(Dated: August 15, 2024)

When the detection threshold in semiconductor detectors is pushed to increasingly low energies, an "excess" signal of apparent energy release events below a few hundred eV is observed in several different kinds of detectors, hindering their sensitivity for rare event signals in this energy range. Using atomistic simulations with classical thermostat and quantum thermal bath, we show that this kind of signal is consistent with energy release from long-term recombination events of complex defects that can be formed by any kind of nuclear recoil radiation events. The recombination events are shown to have a very similar exponential dependence of energy as that observed in experiments. By detailed analysis of recombination events, we show that crossing a low energy barrier ($\leq 0.1 \text{ eV}$) can trigger larger energy releases in an avalanche-like effect. This explains why large energy release events can occur even down to cryogenic temperatures.

I. INTRODUCTION

One possible approach to detect light particle dark matter is by looking for low-energy recoil events in materials that cannot be attributed to conventional matter radiation events [1–3]. Similar methods are also used in coherent neutrino nucleus scattering experiments [4, 5]. This has motivated development of new detector technologies with lower and lower detection threshold.

When the detection threshold in semiconductor detectors has been pushed to increasingly low energies, an "excess" signal of apparent energy release events below a few hundred eV is observed in several different kinds of detectors [6–17]. This excess will mask any potential dark matter signal, and therefore understanding its origin and possible ways to mitigate it are questions of utmost importance. Several different explanations have been offered to this excess, for instance electronic noise [18], stress effects/crack relaxation [19, 20] or solid state effects [21]. However, some recent experiments disfavor an explanation due to external stress or radiation [22]. It seems plausible that there are several components and several different causes of the excess events.

Although there are thus many uncertainties regarding the origin of the effect, on a general level we note that the excess signal is observed in detectors consisting of different materials, manufacturing techniques and different electronics with a very similar exponential energy dependence $\propto \exp(-\alpha E)$, where $\alpha > 0$ is aconstant. This suggests that there may be an inherent mechanism for the observed excess signal (consistent with the evidence for a solid state effects [21]).

In this Article, we analyze the possibility that the excess signal could originate from recombination of nanometer-size range defect clusters. It is well established from both experiments [23–26] and simulations [27–31] that keV recoils in semiconductor materials such as Si produce small disordered zones in the material. Even if the material is not irradiated explicitly, cosmic rays or decay of radioactive impurities that are always present at some concentration in a material and its immediate surrounding environment will produce similar damage pockets. Even if the initial kinetic energy of a radioactive decay event may be in the MeV range, the final damage will be produced by \sim keV recoils, since collision cascades at much higher energies split up into subcascades [28, 32, 33].

The nanometric damage regimes produced in such events are higher in potential energy than the pristine crystal structure, and hence are expected to thermally recombine towards the ground state at a time scale depending on temperature. Any recombination event will thus be associated with an energy release. While there have been previous works analyzing the recombination of radiation-induced disordered regions [27, 29, 34, 35], these have not systematically analyzed the energy distribution of the potential energy release events at cryogenic temperatures. In this article, we analyze this energy release systematically, and show that it leads to recombination events with an exponential energy dependence, very similar to that found in experiments.

II. METHODS

To examine the production of disordered damage zones and their possible energy release on extended time scales, we used a five-stage simulation and analysis procedure: (i) simulation of typical radiation damage creation, (ii) simulation of thermal annealing of this damage on long time scales, (iii) quenching of configurations to 0 K to obtain potential energy release without effects from kinetic energy fluctuations, (iv) obtaining the energy release in recombination events from the time dependence of the potential energy in stage (iii), and (v) analysis of the time scale of annealing. These results are presented in section III. Since at cryogenic temperatures quantum mechanical zero point vibrations can affect atom dynamics, we also employed a quantum thermal bath (QTB) [36, 37] to assess how quantum effects affect the annealing. Results of these simulations are included along with the fully classical ones in the results, and discussed in section IIB. Finally, to understand why annealing is observed even at cryogenic temperatures, we also analyzed what kind of atomic movements in individual recombination events lead to energy release (section IV).

