Abstract: The primary objective of Phase I oncology trials is to assess the safety and tolerability of novel therapeutics. Conventional dose escalation methods identify the maximum tolerated dose (MTD) based on dose-limiting toxicity (DLT). However, as cancer therapies have evolved from chemotherapy to targeted therapies, these traditional methods have become problematic. Many targeted therapies rarely produce DLT and are administered over multiple cycles, potentially resulting in the accumulation of lower-grade toxicities, which can lead to intolerance, such as dose reduction or interruption. To address this issue, we proposed dual-criterion designs that find the MTD based on both DLT and non-DLT-caused intolerance. We considered the model-based design and model-assisted design that allow real-time decision-making in the presence of pending data due to long event assessment windows. Compared to DLT-based methods, our approaches exhibit superior operating characteristics when intolerance is the primary driver for determining the MTD and comparable operating characteristics when DLT is the primary driver.

KEY WORDS: phase I trials; tolerability; dose optimization; Project Optimus; Bayesian design.

1 Introduction

Conventionally, the primary objective of phase I oncology trials has been to identify the maximum tolerated dose (MTD) based on dose-limiting toxicities (DLTs). These toxicities are typically defined as treatment-related grade 3 or higher non-hematologic toxicity or grade 4 or higher hematologic toxicity, according to the NCI Common Terminology Criteria for Adverse Events (CTCAE, 2017). For conventional cytotoxic compounds, which often induce severe and rapid-onset toxicities, DLTs occurring in the first cycle of treatment have served as reliable indicators of safety and tolerability (Siu, 2009; Lin, 2022). However, this framework presents challenges for molecularly targeted agents, immunotherapy, and antibody-drug conjugates. These novel therapies typically result in fewer DLTs compared to cytotoxic compounds, and patients often undergo longer treatment durations involving multiple cycles to maximize efficacy (FDA, 2017). Although patients may not experience DLTs, they may accumulate mild but disruptive toxicities over multiple treatment cycles, significantly impacting their quality of life. This often leads to dose reductions, interruptions, or discontinuations, which can compromise the actual efficacy of the treatment (Paoletti, 2011; Theoret, 2022). The U.S. Food and Drug Administration (FDA) has emphasized tolerability as a key consideration for dose optimization in Project Optimus.

A number of approaches have been proposed to incorporate non-DLT toxicities in identifying the MTD. Bekele and Thall (2004) introduced the total toxicity burden, a weighted sum of toxicity grades across different types, for dose finding. Yuan et al. (2007) presented the equivalent toxicity score, converting various toxicity grades into an equivalent number of DLTs, and developed the quasi-CRM (continuous reassessment method) design. Lee et al. (2011, 2012) proposed the continual reassessment method with multiple toxicity constraints using an ordinal probit model, and utilized regression on historical data to derive severity weights, defining the toxicity burden score. Ezzalfani et al. (2013) suggested the total toxicity profile, defined as the Euclidean norm of severity weights of toxicities, to summarize overall severity. Mu et al. (2018) introduced the generalized Bayesian optimal interval design (gBOIN), offering a unified framework to accommodate various toxicity grade and type scoring systems for dose finding. Lin et al. (2018) developed the model-assisted multiple-toxicity Bayesian

optimal interval (MT-BOIN) design to determine the MTD satisfying multiple toxicity constraints, with a decision table for ease of implementation. [Jiang et al. \(2024\)](#) and [Chen et al. \(2024\)](#) extended the keyboard design to accommodate low grade toxicities.

A practical challenge with existing methods is the multitude and heterogeneity of different types and grades of toxicities. Phase I trials commonly involve the assessment of up to 20-30 different types of toxicities. Moreover, toxicities such as low-grade diarrhea can have significantly different clinical implications depending on their duration. Prolonged occurrences cause much greater patient burden than brief ones ([FDA, 2017](#)). Consequently, assigning appropriate severity scores to each type of grade 1 and 2 toxicity proves extremely challenging, given the large variation and subjectivity involved. This limitation restricts the adoption of the aforementioned designs in practice.

