{K}_h = \mathcal{K} \cap \mathcal{X}_h \subset \mathcal{K}$  holds.

The following Corollary collects some conclusions one might draw from assuming  $\mathcal{K}_h \subset \mathcal{K}$ , and making further assumptions, especially that  $f_h = f$ . Note that (6.17) is Cea's lemma [12, Theorem 2.4.1] in a Banach space. This PDE case, with no active set or free boundary, applies in the glacier context only when the entire domain  $\Omega$  is covered in ice.

**COROLLARY 6.6.** *Make the assumptions of case i) of Corollary 6.4. Also assume that  $f_h(u_h)[u_h] = f(u_h)[u_h]$ . Then*

$$(6.15) \quad \|u - u_h\|^q \leq \inf_{v_h \in \mathcal{K}_h} \left\{ \frac{2}{\alpha} (f(u) - \ell)[v_h - u] + c \|v_h - u\|^{q'} \right\}.$$

*If also the assumptions of Corollary 6.5 hold then*

$$(6.16) \quad \|u - u_h\|^q \leq \inf_{v_h \in \mathcal{K}_h} \left\{ \frac{2}{\alpha} \|f(u) - \ell\|_{\mathcal{B}'} \|v_h - u\|_{\mathcal{B}} + c \|v_h - u\|^{q'} \right\}$$

*If  $f(u) = \ell$ , for example if  $u$  is in the interior of  $\mathcal{K}$ , then*

$$(6.17) \quad \|u - u_h\|^q \leq c \inf_{v_h \in \mathcal{K}_h} \|v_h - u\|^{q'}$$

**7. Application of the theory to numerical glacier models.** Now we can synthesize the theory and apply it to an implicit time step of a Stokes-based glacier simulation. This will give the phrase ‘‘conforming FE method’’ a precise meaning for such glacier simulations. We will combine three previous threads: *i)* well-posedness and *a priori* bounds for the glaciological Stokes problem on a fixed domain (Section 2), *ii)* conjectural well-posedness theory of the surface elevation VI problem (Sections 3 and 4), and *iii)* the abstract error estimate for FE solutions of VIs (Section 6).

Consider an FE method for VI problem (3.23). For a finite-dimensional subspace  $\mathcal{X}_h \subset \mathcal{X}$ , with a constraint set  $\mathcal{K}_h \subset \mathcal{X}_h$ , we seek  $s_h \in \mathcal{K}_h$  solving

$$(7.1) \quad F_{\Delta t}^h(s_h)[r_h - s_h] \geq \ell^n[r_h - s_h] \quad \text{for all } r_h \in \mathcal{K}_h.$$

The operator  $F_{\Delta t}^h$  denotes an FE approximation to the operator  $F_{\Delta t}$  defined in (3.22). The source  $\ell^n = s^{n-1} + \Delta t a^n$  is defined exactly as before, by equation (3.2). We assume that  $s^{n-1} \in \mathcal{K}$  is general; we do not require  $s^{n-1} \in \mathcal{K}_h$ .

Evaluation of  $F_{\Delta t}^h(s_h)$  in the FE VI problem (7.1) requires the nontrivial numerical solution of a glaciological Stokes problem (2.5) over a 3D mesh of the domain  $\Lambda(s_h)$  between  $z = b_h$  and  $z = s_h$  (Figure 7). Such a mesh need not be extruded vertically as shown, nor must  $s_h$  necessarily be piecewise-linear, but the upper and lower surfaces, where boundary conditions (1.6c) and (1.6d) are applied, must be admissible FE functions, i.e.  $s_h, b_h \in \mathcal{X}_h$  with  $s_h \geq b_h$ . The numerical velocity from solving the Stokes problem, over the domain geometry defined by  $s_h$ , is denoted  $\mathbf{u}_h$ , and its surface trace is denoted  $\mathbf{u}_h|_{s_h}$ . Observe that  $\mathbf{u}_h|_{s_h}$  will generally be different from the

surface trace of the exact solution of the same Stokes boundary value problem for the same  $(s_h)$  geometry, denoted by  $\mathbf{u}|_{s_h}$ . Technically, the FE operator is defined as

$$(7.2) \quad F_{\Delta t}^h(s_h)[q] = \int_{\Omega} (s_h - \Delta t \mathbf{u}_h|_{s_h} \cdot \mathbf{n}_{s_h}) q$$

for  $q \in \mathcal{X}_h$ . This is a different operator from  $F_{\Delta t}(s_h)$ , defined in (3.22), because it uses the numerical solution velocity and not the exact velocity.