A. Simulation and analysis stages

In all simulation stages (i-v), we used classical molecular dynamics [38]. Simulations were carried out mainly with the code PARCAS [39]. This code has been extensively used to examine radiation effects in a wide range of materials, and the results have been shown to agree well with experiments in many different measurable quantities [28, 40–44]. Some classical cases were also modelled with the widely used LAMMPS molecular dynamics code [45] and gave the same behaviour as the PARCAS results. The simulations with quantum thermal bath were all done with the LAMMPS codes; details on the specific quantum aspects of the modelling are given in subsection IIB. The analysis of annealing mechanisms in section IV were done with the LAMMPS code since this code has a built-in nudged elastic band (NEB) [46] feature that could be used in analyzing the energy barriers.

The interatomic interactions were described with the Stillinger-Weber potential [47], that has been found to describe well a wide range of properties in Si when compared to experiments [48, 49], DFT calculations [31] and modern machine-learned potentials [49]. We also tested the Tersoff III potential [50], which gave very similar results regarding the energy release. In the following parts of the paper, unless otherwise mentioned the results shown are obtained with the Stillinger-Weber potential.

In stage (i), we simulated the production of damage by recoil events in Si by simulating 5 keV cascades induced by self-recoils in bulk silicon. The energy of 5 keV is above the energy at which cascades break into subcascade in Si, i.e. the specific damage pockets produced by higher energy recoils are similar to those produced by 5

keV ones [28, 51]. The cascades were modelled following standard approaches [28, 52]. Briefly, the cascades were initiated in random directions in 3 dimensions with equal weighting of different directions by solid angle and the development of the cascade was simulated until the system cooled down back to the ambient temperature (0 K in the cascade phase). No temperature or pressure scaling was used in the collisional regions, and heat was removed at the system boundaries. Since in the current work, the emphasis is energy release from damage rather than the production process itself, we did not include the electronic stopping power [53] in the simulations. The simulation cell consisted of a cube with 16 unit cells in each dimension (i.e., a total of 32768 atoms) and periodic boundaries were used in all dimensions. This cell size was slightly smaller than what was normally used in cascade simulation, due to the necessity to be able to simulate annealing over long time scales. To ensure that no thermally induced annealing occurs in these damage generation events, the ambient temperature of the system was 0 K.

In stage (ii), the damage produced in 5 keV cascades was annealed in thermal equilibrium runs over long time scales. In most cases we used 3 ns as the annealing time, but we tested annealing time up to 30 ns. The annealing runs were done for temperatures in the range of 0.05 - 800 K. To enable analysis of damage recombination events that can occur quite rapidly, the atom coordinates of all atoms were output every 2 ps throughout the entire simulation. In the annealing runs, Berendsen temperature control was used on all atoms with a time constant $\tau_T = 300$ fs and pressure control to 0 pressure with a time constant of $\tau_P = 3000$ fs.

In stage (iii), the atom coordinates output from the annealing run were extracted every 2 ps, each one separately, as input coordinates for quenching. The quenching simulations were performed efficiently using Berendsen temperature control [54] towards 0 K while zeroing the velocity of any atom *i* on which the force vector $\vec{F_i}$ was in opposite direction to the velocity vector $\vec{v_i}$, i.e. if $\vec{F_i} \cdot \vec{v_i} < 0$. Using this efficient approach, a quenching time of 1 ps was enough to get the system temperature down below 0.01 K. The quenching was done every time when the atom coordinates were output in the 3 ns (or longer) annealing runs, and the final potential energy was recorded after quenching.

In stage (iv), the potential energy vs. time in stage (iii) was analyzed with respect to energy release. After quenching to 0 K, the energy release events were found to be clearly distinct from minor random fluctuations in potential energy that was < 0.5 eV. To get the total energy release from one recombination event, when energy release > 0.5 eV occurred on subsequent 2 ps time intervals, the energy was summed up as the total release in the same event. Subsequently a statistics of the magnitude of energy release was made. This can be compared with the experimental observations of energy release.