To tackle this challenge, we propose using tolerability as an aggregated endpoint to quantify the consequence and impact of low-grade toxicities, rather than modeling different types and grades of toxicities. Here, tolerability is defined as a binary endpoint indicating whether dose reduction, interruption, or discontinuation occurs due to non-DLT toxicities. This simplification transforms complex multidimensional toxicity endpoints into a single endpoint that directly reflects the clinical impact of toxicities. Additionally, the tolerability endpoint is more measurable and requires less subjective input from physicians ([McKee, 2016](#)), compared to specifying severity scores for different types, grades, and durations of toxicities.

One challenge of using tolerability as the endpoint is the time it takes (multiple treatment cycles) to ascertain. We address this issue using Bayesian data augmentation, which predicts the pending tolerability endpoint based on observed data. We consider both a model-based approach and a model-assisted approach that incorporate both DLT and non-DLT-caused intolerance to determine the MTD. We refer to our designs as dual-criterion designs to emphasize their use of both DLT and non-DLT-caused intolerance in dose escalation and selection. Simulations demonstrate that the proposed designs outperform the approach that only considers DLT.

It's worth noting that under Project Optimus, which emphasizes the consideration of risk-benefit assessment of doses, identifying the MTD remains important as

it establishes the range of safe doses, forming the basis for further optimization (e.g., randomizing patients into MTD and a lower dose to further compare safety, tolerability, efficacy, PK and PK). [Yuan et al. \(2024\)](#) provides a comprehensive review of approaches for dose optimization and refer to it as a two-stage strategy.

The remainder of this article is organized as follows: Section 2 introduces the models and decision rules of the proposed model-based and model-assisted dual-criterion designs. Section 3 presents simulation results comparing the proposed methods with conventional approaches, as well as sensitivity analysis on the proposed methods. Section 4 concludes with a discussion.

2 Method

In a phase I trial with J doses, $d_1 < \dots < d_J$, under investigation, let Y_T and Y_R denote indicator variables for the occurrence of DLT and intolerance due to non-DLT toxicities, respectively. Y_R is intended to capture intolerance due to low-grade non-DLT toxicities. If a patient cannot tolerate a dose due to DLTs, $Y_T = 1$ and $Y_R = 0$. We assume that the assessment window for Y_T and Y_R are T_T and T_R , respectively. In practice, T_T is often the first treatment cycle, whereas T_R spans multiple treatment cycles, e.g., 3 cycles. For example, with a treatment cycle of 21 days, the DLT window $T_T = 21$ days and tolerance window $T_R = 63$ days. The values of T_T and T_R should be chosen based on trial characteristics and be sufficiently long to capture potential DLT and tolerability issues. As described previously, a key challenge is that T_R is relatively long, thus Y_R may not be observed at the time of making dose assignment decisions for the next cohort, posing a major challenge for conducting the trial. In what follows, we first describe a model-based time-to-event dual-criterion design (referred to as TITE-DC), followed by a model-assisted time-to-event dual-criterion design (referred to as TITE-BOIN_{DC}), to address this design challenge. Our designs are also able to handle the case where Y_T is not quickly observed for decision-making, e.g., DLT is also assessed over multiple cycles.

2.1 Model-based TITE-DC Design

2.1.1 Statistical Model

We model the joint distribution of (Y_T, Y_R) using a latent variable approach. Let Z_T and Z_R denote normally distributed latent variables, which are related to (Y_T, Y_R) as follows:

$$Y_k = \begin{cases} 0, & \text{if } Z_k < 0 \\ 1, & \text{if } Z_k \geq 0 \end{cases}; \quad k \in (T, R). \quad (2.1)$$

Z_T and Z_R can be interpreted as the patient's latent traits, and Y_T and Y_R are the clinical manifestations of unobserved Z_T and Z_R . When Z_T and Z_R pass the threshold of zero, certain clinical outcomes (e.g., DLT, intolerance) are observed.

