(Dated: August 26, 2024)

We investigate the role of hyperfine structure in resonant-dipole interactions between two atoms co-trapped in an optical tweezer. Two-body loss rates from light-assisted collisions (LACs) are measured across the ⁸⁷Rb hyperfine spectrum and connected to properties of molecular photoassociation potentials via a semi-classical model. To obtain our results, we introduce an imaging technique that leverages repulsive LACs to detect two atoms in a trap, thereby circumventing parity constraints in tweezers. Our findings offer key insights for exploiting hyperfine structure in laser-induced collisions to control cold atoms and molecules in a broad range of quantum science applications.

Optical tweezers have emerged as a leading platform for controllable many-atom systems, enabling state-of-the-art applications in quantum information and metrology [1–4]. An underlying aspect of control within these systems is the process of light-assisted collisions (LACs), wherein two colliding atoms absorb a photon to form a quasi-molecular state [5]. At large detunings (1–100 GHz), LACs have been used for bound-state molecular photoassociation [6–9] and direct laser cooling to a Bose-Einstein condensate [10]. At smaller detunings, LACs are routinely harnessed for sub-Poissonian loading of tweezers [11–14] and parity imaging in quantum-gas microscopes [15]. Despite their central role in the latter regime, where hyperfine structure and spontaneous emission introduce new complexities [16], accurate predictions of quantitative LAC behavior remain elusive.

The LAC process is defined by the excitation of atom pairs from an $S + S$ to $S + P$ electronic state at a resonant internuclear distance R_C (Condon radius). For homonuclear systems, the $S + P$ resonant dipole interaction yields $1/R^3$ attractive or repulsive potentials where the amplitude and sign is determined by molecular symmetries [5]. Effects from fine and hyperfine interactions, which become important at large and small detunings respectively, introduce additional symmetries that create a multitude of interaction potentials. Atom pairs experiencing an $S + P$ potential can gain kinetic energy during an inelastic LAC before spontaneously decaying back to the $S + S$ ground state (Fig. 1), resulting in loss if the final kinetic energy of the atom(s) exceeds the trap depth.

Two-body losses from LACs were initially studied by measuring the fluorescence decay of an atomic ensemble in a magneto-optical trap (MOT) [17–20]. While this method provides valuable insight, the large atom number and limited variability of the MOT beams prevents the study of isolated two-body dynamics over a wide range of collisional light properties. More recent experiments using optical tweezers avoid these constraints, but have focused primarily on single-atom collisional losses that can enable loading probabilities as high as 96% [11, 21–25]. In both cases, however, the overall role of hyperfine structure is difficult to discern. A direct comparison between loss rates across multiple transitions, both

red- and blue-detuned from resonance, is needed to distinguish the contribution of hyperfine interactions from competing effects in LACs. Such insights could enable precision control over laser-induced collisions in a variety of cold-atom experiments, and help identify atomic or molecular species for AMO-based quantum technologies.

In this Letter, we elucidate the influence of hyperfine-resolved molecular states in resonant dipole interactions by measuring LAC-induced two-body loss rates over the hyperfine spectrum of ⁸⁷Rb for exactly two atoms co-trapped in an optical tweezer. To obtain our results, we introduce a collision-mediated diatomic imaging technique that exploits repulsive LACs to convert two atoms into one. This method circumvents two-atom loss due to collisional blockade effects during fluorescence imaging, which typically precludes differentiation between zero and two atoms [26]. Finally, a model that incorporates molecular photoassociation potentials [27] and the Landau-Zener formalism [28] is used to understand the role of molecular state density and interaction strength in shaping the observed loss-rate spectrum.

FIG. 1. Light-assisted collision process on the D1 line of ⁸⁷Rb. Atoms are excited from $S + S$ to $S + P$ at an internuclear distance R_C , which is resonant with a photon detuned by Δ from the free-space transition frequency ω_0 . Hyperfine-resolved molecular potentials (grey lines) are shown with example repulsive (blue) and attractive (red) potentials. Atoms traversing the potential (dashed red or blue arrows) can gain kinetic energy before spontaneously decaying to $S + S$.

Our experimental procedure [Fig. 2(a)] uses a 1×3 array of optical tweezers, each stochastically loaded with one ^{87}Rb atom. An initial image discriminates the traps containing an atom, allowing us to post-select instances when exactly two atoms are loaded. The atoms are adiabatically merged into a single trap (see Appendix A) where the LAC pulse is applied for a variable duration. A $2 \rightarrow 1$ pre-imaging pulse is then used to remove a single atom if both atoms survive the initial collision, in which case the remaining atom is cooled and detected through fluorescence imaging on an EMCCD camera. The occurrence (absence) of a $2 \rightarrow 0$ loss event is therefore indicated by the presence of zero (one) atoms in the final image.