In stage (v), the annealing time scale was analyzed

by fitting a stochastic time scale law to the data on the time dependence of annealing obtained from molecular dynamics. This allowed us to quantitatively show that annealing of amorphous pockets can occur even at extremely low temperatures relevant for superconducting transition detectors.

For defect analysis, the number of defects in the simulation cells was quantified with the Wigner-Seitz (WS) method [28], which is a geometric method completely independent of the potential energy analysis. This measure is used to quantify the number of defects because its definition has no adjustable parameters, and it gives defect numbers roughly consistent with the simple Kinchin-Pease damage prediction in Si [28, 52]. However, considering the complex nature of the damage pockets in Fig. 2, it is clear that in Si "the number of WS defects" does not correspond to any geometrically simple point defect type such as an isolated vacancy or interstitial. Hence we use the term "the number of WS defect pairs" as the notation of this defect measure.

B. Quantum thermal bath simulations

To assess how significant quantum mechanical zero point vibrations [55] are on the annealing time scale and mechanisms, we employed the quantum thermal bath (QTB) approach [36, 37] as implemented in LAMMPS. This QTB thermostat is a Langevin-style thermostat with a specially tuned noise term that agrees with the energy spectrum of quantized vibrations in crystals. This thermostat does not cause significant extra computational cost compared with standard molecular dynamics, which is a great advantage compared with other methods, for instance, path integral molecular dynamics[56].

The equation of motion is a Langevin style formula, where f(x) is interatomic force, γ is the damping constant and Θ is the noise term:

$$\ddot{x} = f(x) + \sqrt{2m\gamma}\Theta(t) - m\gamma\dot{x} \tag{1}$$

The power spectral density of the noise term Θ is:

$$\Theta(\omega) = \hbar \omega \left[\frac{1}{2} + \frac{1}{\exp\left(\frac{\hbar \omega}{k_B T}\right) - 1} \right]$$
(2)

In the implementation we use [37], the quantum thermal bath has five input parameters, namely, target quantum temperature, damping parameter, a random seed, upper cutoff frequency and the number of frequency bins. To make the results comparable with the classical molecular dynamics simulations, we set the damping parameter to be 0.3 ps (300 fs), the same one used in the purely classical simulations. The upper cutoff frequency was set to be three times the Debye frequency of silicon. The number of frequency bins was 100 in all QTB simulations. When using the thermostat, a Berendsen barostat

FIG. 1. Heat capacity of silicon crystal

with the settings in section II A was also applied to the system.

To check whether these settings enable the compensation of low temperature quantum effect, the heat capacity of pure silicon crystal was calculated by differentiating the mean total energy with respect to temperature, and the result was compared with experiment [57]. The heat capacity curve shown in Fig. 1 demonstrates that QTB thermostat can reproduce the temperature dependence of heat capacity at low temperatures.

With the help of quantum thermal bath, the annealing behavior of the system at very low temperatures can be investigated directly. The five-stage simulation and analysis procedure in section II A was followed, and quantum thermal bath was used in stage(ii) for the annealing simulations.

III. RESULTS AND DISCUSSION

A. Stage (i) Damage production in cascade simulations

An example of a cascade event and the damage produced is shown in a cross-sectional plot in Fig.2. The cross-section shows a very typical damage production event, analyzed in detail in many previous works [28, 52, 58]. As noted above, 5 keV is above the subcascade threshold breakdown, so the damage is split into separate damage production regions. 1000 different 5 keV cascades were simulated, and the final atom coordinates from these were used for annealing runs, quenching and energy release analysis.

B. Stage (ii) Annealing simulations

For the classical molecular dynamics simulations, annealing simulations were performed at several temper-