At a given dose, we model (Z_T, Z_R) using a bivariate normal regression model:

$$\begin{pmatrix} Z_T \\ Z_R \end{pmatrix} \sim N_2 \left(\begin{pmatrix} \alpha_T + \beta_T d_j^* \\ \alpha_R + \beta_R d_j^* \end{pmatrix}, \begin{pmatrix} \sigma_T^2 & \rho \\ \rho & \sigma_R^2 \end{pmatrix} \right), \quad (2.2)$$

where α and β are regression parameters, $d_j^* = d_j/d_J$ is the standardized dose at level j , and ρ quantifies the correlation between Z_T and Z_R (or equivalently Y_T and Y_R). Following [Albert and Chib \(1993\)](#), we fix variance $\sigma_k^2 = 1$ to make the model identifiable.

As described previously, the key challenge is that Y_R is typically not observed at the time of making dose assignment decisions for the next cohort. Under the Bayesian paradigm, one intuitive way to address this missing data issue is to use Bayesian data augmentation, under which we draw the unobserved Y_R from its posterior predictive distribution. This approach has been previously used by [Liu et al. \(2014\)](#) in their data-augmentation continuous reassessment method (DA-CRM), as well as by [Jin et al. \(2014\)](#), [Zhou et al. \(2022\)](#), and [Takeda et al. \(2023\)](#) to address delayed toxicity and efficacy endpoints in phase I/II trial designs.

To proceed, let i index subjects, and X_{Ti} and X_{Ri} represent the time to DLT and intolerance, respectively. For patients who have no DLT nor intolerance issues, X_{Ti} and X_{Ri} can be set as large fixed values greater than T_T and T_R , respectively. Let t_i denote the follow-up time for the i th enrolled patient at the time of making dose assignment decisions for the next cohort. Following the work of [Zhou et al. \(2022\)](#), we make the following assumptions about X_{Ti} and X_{Ri} . We suppress i for brevity:

1. X_T and X_R are conditionally independent: $\Pr(X_T > t, X_R > t | Y_T = 1, Y_R = 1) = \Pr(X_T > t | Y_T = 1) \Pr(X_R > t | Y_R = 1)$. This is a reasonable assumption based on how we defined intolerance, and because T_T is typically shorter than T_R for targeted therapy trials.
2. X_T and X_R are uniformly distributed over their respective assessment windows (e.g., for time to DLT, $\Pr(X_T > t | Y_T = 1) = 1 - t/T_T$). This assumption has been shown to yield robust performance and is widely used in early phase trial designs (Cheung and Chappell, 2000; Liu et al., 2014; Zhou et al., 2022; Takeda et al., 2023).
3. X_T and X_R are independent from d_j conditional on $Y_T = 1$ and $Y_R = 1$. This assumption has been routinely applied in previous designs involving late-onset toxicity (Cheung and Chappell, 2000; Liu et al., 2014; Zhou et al., 2022; Takeda et al., 2023).

By imposing structural constraints, these assumptions allow more efficient use of the (very limited) observed data from small phase I trials, thereby stabilizing the estimation and decision making. In addition, they also simplify the imputation of unobserved Y_{Ri} and Y_{Ti} .