Optical tweezers are generated with 852 nm light focused to a waist of $w_0 = 700$ nm. The LAC pulse is collimated to a waist of 1.4 mm and applied as a π -polarized running wave along the radial dimension of the tweezers with an intensity of $I = 1.2 \times I_{\text{sat}}^{\text{D1}}$ for D1 and $I = 1.3 \times I_{\text{sat}}^{\text{D2}}$ for D2, where $I_{\text{sat}}^{\text{D1}} = 4.5 \frac{\text{mW}}{\text{cm}^2}$ and $I_{\text{sat}}^{\text{D2}} = 2.5 \frac{\text{mW}}{\text{cm}^2}$ [29]. This intensity is chosen to saturate the two-body loss rate (see Appendix B), while the beam geometry (see Appendix E) is chosen to avoid polarization gradient cooling (PGC) or heating effects [30] that can significantly alter atomic density prior to a collision event. Atoms are cooled to an initial temperature of $T = 29(2)$ μK (measured via release and recapture [31]) and prepared in the $|5^2S_{1/2}, F=2\rangle$ state prior to merging into a single trap at a depth of $U/h = 10(1)$ MHz. Collisional light is then applied in conjunction with near-resonant D1 or D2 repump light at $I \approx 0.1I_{\text{sat}}$ to prevent population accumulation in $F=1$.

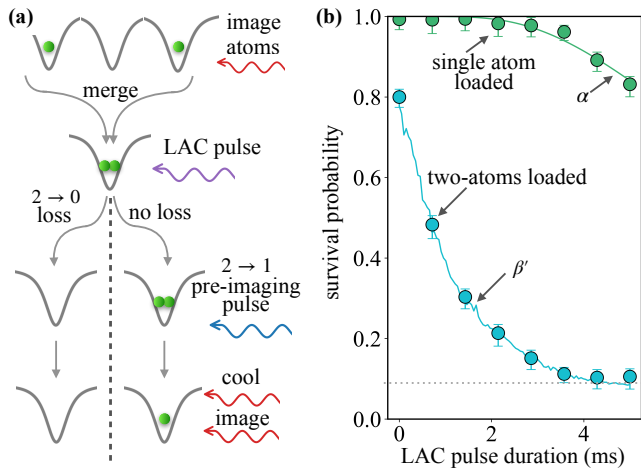

FIG. 2. (a) Experimental diagram for measuring two-body loss rates. An initial image is used to post-select instances when exactly two atoms are loaded. After merging atoms into a single tweezer, the LAC pulse is applied. The $2 \rightarrow 1$ pre-imaging pulse is then used to remove one of the two remaining atoms (if no loss occurred). (b) Example of post-selected two-atom (blue circles) and single-atom (green circles) survival probabilities with the corresponding two-body decay rate β' and single atom heating rate α . Here, collisional light is blue-detuned 100 MHz from the D2 $F = 2 \rightarrow F' = 3$ transition.

After the LAC pulse, the $2 \rightarrow 1$ pre-imaging pulse is focused through a 100 mm achromatic lens to a waist of $w_0 \approx 50$ μm and applied along the radial direction of the tweezer (magnetic fields are zeroed at the atom location). A maximum 80(6)% probability of converting two atoms into one atom ($P_{2 \rightarrow 1}$) is achieved at a trap depth of $U/h = 10$ MHz when using a 15 ms pulse and detuning $\Delta_{\text{D2}} = 12$ MHz blue of the light-shifted [32] $F = 2 \rightarrow F' = 3$ transition. Although D2 light is exclusively used in the experimental procedure, a similar value of $P_{2 \rightarrow 1}$ can be achieved using light that is 25 MHz blue-detuned of the D1 $F = 2 \rightarrow F' = 2$ transition. This high conversion probability, enabled by repulsive potentials that allow for control of the collisional energy gain, is not attainable on all hyperfine transitions. For instance, on the D1 $F = 2 \rightarrow F' = 1$ transition, we measure $P_{2 \rightarrow 1} \approx 20\%$. Figure 3(a) shows $P_{2 \rightarrow 1}$ versus detuning Δ from the D2 $F = 2 \rightarrow F' = 3$ (gold) and D1 $F = 2 \rightarrow F' = 2$ (blue) transitions for a pulse duration of 15 ms. Figure 3(b) shows $P_{2 \rightarrow 1}$ versus pulse duration at the D1 and D2 detunings mentioned above (note the non-zero value of $P_{2 \rightarrow 1}$ at zero pulse duration is due to $2 \rightarrow 1$ collisions from the imaging light). Data in both plots is obtained when using a beam intensity of $I \approx I_{\text{sat}}^{\text{D2}}/50$ for D2 and $I \approx I_{\text{sat}}^{\text{D1}}/5$ for D1. These values are empirically chosen to maximize $P_{2 \rightarrow 1}$, though the difference in intensity and detuning dependence between D1 and D2 is not well understood.