FIG. 2. Cross-sectional view of the damage produced in a 5 keV cascade in Si, as modelled with the Stillinger-Weber potential. The top part shows the evolution of the cascade, and the larger frame at the bottom the final damage state at 10 ps. This cascade was ran at 0 K ambient temperature to ensure there is no thermal annealing. The precise size of the plotted simulation cell region is 81.2 Å in the x (horizontal), 71.3 Å in the y (vertical) and 10.86 Å in the z (out of plane) direction. The colors indicate the potential energy $E_{\rm pot}$ of the atoms relative to the ground state energy $E_{\rm pot,0}$

atures in the range 20 - 800 K for some of the cells, and at 200 K for all the cells. For the Tersoff potential, annealing was done at 300 K for all the cells (since the Tersoff potential has a higher melting point than the Stillinger-Weber and experimental one, 300 K corresponds to roughly the same homologous temperature as 200 K for the Stillinger-Weber potential). For simulations with QTB thermostat, the annealing simulations of 10 ns were conducted at 0.05 K, 10 K, 25 K, 50 K, 100 K, 150 K, 200 K and 300 K. At each temperature,

4

at least 200 annealing simulations with different initial damage were carried out.

Results for the number of defects in the cell as a function of time are shown in Fig. 3 a) for a test 600 K annealing run via classical molecular dynamics. The potential energy has huge fluctuations because a thermodynamic system with a small number of atoms N has natural fluctuations of the kinetic energy around the average of the order of \sqrt{N}/N [59]. Since the total energy remains the same on short time scales, the fluctuations in kinetic energy are also reflected in the potential energy. The fluctations make it very difficult to obtain a quantitative analysis of the potential energy release in a single recombination event. This was the reason why we took into use the quenching scheme to get rid of thermal fluctuations.

C. Stage (iii) Quenching runs

Results of the potential energy and number of WS defect pairs after the quenching scheme (see section II) are shown in Fig. 3 b), for the exact same annealing run as shown in part 3 a). This graph shows much clearer that after the first about 10 ps, the annealing proceeds stepwise, with clear energy release events occuring every now and then, separated by (on the atomic scale) long times when essentially nothing else than thermal vibrations of atoms around their stable or metastable local equilibrium positions happen in the system. The energy releases also correlate very well with decreases of the number of Wigner-Seitz defects, confirming that the potential energy release is indeed associated with partial annealing of damage in the amorphous pockets.

From the potential energy release, one can also obtain the magnitude of the energy released in each annealing event by comparing the total potential energy of the system (after quenching) before and after each 2 ps annealing interval. This is shown in Fig. 3 c) for the same annealing run as in parts a) and b). The graph shows that the energy release varies from an annealing event to another.

We ran similar annealing runs for a few cascades in the temperature range 20 - 800 K. Results for an exemplary case in Fig. 4 show that, as expected, at the highest temperatures efficient annealing of the damage is observed. This is in agreement with the experimental observations that Si cannot be amorphized above about 600 K [60].

However, we also observe that even at the much lower temperatures, down to 100 K, damage recombination is observed throughout the 3 ns simulations. Also in the test 30 ns simulations, recombination events kept occurring throughout the entire simulation time: an example of recombination occurring around 15 ns after the cascade event at 100 K is seen in the inset of Fig. 3 c). We note that Beland and Mousseau have earlier, at 300 K with a hybrid molecular dynamics/barrier search approach, observed annealing events on macrosopic, up to

FIG. 3. a) Annealing of damage produced in a single 5 keV cascade in Si at 600 K. The data shows that both the average potential energy and number of Wigner-Seitz defect pairs decreases with time. b) Same as a) but analyzed after each time step was quenched to 0 K. The inset shows the atomic positions in one disordered pocket before and after the annealing event occurring at t = 1.236 ns. c) Potential energy release per 2 ps intervals from the same cascade. The inset shows that annealing at well-separated times keep occurring also at longer times and even at the cryogenic temperature of 100 K.

FIG. 4. Annealing of damage produced in a single 5 keV cascade in Si at different temperatures. The data shows that both the average potential energy and number of Wigner-Seitz defect pairs decreases with time at all the considered temperatures.

1 s, time scales [35]. Occasional recombination events are observed in the 50 and 20 K simulations even in the classical simulations with no quantum thermal vibrations. An explanation to this surprising observation is given in section IV.

D. Stage (iv) Statistics of energy release

To enable a comparison with the experimental observations of the energy dependence of the low-energy excess, we made a statistics of the annealing data similar to that shown in Fig. 4 but summing up all events over at least 50 independent cases (separate cascades) to obtain a statistically better picture of the annealing.