At the time of decision-making, there are three possible missing data patterns: i) both Y_{Ti} and Y_{Ri} are pending, ii) Y_{Ti} is observed but Y_{Ri} is pending, and iii) Y_{Ti} is pending but Y_{Ri} is observed. Let $p_{ab} = \Pr(Y_T = a, Y_R = b)$, where $a, b \in (0, 1)$. For these three patterns, the pending values can be drawn from their posterior predictive distributions as follows (see Supplementary Materials for the derivation):

- For patients with Y_T and Y_R pending, we draw the unobserved (Y_T, Y_R) from the following posterior distribution (suppressing i for brevity):

$$\begin{aligned} & \Pr(Y_T = 1, Y_R = 1 | X_T > t, X_R > t) \\ &= \frac{(1 - \frac{t}{T_T})(1 - \frac{t}{T_R})p_{11}}{p_{00} + (1 - \frac{t}{T_R})p_{01} + (1 - \frac{t}{T_T})p_{10} + (1 - \frac{t}{T_T})(1 - \frac{t}{T_R})p_{11}} \end{aligned}$$

$$\begin{aligned} & \Pr(Y_T = 1, Y_R = 0 | X_T > t, X_R > t) \\ &= \frac{(1 - \frac{t}{T_T})p_{10}}{p_{00} + (1 - \frac{t}{T_R})p_{01} + (1 - \frac{t}{T_T})p_{10} + (1 - \frac{t}{T_T})(1 - \frac{t}{T_R})p_{11}} \end{aligned}$$

$$\begin{aligned} & \Pr(Y_T = 0, Y_R = 1 \mid X_T > t, X_R > t) \\ &= \frac{(1 - \frac{t}{T_R})p_{01}}{p_{00} + (1 - \frac{t}{T_R})p_{01} + (1 - \frac{t}{T_T})p_{10} + (1 - \frac{t}{T_T})(1 - \frac{t}{T_R})p_{11}} \end{aligned}$$

$$\begin{aligned} & \Pr(Y_T = 0, Y_R = 0 \mid X_T > t, X_R > t) \\ &= \frac{p_{00}}{p_{00} + (1 - \frac{t}{T_R})p_{01} + (1 - \frac{t}{T_T})p_{10} + (1 - \frac{t}{T_T})(1 - \frac{t}{T_R})p_{11}}. \end{aligned}$$

- For patients with Y_T observed and Y_R pending, we draw the unobserved Y_R from the following posterior distribution:

$$\Pr(Y_T = y_T, Y_R = 1 \mid X_R > t) = \left[\frac{(1 - \frac{t}{T_R})p_{11}}{(1 - \frac{t}{T_R})p_{11} + p_{10}} \right]^{y_T} \left[\frac{(1 - \frac{t}{T_R})p_{01}}{(1 - \frac{t}{T_R})p_{01} + p_{00}} \right]^{1-y_T}.$$

- For patients with Y_T pending and Y_R observed, we draw the unobserved Y_T from the following posterior distribution:

$$\Pr(Y_T = 1, Y_R = y_R \mid X_T > t) = \left[\frac{(1 - \frac{t}{T_T})p_{11}}{(1 - \frac{t}{T_T})p_{11} + p_{01}} \right]^{y_R} \left[\frac{(1 - \frac{t}{T_T})p_{10}}{(1 - \frac{t}{T_T})p_{10} + p_{00}} \right]^{1-y_R}.$$

To fit the model, we perform Bayesian data augmentation as follows:

1. Initialize p_{ab} with their posterior estimates, obtained by fitting the proposed model (2.2) to the observed data using Gibbs sampling, ignoring pending Y_T and Y_R .
2. I (imputation) step: draw pending Y_T and/or Y_R according to the patient's missing data pattern, as described above, to acquire a complete dataset.
3. P (posterior) step: draw the unknown parameters based on the complete dataset, using Gibbs sampling, and update p_{ab} .
4. Iterate between the I and P steps until the algorithm converges.

2.1.2 Prior Specification

A hallmark of phase I trials is small sample sizes. Thus, it is critical to appropriately specify the prior: it should be sufficiently vague such that data will dominate the posterior and drive decision-making, while also not being too diffuse (e.g., with a very large variance). Diffuse priors can cause estimation instability due to limited data and a high likelihood of drawing extreme parameter values, especially at the early stage

of the trial when only a few cohorts of patients are treated. We follow the approach of Guo et al. (2017) to specify the priors.