FIG. 3. (a) $2 \rightarrow 1$ collision probability as a function of detuning from the light-shifted ($U/h = 10$ MHz) resonance of the D1 $F = 2 \rightarrow F' = 2$ (blue) and D2 $F = 2 \rightarrow F' = 3$ (gold) transitions using a 15 ms pulse duration with $I \approx I_{\text{sat}}^{\text{D1}}/5$ for D1 and $I \approx I_{\text{sat}}^{\text{D2}}/50$ for D2. (b) $2 \rightarrow 1$ collision probability as a function of pulse duration for detunings of 25 MHz (D1) and 12 MHz (D2) (I and U same as above).

The two-body loss rate is defined as $\beta = \beta'VN(N-1)$ where $V = (4\pi k_b T / m\bar{\omega}^2)^{3/2}$ is the atomic volume with $\bar{\omega} = (\omega_r^2 \omega_a)^{1/3}$, and N is the number of atoms [33]. We measure β' by varying the collisional pulse duration and fitting the two-body decay profile with a Monte Carlo model (MC1) [21]. MC1 accounts for statistical contributions of the $2 \rightarrow 1$ pre-imaging pulse as well as single-atom heating rates that are measured via post-selection of data sets containing only one initial atom [Fig. 2(b)]. The 80(6)% upper limit of atom-pair survival probability is set by the $2 \rightarrow 1$ pre-imaging pulse, while the lower limit of 0.1-0.2 results from occasional $2 \rightarrow 1$ events driven by the LAC pulse or the imaging light. Both limits are ac-