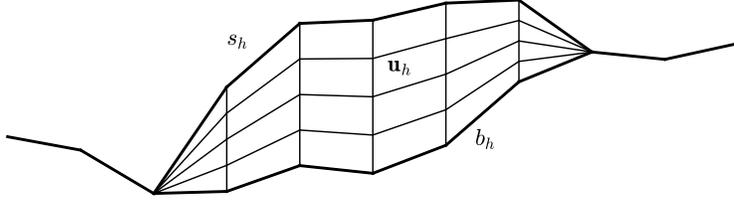

FIG. 7. Evaluating  $F_{\Delta t}^h(s_h)$  in (7.1) requires numerically solving a Stokes problem on a mesh between  $b_h$  and  $s_h$ , and then evaluating its upper surface trace:  $\mathbf{u}_h|_{s_h}$ .

A key concern in applying abstract Theorem 6.3 or its Corollaries in a glaciological context is the choice of the numerical bed elevation  $b_h \approx b$ , which defines the constraint set  $\mathcal{K}_h$ . We will assume that  $b$  is continuous on the closed domain  $\bar{\Omega}$ . (An abstract  $b \in C(\bar{\Omega}) \cap \mathcal{X}$  can indeed be considered, but in practice  $b$  is provided via a high resolution map derived from ice-penetrating radar [35]. It may already be in a continuous FE space, but often on a finer mesh.) We assert that it is better to choose  $b_h \in \mathcal{X}_h$  to satisfy  $b_h \geq b$ . A monotone nodal operator (6.14), or similar, can be applied,  $b_h = R^\oplus b$ . As one would in “conforming” FE methods for PDE problems [15], we will also assume  $b_h = b$  along the fixed boundary  $\partial\Omega$ .

Define an interpolation and truncation operation  $\Pi_h : \mathcal{X} \rightarrow \mathcal{K}_h$  as follows. For  $r \in \mathcal{X}$  this gives the unique FE function  $\Pi_h(r) \in \mathcal{X}_h$  so that

$$(7.3) \quad \Pi_h(r)(x_j) = \max\{b_h(x_j), r(x_j)\}$$

for every interior node  $x_j \in \mathcal{T}_h$ , with  $\Pi_h(x_j) = b(x_j)$  if  $x_j \in \partial\Omega$ . Observe that definition (7.3) only yields nodal admissibility. The FE space must be such that this implies admissibility *per se*, namely that  $\Pi_h(r)(x) \geq b_h(x)$  for all  $x \in \Omega$ , so that  $\Pi_h(r) \in \mathcal{K}_h$ . This condition is satisfied by the continuous and piecewise-linear FE space  $P_1$ , but not, for example, by  $P_2$  [8], but compare the higher-order approach taken in [29].

Collecting the above assumptions, from now on we make these standard assumptions for solving VI problem (3.23) using numerical scheme (7.1).

STANDARD ASSUMPTIONS. *The following data are given:*

1. A bounded, convex polygon  $\Omega \subset \mathbb{R}^2$ .
2. An exponent  $r > 2$ , with conjugate exponent  $r' = r/(r-1)$ .
3. A time-dependent SMB function  $a \in C([0, T]; L^{r'}(\Omega))$ .
4. A bed topography function  $b \in C(\bar{\Omega}) \cap W^{1,r}(\Omega)$ , with piecewise-linear boundary values  $b|_{\partial\Omega}$ .

We make these definitions:

5.  $\mathcal{X} = W^{1,r}(\Omega)$ , with the norm as defined in (3.8).
6.  $\mathcal{K} = \{r \in \mathcal{X} : r|_{\partial\Omega} = b|_{\partial\Omega} \text{ and } r \geq b\}$ .

7.  $\mathcal{X}_h \subset \mathcal{X}$  denotes a finite-dimensional and conforming FE space, from a mesh  $\mathcal{T}_h$  exactly tiling  $\bar{\Omega}$ .

The following are assumed to hold:

8. Conjecture A, with Lipschitz constant  $C_A > 0$ .  
 9. Conjecture B, with exponent  $q > 1$  and coercivity constant  $\alpha > 0$ .