Defining $\pi_{kj} = p(Y_k = 1 | d_j)$ and integrating out the latent variables Z_k in model (2.2), π_{kj} follows a probit model: $\text{probit}(\pi_{kj}) = \alpha_k + \beta_k d_j^*$, where $k = T, R$. Therefore, we assign a normal $N(0, 1.25^2)$ prior to the intercept α_k . This prior spans the probability between 0.006 and 0.994 when α_k deviates from its prior mean by one standard deviation on each side. We assign the slope β_k a half-normal $N(0, 1.24^2)$ prior to ensure that toxicity monotonically increases with dose. This prior is centered at 1 to reduce positive bias due to truncation when the true value is close to 0. We set the standard deviation of 1.24 such that a standard deviation change will move the probit probability to 0.994 at d_J and $\alpha_k = 0$. Finally, we assign a positive uniform prior $U(0, 1)$ to the correlation parameter ρ , as we expect DLT to be positively correlated with intolerance.

2.1.3 Dose-finding algorithm

Let ϕ_T and ϕ_R represent pre-specified target probabilities for Y_T and Y_R , respectively. The dose-finding algorithm of TITE-DC is described as follows:

1. Treat the first cohort of patients at d_1 or a prespecified starting dose.
2. Based on observed interim data D , obtain the posterior estimates of π_{kj} (denoted as $\hat{\pi}_{kj}$), and identify the dose with $\hat{\pi}_{Tj}$ being closest to ϕ_T and the dose with $\hat{\pi}_{Rj}$ being closest to ϕ_R . Let j^* denote the lower dose level between the two identified doses, defined as $j^* = \min(\arg \min_{j \in \{1, \dots, J\}} |\hat{\pi}_{kj} - \phi_k|)$ where $k = T, R$. Let j^c denote the current dose level. Perform dose escalation or de-escalation as follows:
 - If $j^c < j^*$ and $j^c < J$, escalate the dose level to $j^c + 1$.
 - If $j^c > j^*$ and $j^c > 1$, de-escalate the dose level to $j^c - 1$.
 - Otherwise, retain the dose level at j^c .
3. Repeat Step 2 until reaching the maximum sample size. Based on the final data, identify j^* and select it as the MTD.

In Step 2, the dose escalation/de-escalation decision is based on both Y_T and Y_R (i.e., taking the more conservative one), which distinguish it from conventional dose-finding designs where the dose decision depends solely on Y_T .

To safeguard patients from overly toxic or intolerable doses, we impose the following overdosing and early stopping rule: during the trial, if $\Pr(\pi_{Tj} > \phi_T | D) > 0.95$ and/or $\Pr(\pi_{Rj} > \phi_R | D) > 0.95$, eliminate dose level j and all higher dose levels. If all dose levels are eliminated, the trial should be terminated, and no dose should be selected as the MTD. Additionally, to reduce the uncertainty caused by pending data, patient enrollment and dose decisions will be suspended when the ratio of patients with pending to non-pending DLT and intolerance data at the current dose is ≥ 0.5 .

2.2 Model-Assisted TITE-BOIN_{DC} Design

2.2.1 Statistical Model

In this section, we introduce a model-assisted dual-criterion design, TITE-BOIN_{DC}, as an extension of the TITE-BOIN design (Yuan et al., 2018). Unlike TITE-DC, which models dose-toxicity and dose-intolerance curves, TITE-BOIN_{DC} directly estimates π_{Tj} and π_{Rj} using the sample mean based on the local data observed at dose level j , making it simpler to implement and also more robust.

Let n_j denote the number of patients dosed at level j , and m_{Tj} and m_{Rj} denote the observed number of patients experiencing DLT and intolerance. When there is no pending Y_T and Y_R , π_{Tj} and π_{Rj} are simply estimated by their sample means $\hat{\pi}_{Tj} = m_{Tj}/n_j$ and $\hat{\pi}_{Rj} = m_{Rj}/n_j$. As described previously, the challenge is that often some Y_T and Y_R are pending at decision times.