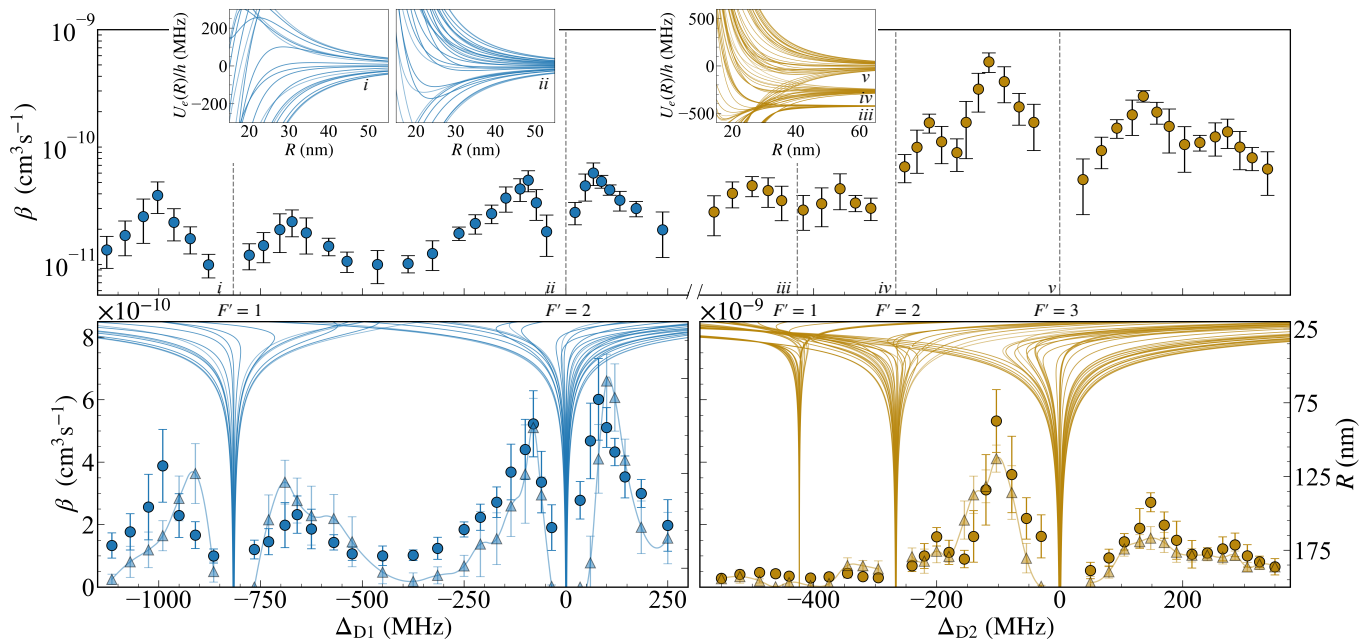

FIG. 4. Two-body loss rates on a log (top) and linear (bottom) scale as a function of collisional light detuning (Δ_{D1}, Δ_{D2}) from the light-shifted ($U/h = 10$ MHz) resonances (dashed vertical lines) of the $F = 2$ ground state to the hyperfine transitions ($i-v$) of the D1 (blue circles) and D2 (gold circles) lines of ^{87}Rb . Intensity is fixed at $I = 1.2 \times I_{\text{sat}}^{D1}$ for D1 and $I = 1.3 \times I_{\text{sat}}^{D2}$ for D2. The insets (top) and right vertical axis (bottom) show calculated hyperfine-resolved molecular potentials $U_e(R)$ as a function of internuclear distance R , which are used to generate the simulated loss probabilities (triangles) from our model MC2.

counted for in MC1, and found to be within the error bars in β' (see Appendix D). All experimental errors represent a $1 - \sigma$ equal-tailed Jeffrey's prior confidence interval [34] over 200 repetitions, approximately 75 of which contain exactly two atoms.

Figure 4 shows two-body loss rates on a logarithmic (top) and linear (bottom) scale as a function of the LAC pulse detuning (Δ_{D1}, Δ_{D2}) across the hyperfine transitions ($i-v$) of the D1 (blue circles) and D2 (gold circles) lines of ^{87}Rb (we omit the forbidden D2 $F = 2 \rightarrow F' = 0$ transition). The corresponding molecular photoassociation potentials $U_e(R)$ are calculated and plotted as a function of internuclear distance R , where each potential belongs to one of 14 molecular symmetries determined by the projection of total electronic and nuclear angular momentum along the internuclear axis [5]. To simplify our calculation, we ignore effects from rotation due to the small initial velocity of the atoms (≈ 0.5 cm/s) and large interatomic distances at which collisions occur [35].

Triangles in the bottom plot show simulated two-body loss probabilities from a Monte Carlo model (MC2) that simulates the trajectory of two atoms in a Gaussian potential, assuming a fixed temperature of $T = 29(2)$ μK . When atoms reach a Condon radius for a given detuning, the Landau-Zener transition probability $P_{LZ} = \exp(-2\pi\hbar\Omega^2/\alpha|v_{rel}|)$ is used to calculate the inelastic collision probability [28]. Here, Ω is the resonant electronic Rabi rate, v_{rel} is the relative velocity of the atoms along the internuclear axis, and $\alpha \approx |\partial[U_e(R)]/\partial R|_{R=R_C}$ is the slope parameter for any one of the 384 potentials.

If a collision occurs, we solve the classical equations of motion for a single atom experiencing the potential for the duration of the excited-state lifetime. The kinetic energy gain is then evenly distributed between the two atoms along the internuclear axis. If the final kinetic energy of each atom exceeds the trap depth, a two-body loss event is recorded (additional details are provided in the Supplemental Material [36]).

Modelling the hyperfine dependence of loss rates is complicated by unknown Rabi rates and excited-state lifetimes of potentials that conform to specific molecular symmetries, which may differ from those of the atomic dipole transition [37]. To address this, we treat Ω for each hyperfine transition as a free parameter, adjusting it to optimize agreement with experimental data. Values for Ω are listed in Ref. [36], along with the corresponding single-atom values for oscillator strengths, relative hyperfine intensities, and branching ratios [29, 38], all of which are included in MC2. To account for the difference in units between simulation and experiment, each loss probability is scaled by a uniform conversion constant that approximately aligns the scales of loss rates and loss probabilities assuming the atomic Rabi rate. While this limits the predictive capability of MC2 with respect to the absolute scale of Ω , the relative Rabi rates between transitions offer valuable insight into the role of molecular potentials in shaping the loss-rate spectrum.

The excited-state lifetime is randomly sampled from an exponential distribution corresponding to a decay rate of $\Gamma = 2\Gamma_a + \Gamma_s(\Delta)$, where Γ_a is the natural linewidth of the

atomic electronic dipole transition and $2\Gamma_a$ is the molecular linewidth [39]. The stimulated emission rate $\Gamma_s(\Delta)$ suppresses excited-state lifetimes near resonance where most models become unreliable and overestimate loss on attractive potentials [16]. This does not impact results for near-resonant blue detunings, where the kinetic energy gain is already insufficient for a single collision to yield loss. MC2 tends to underestimate loss probability in this regime by precluding the possibility of multiple collisions. Beyond the smallest detunings explored in this work, our model suggests that the loss rate β and inelastic collision rate become equivalent as a single collision yields kinetic energy far beyond the trap depth.