Since the main aim of the current work is to compare the results with the experimentally observed exponential low-energy excess signal, we plot the results with a logarithmic y axis vs. linear x axis for the energy.

For classical molecular dynamics simulations the results for the temperatures 100 - 500 K are shown in Fig. 5 (a). Also included in this plot are results obtained with the Tersoff interatomic potential at 300 K. The results show that, remarkably, the energy release statistics is independent of temperature in the range 100 - 500 K within the statistical uncertainty. This gives high confidence that also lower temperatures would show a similar dependence with energy. Moreover, the Tersoff interatomic potential gives results practically identical to those of the Stillinger-Weber potential. Since the Tersoff and Stillinger-Weber potential are developed completely independent of each other, have different functional forms, and are fitted to different properties [47, 50], this gives high confidence that the obtained results are not an interatomic potential artifact.

For simulations with QTB themostat, the results at various temperatures are shown in Fig. 5 (b). It is very clear that the energy release statistics is independent of temperature.

In both Fig. 5 (a) and Fig. 5 (b), the data are clearly close to linear on the log-lin plot, showing that the energy release statistics follows an exponential dependence with energy, in agreement with the experimental observations [6–15]. As expected from the linear dependence of the plots, the data can be fit very well with the functional form

$$f(E) = Ae^{-\alpha E} \tag{3}$$

where E is the energy release and A and α are fitting constants. The fits were done with the Levenberg-Marquardt approach for least square fitting of arbitrary functional forms [61, 62]. The same functional form has been used earlier to fit the low-energy tail of the experimentally observed energy releases [18, 63]. Results for the fits of the slope coefficient α are given in table I. Considering the statistical uncertainties, one can conclude that the slope of the energy release depends either very weakly or not at all on temperature.

The simulated and experimental data from a silicon detector are compared to each other in Fig. 6. The y axis scale is in arbitrary units, since in experiments the absolute values of the signal depends on factors such as detector size, detection efficiency, concentration of radioactive impurities creating the initial damage, and damage recoil spectrum, all of which are not fully well known. However, the functional dependence of the signal on energy can be used for a direct comparison between simulation and experiments. The figure shows a very good agreement: both the simulation and low-energy tail of the experimental data clearly follows an exponential trend with a very similar slope. The slope obtained from a fit to the simulation data at 0.05 K (QTB thermostat) was $\alpha_{\rm sim} = 0.58 \pm 0.05$ 1/eV, which is in perfect agreement with a fit of the same exponential law to the low-energy tail of the experimental data citeHei22 $\alpha_{exp} = 0.57 \pm 0.01$ 1/eV (to enable direct comparison, this value was obtained by fitting the experimental data with the same software as used to fit the simulated ones). We emphasize that no fitting of the simulations to the experiments has been used for obtaining this outstanding agreement.

E. Stage (v) Analysis of annealing time scales

We finally analyze the time dependence of the annealing events such as those shown in Fig. 3 and 4. To be able to roughly estimate the annealing time scales as a function of temperature and extrapolate to even lower temperatures, we analyzed the time dependence of the annealing curves.

Since the number of disordered pockets in a single event is small, the annealing curves of single events have huge statistical fluctuations. This is illustrated in Fig.

FIG. 5. Statistics of the magnitude of the energy release events during annealing runs at different temperatures. To enable easy comparison of the slopes, the curves at different temperatures have been scaled to 1 at 1 eV. a) Classical molecular dynamics, b) Molecular dynamics with quantum thermal bath

7. To obtain a statistically reliable analysis, we carried out an analysis of at least 200 different cascade events in the temperature range 0.05 - 300 K. To be able to compare cases with different numbers of initial defects and stored energy in them, the analysis was done for the average relative fraction of potential energy remaining at time t compared to the initial potential energy at t = 0. The fraction f was calculated for each cascade event separately before averaging. The results of the averaged fraction analysis are shown in Fig. 8. As expected, time evolution of the fraction of remaining Wigner-Seitz defects showed a similar behaviour.

The averaged annealing curves show that the annealing behaviour can be divided in two stages: a rapid annealing occurring roughly during the first 0.5 ns after the damage event, and a subsequent much slower annealing after this.