We first consider the estimation of π_{Rj} when some of Y_R is pending. Following the approach of TITE-BOIN, we first perform single imputation by replacing the pending Y_R with its expectation. Given the imputed complete data, we then estimate $\hat{\pi}_{Rj}$ using its sample mean. Let M_R represent the set of patients with pending Y_R . For $i \in M_R$, the corresponding pending Y_R can be imputed by

$$\hat{Y}_{Ri} = \Pr(Y_{Ri} = 1 | X_{Ri} > t_i, d_j) = \frac{\pi_{Rj}(1 - \frac{t_i}{T_R})}{\pi_{Rj}(1 - \frac{t_i}{T_R}) + (1 - \pi_{Rj})} n_j, \quad (2.3)$$

where unknown probability π_{Rj} can be replaced by its posterior mean estimate based on the observed data, using a beta-binomial model $m_{Rj} \sim \text{Binomial}(n_j, \pi_{Rj})$ with

a vague prior $\pi_{Rj} \sim \text{Beta}(\alpha_R, \beta_R)$, $\alpha_R = 0.5\phi_R$ and $\beta_R = 1 - \alpha_R$, representing an effective sample size of 1. As noted by Yuan et al. (2018), this observed-data-based estimate slightly overestimates π_{Rj} , but this is not a concern as it leads to a conservative estimate of Y_{Ri} , thereby improving the safety of the design. Given the imputed \hat{Y}_{Ri} , an estimate of π_{Rj} is given by

$$\hat{\pi}_{Rj} = \frac{m_{Rj} + \sum_{i \in M_{Rj}} \hat{Y}_{Ri}}{n_j}.$$

The estimation of π_{Tj} , when some of Y_T is pending, can be performed in a similar way as above, by imputing pending Y_{Ti} as

$$\hat{Y}_{Ti} = \frac{\pi_{Tj}(1 - \frac{t_i}{T_T})}{\pi_{Tj}(1 - \frac{t_i}{T_T}) + (1 - \pi_{Tj})} n_j \approx \frac{\pi_{Tj}(1 - \frac{t_i}{T_T})}{(1 - \pi_{Tj})}. \quad (2.4)$$

The approximation on the right-hand side of the equation is appropriate as π_{Tj} is often small in most phase 1 trials. This approximation is optional. It simplifies the calculation and is used by TITE-BOIN. Similarly, the unknown probability π_{Tj} can be replaced by its posterior mean estimate based on observed data, using a beta-binomial model.

2.2.2 Dose-finding algorithm

Let λ_{Te} and λ_{Td} denote the BOIN dose escalation and de-escalation boundaries, respectively, for the target ϕ_T . Define λ_{Re} and λ_{Rd} similarly for the target ϕ_R . The dose-finding algorithm of TITE-BOIN_{DC} is described as follows:

1. Treat the first cohort of patients at d_1 or a prespecified starting dose.
2. Based on observed interim data D , calculate $\hat{\pi}_{Rj}$ using (2.3) and $\hat{\pi}_{Tj}$ using (2.4), and apply their respective BOIN boundaries to determine their individual recommended doses j_k^* for Y_k , $k = T, R$, as follows:
 - If $\hat{\pi}_{kj} \leq \lambda_{ke}$ and $j^c < J$, set $j_k^* = j^c + 1$.
 - If $\hat{\pi}_{kj} \geq \lambda_{kd}$ and $j^c > 1$, set $j_k^* = j^c - 1$.
 - Otherwise, set $j_k^* = j^c$.

Perform dose escalation/de-escalation by treating the next cohort of patients at dose level $j^* = \min(j_T^*, j_R^*)$.