The measured spectrum of Fig. 4 exhibits loss-rate maxima 70–200 MHz red- and blue-detuned of each transition, with amplitudes spanning an order of magnitude. The detuning at which loss rates peak is believed to result from the balance between the inelastic collision probability and kinetic energy gain needed for atoms to escape the trap. In general, the kinetic energy gained in a LAC will be greater when the collision occurs at a smaller internuclear distance (or equivalently, larger detuning). However, atoms in a thermal state are less likely to reach small internuclear distances where highly energetic collisions can occur. This behavior is confirmed in MC2 and similar models of trap loss [37, 39]. While the presence of bound states in attractive potentials can also yield an enhancement of loss rates [40], they are generally too dense to be experimentally resolvable for the detunings explored in this work [16]. Our simulation also suggests that double-peak structures, like the one observed near –200 MHz of the D2 $F=2 \rightarrow F'=3$ transition, can arise in regions where closely spaced transitions cause attractive and repulsive potentials to intersect.

The maximum loss rate on the D2 line (~ 110 MHz red-detuned of $F=2 \rightarrow F'=3$) is about 8 times larger than the maximum D1 rate (~ 70 MHz blue-detuned of $F=2 \rightarrow F'=2$). At least half of this difference can be attributed to single atom physics such as the dipole oscillator strength, which is twice as large for D2 than for D1. Branching ratios are also likely to play a role as the closed $F=2 \rightarrow F'=3$ transition effectively shields atoms from the $F=1$ ground state [38] where two-body loss is less likely to occur (due to low intensity and near-resonant detuning of the repump light). In contrast, populations in $F'=2$ have an equal probability of decaying to the $F=2$ or $F=1$ ground state, yielding LACs at roughly half the rate of atoms in $F'=3$. Similarly, the relative strength of the D2 $F=2 \rightarrow F'=3$ hyperfine transition is twice as large as the D1 $F=2 \rightarrow F'=2$ [29].

The influence of hyperfine-dependent collisional effects is most unambiguously demonstrated by the two-fold difference in maximum rates between the D1 $F'=2$ and $F'=1$ transitions, where the only significant difference in single-atom physics is the branching ratios of 1/2 and 5/6 respectively [38]. Scaling the loss-rate amplitude of each transition by the branching ratio, properties of the molecular potentials are estimated to contribute a factor

of 10/3 to the relative difference in measured loss rates. MC2 indicates that a factor of 2 comes from the density of molecular states, where roughly 40 potentials exist for $F=2 \rightarrow F'=2$ but only 10 exist for $F=2 \rightarrow F'=1$ (thus providing fewer opportunities for collisions). The remaining contribution likely results from variations in molecular Rabi rates and lifetimes, as the average Condon radius is similar for both transitions.

While the novelty of our results lie in the quantitative loss-rate variations across hyperfine transitions, the amplitude of absolute rates provides a useful indicator of single-atom loading timescales (see Appendix D) as well as for comparison to previous loss rate studies. In the most comparable tweezer-based experiment [21], loss rates measured near the D2 $F=2 \rightarrow F'=3$ transition were found to be 5 times larger than our reported value at a similar detuning of –30 MHz. This difference could be due to the high atomic temperatures or 3-body processes in Ref. [21]. Other loss-rate experiments in tweezers [22, 26], dipole traps [41], and MOTs [42–44] report loss-rate values anywhere from 2 to 5 times smaller than ours (β from Refs. [22, 26] are estimated). Direct comparison with these experiments is complicated by significant differences in detuning, intensity, and temperature. For example, when applying collisional light 150 MHz blue-detuned of D1 $F=2 \rightarrow F'=2$, we observe a factor of 2.5 decrease in β for atoms prepared at $T=50 \mu\text{K}$ compared to $T=15 \mu\text{K}$. MC2 indicates that temperature dependence is a function of detuning, where an increase in temperature will lead to a decrease (increase) of β at large (small) detunings. This is primarily due to a decrease in the relative distance between the average Condon radius and the radius corresponding to the atomic volume. However, the contribution of higher-order partial waves becomes important at hotter temperatures, resulting in a larger inelastic scattering cross-section that would further enhance loss rates.

In conclusion, our work sheds new light on the hyperfine dependence of resonant dipole interactions, and defines a quantitative benchmark for cold-atom/molecule applications where precision control over laser-induced collisions is advantageous. This backdrop of information will be helpful in tracing hyperfine-resolved molecular-state contributions to enhanced sub-Poissonian loading, which for example, has been observed to work particularly well on the D1 $F=2 \rightarrow F'=2$ transition of ^{87}Rb [24]. Furthermore, applications are not limited to only enhanced loading, but also number-resolved imaging [22] and laser cooling processes in high density systems [45]. More broadly, harnessing methods demonstrated in this work will aid in comparing LACs amongst atomic species, 3-body systems, and even molecules.