We also assume and define:

10.  $b_h \in \mathcal{X}_h$  is given, with  $b_h \geq b$  on  $\bar{\Omega}$  and  $b_h = b$  along  $\partial\Omega$ .  
 11.  $\mathcal{K}_h = \{r_h \in \mathcal{X}_h : r_h|_{\partial\Omega} = b_h|_{\partial\Omega} \text{ and } r_h \geq b_h\}$ .  
 12. Interpolation/truncation  $\Pi_h$  yields admissible elements in  $\mathcal{K}_h$ .

The conforming condition  $\mathcal{K}_h \subset \mathcal{K}$  follows from assumptions 10 and 11, with advantages to follow. As seen in the proof of Theorem 4.1, assumptions 8 and 9 show that  $F_{\Delta t}$  is  $q$ -coercive and Lipschitz on bounded subsets of  $\mathcal{K}$ . By Theorem 4.1 and case *i*) of Corollary 6.4 we have the following Lemma.

LEMMA 7.1. *Make the Standard Assumptions. Suppose that  $s^{n-1} \in \mathcal{K}$  and define  $\ell^n \in \mathcal{X}'$  by (3.2). Let  $s \in \mathcal{K}$  be the unique surface elevation satisfying the implicit time-step VI problem (3.23). Assume that  $s_h \in \mathcal{K}_h$  solves problem (7.1). Let  $R_h = \max\{\|s\|_{\mathcal{X}}, \|s_h\|_{\mathcal{X}}\}$ . Then there is a constant  $c_0 > 0$ , depending on  $R_h$  and  $\Delta t$ , but not otherwise on  $s$  or  $s_h$ , so that*

$$(7.4) \quad \begin{aligned} \|s - s_h\|_{\mathcal{X}}^r &\leq \frac{2}{\alpha \Delta t} \inf_{r_h \in \mathcal{K}_h} (F_{\Delta t}(s) - \ell^n)[r_h - s] \\ &\quad + \frac{2}{\alpha \Delta t} (F_{\Delta t}(s_h) - F_{\Delta t}^h(s_h))[s_h] \\ &\quad + c_0 \inf_{r_h \in \mathcal{K}_h} \|r_h - s\|_{\mathcal{X}}^q. \end{aligned}$$

Each term in estimate (7.4) turns out to have a clear glaciological meaning, which we expose in the following Theorem. Recall that  $\mathcal{V} = W_b^{1,p}(\Lambda_{s_h}; \mathbb{R}^3)$  is the velocity space for the Stokes problem (2.5),  $h$  denotes the maximum diameter of cells in  $\mathcal{T}_h$ , and  $\Lambda_{s_h}$  denotes the 3D domain defined by  $s_h$ ,  $\gamma_p(\Lambda_{s_h})$  denotes the trace constant of that domain (Lemma 2.5).

THEOREM 7.2. *Make the Standard Assumptions. Let  $s \in \mathcal{K}$  be the unique solution of (3.23), and  $s_h \in \mathcal{K}_h$  a solution of (7.1). Define*

$$(7.5) \quad \Omega_A(s) = \{x \in \Omega : s(x) = b(x)\},$$

the active set for  $s$ . Then

$$(7.6) \quad \begin{aligned} \|s_h - s\|_{\mathcal{X}}^r &\leq \frac{2}{\alpha \Delta t} \int_{\Omega_A(s)} (b - \ell^n)(b_h - b) && \text{[term 1]} \\ &\quad + \frac{1}{\alpha} \Gamma(s_h) \|\mathbf{u}_h - \mathbf{u}\|_{\mathcal{V}} && \text{[term 2]} \\ &\quad + c_0 \|\Pi_h(s) - s\|_{\mathcal{X}}^q. && \text{[term 3]} \end{aligned}$$

The constant  $c_0 > 0$  is from Lemma 7.1. The coefficient in term 2, namely

$$(7.7) \quad \Gamma(s_h) = c_1 \left( \frac{\gamma_p(\Lambda_{s_h})}{[H]} \right)^{1/p} (|\Omega| + [L]^{-r} \|s_h\|_{\mathcal{X}}^r)^{1/(p'r)},$$

depends nontrivially on  $s_h$ , but  $c_1 > 0$  depends only on the exponents  $r, p$ .

Before proving the Theorem we sketch the meaning of each term; more detail appears after the proof.