FIG. 6. Comparison of the energy dependence of energy release events with experiments. Note that the red line is a fit of an exponential form to the simulation data only, showing that the slope of the low-energy signal from simulations agrees excellently with experiments. The experimental data is from Ref. [64].

	10	Qtb.	0.50 ± 0.06
	0.05	Qtb.	0.58 ± 0.05
Experiment	0.04	-	0.57 ± 0.01

The first stage clearly is due to recombination of the most metastable defects, whereas the later recombination is an average over occasional well-separated recombination events (corresponding to the late energy release events shown in Fig. 3).

By comparing the individual cases shown in Fig. 7, an additional important point is illustrated: the damage in some events (those with large damage pockets) can anneal much slower than the average release. On long time scales, annealing from such cases would dominate the residual recovery signal.

FIG. 7. Annealing of damage produced on average in several 5 keV cascades in Si at 200 K plotted in terms of the fraction of Wigner-Seitz defects compared to the initial state in 7 individual cases (shades of gray) and the average over 50 cases (red). Not All individual cases are shown since it is difficult to read fifty shades of gray.

FIG. 8. Average potential energy curves after quenching (with quantum thermal bath). The values are rescaled so that the initial value is one. In this way, the curves show the relative amount of excessive potential energy.

The curves in Fig. 8 were fitted against the exponential function $A \exp(-t/\tau)$. In the fitting practice, the initial 1 ns in the potential energy curves was truncated, and the rest of the curves were fitted. The fitting results and the comparison with the results from purely classical annealing are shown in Fig. 9 and table II.

From these results, it is very clear that the low temperature quantum effect can facilitate annealing significantly. The simulation at 0.05 K with QTB thermostat shows that the annealing time parameter τ has a magni-

FIG. 9. Fit of annealing time parameter.

tude of microseconds at the operation temperature of the detectors. The fact that at 10 K and 0.05 K time constants are almost the same indicates that at temperatures $\lesssim 10$ K, the triggering of annealing effects is dominated by the quantum effect.

The exponential decay of annealing effects could be detectable if the time resolution of the experiments is shorter than the time constants τ . Conversely, in case the time resolution is much longer than this, the energy release events would seem to appear at random times with average constant rate (that would be determined by the concentration of radioactive impurities that produce the initial damage).

IV. AVALANCHE MECHANISM OF LOW-TEMPERATURE ANNEALING

The observation described in subsection IIIC of annealing occuring at cryogenic temperatures may seem surprising, as the temperature of 100 K corresponds to only roughly 0.01 eV/atom, much lower than the chemical bond energy of roughly 2 eV/bond. It is also not consistent with the traditional picture of radiation damage annealing being described to be caused by point defect migration with well-defined migration barriers.

However, the result can qualitatively be understood as follows. The complex disordered damage pockets (cf. Fig. 2) will inadvertently have metastable bonds with a much lower energy barrier to recombination. Furthermore, once a metastable bond recombines towards the ground state energy, it can induce a localized recombination "chain reaction": one bond starts annealing, then the released energy heats up the sample locally which can induce additional bond recombination. To illustrate this argument with a rough calculation, even a low energy release of 2 eV of one recombining bond corresponds to a transient heating of the nearest ten atoms by about 1000 K. To quantify this deduction, we now analyze in atomic-level detail what kind of mechanisms can lead to the energy releases of several eV's even when the temperature is so low that thermal activation cannot possibly lead to crossing an energy barrier in the eV range.

To do the analysis, some of the the 2 ps intervals where energy release events took place were picked out. Annealing simulations were restarted at the beginning of these intervals, and atomic information was recorded every 10 fs. The atomic configuration extracted every 10 fs became the input for quenching. Quenching was performed in the same way as before (Section II) to find out energy minima along the reaction path. Finally, transition state search by NEB method was carried out between neighboring energy minima to find out the energy barriers.