We would like to thank Paul Julienne, Antoine Browaeys, Mikkel Anderson, and Klaus Mølmer for helpful discussions, as well as Zhenpu Zhang and Ting-Wei Hsu for their assistance. Appendix A: Atom Merging Procedure

Single atoms are loaded into 2 of the 3 available tweezers with 35% probability. After initial imaging and cooling, the tweezers are ramped to a trap depth of $U/h = 1.9$ MHz for the merging process. Here, the two outer tweezers are linearly ramped toward the central tweezer to achieve a final array spacing of 440 nm, creating an

effective single trap that now contains all atoms from the 1×3 array. The outer tweezers are then adiabatically removed to achieve the desired trap depth and frequency. Single- and two-atom temperatures measured before and after merging the traps indicate negligible heating is incurred in the process. The most-likely source of loss in the merging process comes from background gas collisions, which set our vacuum lifetime at 4.8(1) s.

Appendix B: Intensity dependence

We examine loss rates as a function of intensity (Fig. 5) with D1 light blue-detuned 65 MHz of $F = 2 \rightarrow F' = 2$ (blue circles) and D2 light red-detuned 110 MHz of $F = 2 \rightarrow F' = 3$ (gold circles). Light is applied in a polarization gradient cooling configuration to minimize effects of recoil and radiation pressure heating at different intensities. The saturation parameter s is defined as I/I_{sat} where $I_{\text{sat}}^{\text{D1}} = 4.5 \frac{\text{mW}}{\text{cm}^2}$ for D1 and $I_{\text{sat}}^{\text{D2}} = 1.6 \frac{\text{mW}}{\text{cm}^2}$ for D2 [29]. Loss rates are observed to saturate close to I_{sat} , which is consistent with previous studies [21, 46] and the intuition that inelastic scattering rates should be constrained by the dipole Rabi rate.

FIG. 5. Two-body loss rates as a function of the LAC pulse saturation parameter s , where $\Delta_{\text{D1}} = 65$ MHz blue-detuned of D1 $F = 2 \rightarrow F' = 2$ (blue circles), and $\Delta_{\text{D2}} = 110$ MHz red-detuned of D2 $F = 2 \rightarrow F' = 3$ (gold circles). Corresponding fits are given by a tanh function.

Appendix C: Freespace resonance calibrations

The D1 and D2 laser frequencies are stabilized via an offset lock from a reference laser locked to a Rb vapor cell. We calibrate the free-space resonance by measuring the in-trap resonance as a function of trap depth, where a linear fit of the data is used to extrapolate the frequency corresponding to free space. Statistical uncertainty in the frequency calibration is added in quadrature with variation in the reference laser lock point, yielding a total uncertainty of ± 4 MHz.

FIG. 6. The $1/e$ time (τ) of atom pair survival as a function of collisional light detuning across the hyperfine spectrum. Refer to caption of Fig. 4 for trap and collisional light details.

Appendix D: $1/e$ time vs detuning

A complimentary perspective to the loss-rate plot (Fig. 4) is shown in figure 6, where the $1/e$ time τ of atom pair survival is plotted as a function of the collisional light detuning across the hyperfine spectrum. Here, $\tau = 1/\beta'$ where β' is the raw two-body decay constant that is independent of MC1, and therefore does not account for single atom heating effects. Hence, τ near resonance is slightly smaller than Fig. 4 would suggest. The very short timescale of atom-pair survival on the D2 $F=2 \rightarrow F'=3$ transition is believed to be largely responsible for the fast single-atom loading times ($\sim 10 - 20$ ms). In contrast, we find loading on either of the D1 transitions, where the τ is much longer, generally takes on the order of 100 ms. However, implications of absolute rates on enhanced loading timescales are a topic of ongoing research.

Appendix E: Collisional Beam Geometry

The LAC pulse is collimated to a waist of 1.4 mm and applied in the $-y$ direction [Fig. 7(a)]. A shutter is used to block or transmit the back reflection of the LAC beam, enabling a running wave or standing wave condition for the LAC process. Only in the measurement of β vs s (Fig. 5) do we keep the shutter open. When a well-defined polarization is desired, an external magnetic field is applied in the $-z$ direction. D2 repump is applied along the diagonal MOT beam paths (not shown in the diagram), while D1 repump is applied along the LAC path.

In the case of the $2 \rightarrow 1$ pre-imaging pulse, light is focused through a 100 mm achromatic lens to a waist of $w_0 \approx 50 \mu\text{m}$ and applied in a running wave configuration along the $-z$ direction [Fig. 7(b)]. Magnetic fields are zeroed at the atom location, however, this is not a necessary condition to drive $2 \rightarrow 1$ collisions with high probability.