- term 1: This term comes from FE approximation of the bed in the ice-free area  $\Omega_A(s)$ . If the bed were exactly representable ( $b_h = b$ ) then it would be zero. Note that  $s_h \geq b_h \geq b = s$  in the ice-free area  $\Omega_A(s)$ , so the factor  $b_h - b$  in the integrand reflects the smallest possible difference  $s_h - s$ . Also  $b - \ell^n \geq 0$  (Section 3) so the integrand is nonnegative.
- term 2: This term quantifies how numerical errors in solving the Stokes problem, over the domain  $\Lambda_{s_h}$ , will affect the geometrical error in  $s_h$ .
- term 3: An interpolation error term like this arises in the classical Cea's lemma argument for quasi-optimality of FE methods for PDEs [12]. However, here the interpolant of  $s$  must also be truncated into  $\mathcal{K}_h$ , using operation (7.3), and also nodal admissibility must imply admissibility.

*Proof.* Because  $s$  solves (3.23), the residual  $\Psi = F_{\Delta t}(s) - \ell^n \in \mathcal{X}'$ , while generally nonzero, is non-negative. In particular, if  $\phi \in C_c^\infty(\Omega)$  is nonnegative then  $r = s + \phi \in \mathcal{K}$  and  $\Psi[r - s] = \Psi[\phi] \geq 0$ . Thus  $\Psi \in \mathcal{X}'$  is a non-negative distribution, and so it is represented by a positive Borel measure  $\mu$  [32, Theorem 6.22], that is,  $\Psi[\phi] = \int_\Omega \phi d\mu$ . However, by the proof of Theorem II.6.9 in [30] this measure is supported in  $\Omega_A(s)$  and has density  $b - \ell^n$ . (Recall from Section 3 that  $b - \ell^n \geq 0$  on  $\Omega_A(s)$ .)

Apply Lemma 7.1. Note that  $\mathbf{u}|_s = \mathbf{0}$  and  $s = b$  on  $\Omega_A(s)$ . From the first term in (7.4) we now get term 1 when we set  $r_h = b_h \in \mathcal{K}_h$ :

$$(7.8) \quad (F_{\Delta t}(s) - \ell^n)[r_h - s] = \int_\Omega (b_h - s) d\mu = \int_{\Omega_A(s)} (b - \ell^n)(b_h - b).$$

Consider the second term in (7.4). Recall that  $dS = |\mathbf{n}_{s_h}| dx$  is the surface area element for the surface  $\Gamma_{s_h} \subset \partial\Lambda_{s_h}$ . After definitions (3.22) and (7.2), apply the triangle and Hölder inequalities:<sup>8</sup>

$$(7.9) \quad \begin{aligned} (F_{\Delta t}(s_h) - F_{\Delta t}^h(s_h))[s_h] &= -\Delta t \int_\Omega (\mathbf{u}|_{s_h} - \mathbf{u}_h|_{s_h}) \cdot \mathbf{n}_{s_h} s_h \\ &\leq \Delta t \int_\Omega |\mathbf{u}|_{s_h} - \mathbf{u}_h|_{s_h}| |\mathbf{n}_{s_h}|^{1/p} |\mathbf{n}_{s_h}|^{1/p'} |s_h| \\ &\leq \Delta t \left( \int_\Omega |\mathbf{u}|_{s_h} - \mathbf{u}_h|_{s_h}|^p |\mathbf{n}_{s_h}| \right)^{1/p} \left( \int_\Omega |\mathbf{n}_{s_h}| |s_h|^{p'} \right)^{1/p'} \\ &\leq \Delta t \left( \int_{\Gamma_{s_h}} |\mathbf{u} - \mathbf{u}_h|^p dS \right)^{1/p} \left( \int_\Omega |\mathbf{n}_{s_h}|^r \right)^{1/(p'r)} \|s_h\|_{L^{p'r'}} \end{aligned}$$

Now apply the trace inequality (Lemma 2.5) and use the fact that  $(1 + \alpha)^{r/2} \leq 2^{(r-2)/2} (1 + \alpha^{r/2})$  if  $\alpha \geq 0$ :

$$(7.10) \quad \begin{aligned} (F_{\Delta t}(s_h) - F_{\Delta t}^h(s_h))[s_h] &\leq \Delta t \left( \frac{\gamma_p(\Lambda_{s_h})}{[H]} \right)^{1/p} \|\mathbf{u} - \mathbf{u}_h\|_{\mathcal{V}} \\ &\quad \cdot \left( 2^{(r-2)/2} \int_\Omega 1 + |\nabla s_h|^r \right)^{1/(p'r)} \|s_h\|_{L^{p'r'}}. \end{aligned}$$

Recalling norm definition (3.8), we have term 2.