Fig. 10 and Fig. 11 shows two energy release events whose energy release are larger than 8 eV, taking place at 0.05 K (QTB thermostat). In Fig. 10 and Fig. 11, (c)(d)(e)(f) shows the atomic motion. Both of the events go through multiple steps of energy drops, instead of releasing all energy at once. From Fig. 10 (b) and Fig. 11 (b) we see that the energy barriers of the fundamental steps are lower than 0.1 eV, making it possible for the energy releases to take place at very low temperatures. Moreover, both events involve the migration of several atoms, not just one or two of them.

The results show that at cryogenic temperature, all energy barriers for annealing are very small, and most, if not all of them, are below 0.1 eV. If a metastable configuration overcomes a small energy barrier at first, additional atom rearrangement nearby can be triggered, and much more energy can be released, which can be viewed as an "avalanche" effect. In other words, the effect is a variety of self-organized critical phenomena, well known e.g to explain dynamics in sandpiles [65, 66].

FIG. 10. An example of the energy barriers in an individual annealing event. In this case the total energy release was 10.24 eV. In (c)(d)(e)(f), the color coding is atomic displacement.

Since the primary radiation damage event will lead to a multitude of complex damage configurations, there is no minimum temperature at which annealing can occur, as there will be barriers of all height present. Therefore, energy release avalanches can be triggered at any temperature.

V. DISCUSSION AND CONCLUSION

The main result of this paper is that recombination of damage produced by radioactive events can cause energy release on very long time scales after the damage production, even at cryogenic temperatures. The simulations in this work were done on silicon, but considering that it is known that other covalently bonded semicon-

FIG. 11. An example of the energy barriers in an individual annealing event. In this case the total energy release was 8.92 eV. In (c)(d)(e)(f), the color coding is atomic displacement.

ductor materials such as Ge and GaAs produce damage in very similar (and even larger) damage pockets as Si [23, 24, 67, 68], it is very likely that very similar behavior would occur in also other covalently bonded semiconductors.

Many ionic materials also undergo amorphization [69–71], and hence a similar mechanisms might be active in at least some of them. Elemental metals do not amorphize

[72], however, metastable damage pockets can be formed in them in the form of ordered damage clusters (e.g. C15 structure) and dislocation loops [73–76]. However, separate simulation work with appropriate interatomic interaction models for ionic and metallic materials would be needed to deduce whether energy release from such structures would have a similar energy dependence.

The effect described in this paper has a time depen-

dence on the ns to tens of nanoseconds time scale. Most experiments observing the low-energy excess have not reported such time dependence. This is most likely because their time resolution is large (of the order of ms). Hence if there is sufficient amounts of radioactive impurities or any other damage sources in the sample that numerous decays occur in the detector within the time resolution, the average signal on the long time scales would appear constant, as the detector effectively sums up multiple events. On the other hand, we do note that the predicted exponential time dependence of the energy release events on time scales of tens of nanoseconds at room temperature might be experimentally testable with time-resolved pulsed ion beam experiments [77, 78] and sufficiently fast detectors.

Moreover, as we have shown earlier, a dark matter signal could have a distinct daily variation [3, 79, 80], which the excess signals from radioactive decays would not have.

In conclusion, using molecular dynamics simulations of radiation events and their annealing in silicon, we have shown that even at cryogenic temperatures, energy release events of up to 10's of electron volts can be caused by random annealing of complex disordered

atom pockets. We show that the recombination can occur by avalanche-like events, where a metastable defect configuration first crosses an energy barrier of about 0.1eV. Crossing this kind of small barrier can then trigger a rapid additional bond recombinations, that lead to partial recrystallization and energy releases exceeding 10 eV. This explains why large energy release events can occur even down to cryogenic temperatures. These events occur randomly up to macrosopic time scales after the initial picosecond time scale radiation event. Hence, in a sensitive detector they could be caused by annealing of damage produced e.g. by decay of radioactive impurities either in the detector itself or in materials surrounding it. These energy release events have an exponential energy dependence that agrees very well with the experimentally observed low-energy excess energy release in semiconductor detectors.

ACKOWLEDGEMENTS

Grants of computer time from the Finnish IT Center for Science in Espoo, Finland, and the financial support from the Research Council of Finland (grant# 342777) are gratefully acknowledged.