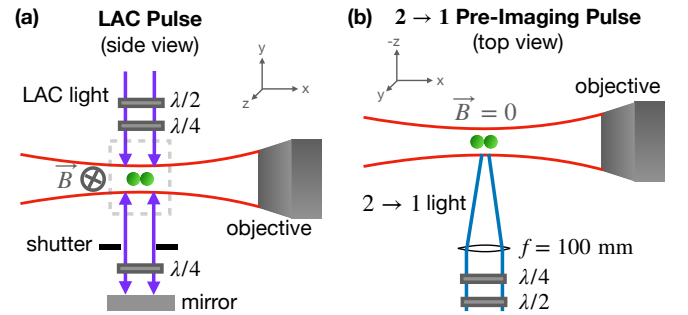

FIG. 7. Beam geometry for the LAC pulse (a) and the $2 \rightarrow 1$ pre-imaging pulse (b).

DETAILS OF NUMERICAL MODEL (MC2)

We calculate the classical trajectory of two atoms in a Gaussian potential with initial position and velocity components randomly generated from a normal distribution spanning $\delta r_{x,y,z} = \pm \sqrt{k_B T / m \omega_{r,a}^2}$ and $\delta v_{x,y,z} = \pm \sqrt{k_B T / m}$, where ω_r (ω_a) is the radial (axial) trap frequency. When atoms reach a resonant internuclear distance R_C (Condon radius), where transitions to the $S+P$ molecular potentials occur, the Landau-Zener model is used to calculate the inelastic collision probability P_R or P_A for a repulsive or attractive potential $U_e(R)$ as [16, 22]:

$$P_R = 2P_{LZ} (1 - P_{LZ}) \quad P_A = 1 - \frac{P_{LZ}}{2 - P_{LZ}} \quad (\text{E1})$$

$$P_{LZ} = \exp\left(-\frac{2\pi\hbar\Omega^2}{\alpha|v_{rel}|}\right). \quad (\text{E2})$$

Here, $\Omega = d\sqrt{2I/c\epsilon_0\hbar^2}$ is the electronic Rabi rate in terms of the atomic dipole transition matrix element d , the LAC laser intensity I , and the relative velocity of

the atoms along the internuclear axis v_{rel} . The slope parameter, $\alpha \approx |\partial[U_e(R)]/\partial R|_{R=R_C}$, is calculated at R_C for any one of the 384 hyperfine potentials (Fig. 4 of the main text), all of which can participate in a collision. We ignore interaction on the ground state potential, which is both standard in the Landau-Zener model and also a good approximation for long-range collisions. The different expressions for P_R and P_A result from the difference in available collisional pathways for attractive and repulsive potentials. In the case of repulsive potentials, atoms are either excited at R_C when first approaching or moving away from one another. For attractive potentials, atoms can oscillate around R_C an infinite number of times, resulting in a probability P_A defined by the summation of each possible excitation [16].

Dipole-dipole interactions are typically studied with respect to a single potential defined by $U_e(R) = \pm C_3/R^3$, where C_3 is the dispersion coefficient that characterizes the strength of the electrostatic interaction. In this case, there is a single Condon radius for each detuning. In our case, where 384 potentials exist, each detuning can have dozens of Condon radii ranging from small to large internuclear distances. We determine the possible Condon radii by calculating the intersection of the detuning energy and molecular potentials of a given transition. The interaction region near a Condon radius defines where a collision can occur, and is determined by $\Delta R = |R_+ - R_-|$, where R_{\pm} is given by the radial solutions of $U_e(R) = \hbar\Delta \pm \hbar\Omega/2$. Here, Δ is the collisional light detuning from a hyperfine resonance and Ω is the corresponding Rabi rate. The resulting interaction regions range from several nanometers (in the case of small detunings) to several picometers (in the case of large detunings or steep potentials).

When atoms reach an available Condon radius in the simulation, a collision occurs and we solve the classical equations of motion for a single atom experiencing the molecular potential. The final velocity, which depends on the initial conditions of the atoms, the potential being sampled, and the molecular lifetime, is evenly distributed between the two atoms along the internuclear axis. The final kinetic energy of each atom is then calculated to determine if it exceeds the depth of the trap. If a loss event is recorded, it is then weighted by the inelastic collision probability to incorporate the contribution of Landau-Zener in the loss probability. If a loss event does not occur, a new trajectory is initiated, therefore excluding the possibility of multiple collisions prior to a loss event. While multiple collisions are likely important at the smallest detunings, the slight improvement in accuracy was found to come at a large cost in simulation time.