Term 3 follows by substituting  $r_h = \Pi_h(s)$  into the third term in (7.4).  $\square$

<sup>8</sup>A similar argument was used in the proof of Lemma 3.1.

Regarding term 1, consider those portions of  $\Omega_A(s)$  which are also ice-free according to the FE solution, namely points  $x \in \Omega_A(s) \cap \Omega_A^h(s_h)$  where  $\Omega_A^h(s_h) = \{x \in \Omega : s_h(x) = b_h(x)\}$ . In such areas generally  $b_h > b$ , for example because of the monotone restriction used for assumption 10. This implies that there is a positive “fake ice thickness” error for the FE solution, namely  $s_h - b = b_h - b > 0$ , but the numerical model reports zero thickness ( $s_h - b_h = 0$ ). In areas of strong ablation, and far from the nearest flowing glacier, one might simply declare that such “fake ice” does not represent an FE-generated error, and then the magnitude of term 1 can be reduced accordingly, by excluding obviously ice-free areas from the integral. However, generally  $s$  is unknown, and therefore such exclusion is not appropriate, nor implementable, near the unknown free boundary  $\Omega \cap \partial\Omega_A(s)$ . A climate which puts the bed elevation near the equilibrium line altitude [22] in any ice-free area would also make such casual exclusion of a potentially real FE error unwise.

Note that a time-stepping FE solution of any fluid-layer VI problem like (3.23) commits a mass conservation error near the (unknown) exact free boundary even when there is no difference between the exact and FE obstacles. The mass conservation barrier theory in [6] addresses this concern, in terms of the fluid layer thickness. (For thicknesses the obstacle is the zero function; it has an exact FE representation.) While the theory in [6] applies here as well, term 1 in bound (7.6) is novel relative to the various mass-conservation errors identified there. (See in [6]: retreat loss, boundary leak, and cell slop.)

The Stokes velocity error norm  $\|\mathbf{u}_h - \mathbf{u}\|_{\mathcal{V}}$  in term 2 of (7.6) describes the error in solving problem (2.5) on a particular (“fixed”) 3D domain  $\Lambda_{s_h}$ . One may use reasonable assumptions and existing techniques to derive a convergence rate for this term if one supposes *counter-factually* that  $\Lambda_{s_h}$  does not change under mesh refinement. The following sketch does this; it is from [28, Theorem 4.9]; see also the FE theory for linear Stokes in [15], for example. One assumes solution regularity for the Stokes problem (2.5), specifically that  $\mathbf{u} \in W^{2,\kappa}(\Lambda_{s_h}; \mathbb{R}^3)$  and  $p \in W^{1,\kappa'}(\Lambda_{s_h})$  for some  $\kappa \in [p, 2]$ . The mixed FE method for (2.5) is assumed to satisfy Bramble-Hilbert type interpolation bounds in  $W^{1,\kappa}(\Lambda_{s_h})$  and  $L^{\kappa'}(\Lambda_{s_h})$  for the discrete velocity and pressure spaces, respectively; see [28, inequalities (4.26), (4.27)]. Finally one assumes that the mixed FE method satisfies a discrete inf-sup condition [28, equation (4.1)]. One then concludes that

$$(7.11) \quad \|\mathbf{u}_h - \mathbf{u}\|_{\mathcal{V}} \leq Ch^{\kappa/2}$$

for a constant  $C > 0$  which depends on the regularity norms of  $\mathbf{u}, p$ , the discrete inf-sup constant, and the domain  $\Lambda_{s_h}$ . To apply such a technique to VI problem (3.23), via Theorem 7.2, one would at least need to prove two bounds. First, one would need a bound showing the regularity of the solution  $\mathbf{u}, p$  of (2.5), over the domain  $\Lambda_{s_h}$ , when  $s_h \in \mathcal{X}_h \subset W^{1,r}(\Omega)$ ; this extends Conjecture A. Second, seemingly more difficult and not remotely attempted here, one must bound how the constant in (7.11) depends on the properties of  $\Lambda_{s_h}$ .

One might also try to bound term 3 in (7.6) via estimates for FE interpolation. From [12, Theorem 3.1.6], for example, if  $\mu \in [r, +\infty]$  then there is  $C > 0$ , depending only on the finite element family for  $\mathcal{X}_h$ , so that for all  $r \in W^{2,\mu}(\Omega)$ ,

$$(7.12) \quad \|\pi_h(r) - r\|_{\mathcal{X}} \leq Ch|\Omega|^{(1/r)-(1/\mu)} \|r\|_{W^{2,\mu}}.$$

Here  $\pi_h$  is the ordinary interpolation into  $\mathcal{X}_h$ , not including truncation into  $\mathcal{K}_h$  as with operation (7.3). For simplicity suppose we somehow arrange that  $\mathcal{K}_h = \mathcal{K}$ , thus

that  $\Pi_h = \pi_h$ . Now suppose that the exact solution  $s \in \mathcal{K}$  of VI problem (3.23) also satisfies  $s \in W^{2,\mu}(\Omega)$  for some  $\mu \in [r, +\infty]$ . Then it follows that term 3 in (7.6) is  $O(h)$  with a coefficient that depends on the  $W^{2,\mu}$  norm of  $s$ . (Compare the argument for [26, Theorem 4.3], which makes a comparably strong regularity assumption for a power of the thickness function, but in an SIA problem.)

However, the sketch in the previous paragraph is a fantasy. The hypothesis that  $s \in W^{2,\mu}(\Omega)$  is too strong even if the data  $a, b$  entering into VI problem (3.23) are arbitrarily smooth. It is true that in classical obstacle problems the solution is generically tangential along the free boundary, which permits such regularity [30, Chapter IV]. However a glacier's surface gradient need not approach the bed gradient at points along the ice margin (Subsection 4.3). While  $s \in \mathcal{X} = W^{1,r}(\Omega)$  is credible,  $s \in W^{2,\mu}(\Omega)$  is not, which means that such direct use of interpolation theory to prove convergence is unlikely to work.

**8. Discussion and conclusion.** The major result of this paper is Theorem 7.2, which bounds the numerical surface elevation error when a glacier is modeled using non-shallow Stokes dynamics. The bound, inequality (7.6), only estimates the FE error made in a single implicit time step, namely VI problem (3.23). The first two terms in the bound can be reduced by improving bed elevation interpolation, and by solving the Stokes problem more accurately, respectively. However, the surface elevation solution to (3.23) must be expected to have low regularity, especially across the ice margin (free boundary). Near-margin mesh refinement may be the only technique which reduces the FE interpolation/truncation error in the surface elevation, which is the third and final term in the bound.

However, the results here leave us far from an FE convergence proof for the main time-evolution problem of glaciology. This problem is written in the Introduction; it combines NCP (1.3) coupled with the Stokes problem (1.5)–(1.6). It is a parabolic VI [20], on which analysis is generally more difficult than for the (roughly) elliptic single-step VI problem (3.23). Turning Theorem 7.2 into a convergence proof would therefore be a major step requiring a significantly-extended theory; see the end of Section 7.

Neither do we have a proof of the well-posedness of the continuous-space, implicit-step problem (3.23) itself. Much of the current paper is devoted to conjecturing such well-posedness (Sections 3–5). The abstract FE bound in Theorem 6.3 applies to problem (3.23) because of Theorem 4.1, an immediate consequence of Conjectures A and B. Our attempt at least clarifies which properties of the surface motion part of the surface kinematical equation—actually an NCP or VI problem—need to hold if we seek such well-posed time steps in a non-shallow glacier model.

The root of the matter is coercivity of this surface motion, namely Conjecture B. A strategy for proving this Conjecture is not clear to this author. A weaker version of the Conjecture comes from setting  $r = s + \epsilon\phi$  for  $\phi$  supported where  $s > b$ . That is, one would consider admissible perturbations of the glacier surface which do not move the glacier margin. This may be easier to prove, but it is not sufficient for Theorem 4.1, and it does not address the marginal shape and overhang issues discussed in Section 4. On the other hand, one might modify or regularize the operator definition (3.22) in some manner, e.g. by adding an elliptic regularization. Our numerical evidence for coercivity of the existing operator, from a very basic numerical approach, is quite weak (Section 5), but in a regularized model the near-margin numerical approximation might be easier.