Accurately modelling collisional loss is complicated by unknown excited state lifetimes and Rabi rates for molecular potentials belonging to specific symmetry groups, which can vary significantly from those of the atomic dipole transition [37]. We use an average molecular lifetime that is randomly sampled from a decaying ex-

ponential distribution corresponding to a decay rate of $\Gamma = 2\Gamma_a + \Gamma_s(\Delta)$. Here, Γ_a is the natural linewidth of the atomic electronic dipole transition, $2\Gamma_a$ is natural molecular linewidth [39], and the detuning-dependent stimulated emission rate is

$$\Gamma_s(\Delta) = \frac{\pi\mu^2}{3\epsilon_0\hbar^2} \frac{I(\Delta)}{1 + I(\Delta)/I_{\text{sat}}} \quad (\text{E3})$$

with laser intensity $I(\Delta) = \frac{\Gamma_a/2}{\Delta^2 + (\Gamma_a/2)^2}$. Effects from stimulated emission are expected to be important for near-resonant collisions [39], providing strong suppression of the molecular-state lifetimes and corresponding two-body loss probabilities. In this small-detuned regime, most models (including Landau-Zener) become unreliable and tend to over-estimate two-body loss on attractive potentials [16].

To account for variations in the molecular Rabi rates, we treat the Rabi rate Ω in Eq. (E2) as a free parameter for each hyperfine transition, adjusting as necessary to optimize agreement with experiment. Optimal values for Ω are listed in Table I, and are categorized by attractive and repulsive potentials for a given transition. To implement this in the simulation, where potentials belonging to different transitions can overlap near a given detuning, we determine the dissociation limit belonging to the potential and apply corresponding Rabi rate to both inelastic scattering probability $P_{R,A}$ and interaction region ΔR . In addition to the molecular Rabi rate, single light-atom interactions such as the relative hyperfine intensity [29], absorption oscillator strength, and branching ratios (without m_F resolution) [38] are accounted for by scaling the inelastic collision probability for each transition by the appropriate factors from table I. Since we are modelling a two-body loss probability instead of directly modelling the two-body loss rate, we scale all of the simulated results by a single conversion constant of 7×10^3 to account for the difference in units. This constant is selected to approximately align the scales of loss rates and loss probabilities when using the atomic Rabi rate in P_{LZ} . As a result, MC2 only provides a rough estimate of the absolute Rabi rates. However, the relative differences between Rabi rates offer valuable insights into the

Transition	Ω_R	Ω_A	I_{HF}	BR	f_{osc}
D1 $F=2 \rightarrow F'=2$	$\Omega_0/3$	$\Omega_0/5$	1/2	5/6	0.34
D1 $F=2 \rightarrow F'=1$	$\Omega_0/3$	$\Omega_0/6$	1/2	1/2	0.34
D2 $F=2 \rightarrow F'=3$	$\Omega_0/7$	$\Omega_0/5$	7/10	1	0.70
D2 $F=2 \rightarrow F'=2$	$\Omega_0/7$	$\Omega_0/10$	1/4	1/2	0.70
D2 $F=2 \rightarrow F'=1$	$\Omega_0/10$	$\Omega_0/10$	1/20	1/6	0.70

TABLE I. Rabi rate values used in the simulated two-body loss probability data (Fig. 4 of the main text) for attractive (Ω_A) and repulsive (Ω_R) potentials corresponding to each hyperfine transition on the D1 and D2 lines. Single-atom values for the relative hyperfine intensity I_{HF} and dipole absorption oscillator strengths f_{osc} are taken from [29], while values for the branching ratios (BR) are calculated from Ref. [38].

influence of molecular potentials in shaping the loss-rate spectrum.

Our model makes several simplifying assumptions to reduce computational overhead and mathematical complexity. First, we assume constant temperature before a collision occurs, determined by randomly sampling from a normal distribution of the experimentally measured temperature and uncertainty of $29(2) \mu\text{k}$. We do not account for changes in momentum imparted from elastic scattering processes, and therefore assume a fixed oscillatory path defined by the initial conditions. In reality, the momentum vectors of the atoms are changing direction as they scatter photons and evolve in the

trap. We approximate this effect by computing tens of thousands of trajectories over a $5 \mu\text{s}$ period at each detuning. Due to the randomly generated initial positions, this approach also ensures that the atoms sample a wide variety of potentials occurring at different interatomic distances. The error bars represent a standard error over 6 averages, where each average contains 10,000 trajectories. Additionally, we ignore the possibility of bound vibrational states and molecular-state coupling (fine/hyperfine-structure changing collisions and Stueckelberg oscillations), all of which have been shown to be negligible for the detunings explored in this work [16, 47].