3. Repeat Step 2 until reaching the maximum sample size. Based on the final data, select the MTD as $j^* = \min(\arg \min_{j \in (1, \dots, J)} |\hat{\pi}_{kj} - \phi_k|)$, $k = T, R$, where $\hat{\pi}_{Tj}$ and $\hat{\pi}_{Rj}$ are isotonic estimates of DLT and intolerance rate, based on isotonic regression (Yuan et al., 2016).

The same overdosing and early stopping rule as described in Section 2.1.3 will be used, except that $\Pr(\pi_{kj} > \phi_k | D)$ will be evaluated based on a beta-binomial model: $m_{kj} \sim \text{Binomial}(n_j, \pi_{kj})$ with a vague prior $\pi_{kj} \sim \text{Beta}(1, 1)$. Additionally, the same accrual suspension as in Section 2.1.3 will be employed to reduce the uncertainty resulting from excessive pending data.

3 Simulation

3.1 Simulation Setting

We performed simulation to evaluate the operating characteristics of TITE-DC and TITE-BOIN_{DC} designs. We considered $J = 5$ dose levels with target $\phi_T = 0.25$ for DLT, and $\phi_R = 0.5$ for intolerance. Patients are enrolled in cohorts of 3, with the first cohort receiving the lowest dose level. The maximum sample size is $N = 30$ patients, consisting of 10 cohorts. The treatment cycle is 21 days. The DLT assessment window is the first cycle, and the intolerance assessment window is 3 cycles. The enrollment follows a Poisson process with a rate of 1 patient per 10 days. Among patients experiencing DLT and/or intolerance, the times to event X_T and X_R are generated from uniform distributions.

We constructed 11 scenarios to cover different shapes of dose-DLT and dose-intolerance curves (Table 1). Scenarios 1-7 consider cases where the target dose is driven by intolerance rather than DLT. Scenarios 8-9 consider cases where the target dose is driven by DLT. Scenarios 10-11 consider cases where the target dose is driven by both DLT and intolerance.

We compared TITE-DC and TITE-BOIN_{DC} with their complete-data versions (denoted as DC and BOIN_{DC}, respectively), which require Y_T and Y_R to be fully observed before enrolling the next cohort of patients. These complete-data versions provide a useful benchmark to evaluate how well our methods handle pending data, although they are often infeasible in practice due to long trial durations caused by

frequent enrollment suspension. To demonstrate the importance of considering both DLT and intolerance, we also compared TITE-DC and TITE-BOIN_{DC} against the BOIN design, which considers only DLT. Previous research shows that CRM has similar operating characteristics as BOIN (Zhou et al., 2018), so we included only BOIN for comparison. In each scenario, we simulated 1000 trials.

3.2 Operating Characteristics

Scenarios 1-7 consider cases where the MTD is driven by intolerance rather than DLT. In scenario 1 for example, the MTD is dose level 3, for which the intolerance rate equals the target $\phi_R = 0.5$, but the DLT rate is lower than the target $\phi_T = 0.25$. If only DLT is considered, ignoring intolerance, the MTD would be dose level 5. In this case, the percentage of correct selection (PCS) of the MTD is 65.8% for TITE-DC and 61.9% for TITE-BOIN_{DC}, substantially higher than the 24.6% PCS for BOIN. Since BOIN only considers DLT, it tends to select dose level 5 as the MTD, which has an unacceptable intolerance rate of 0.9. This highlights the importance of considering both DLT and intolerance.

The performance of TITE-DC and TITE-BOIN_{DC} is comparable to their complete-data counterparts, DC and BOIN_{DC}, showing that our methods handle pending data efficiently. DC and BOIN_{DC} require repeated suspensions, leading to substantially longer trial durations (e.g., 28.7 and 29.0 months) compared to TITE-DC and TITE-BOIN_{DC} (18.3 and 17.6 months). This demonstrates that TITE-DC and TITE-BOIN_{DC} can dramatically shorten trial duration without compromising the performance in identifying the MTD. Similar results are observed in scenarios 2-7.

Between TITE-DC and TITE-BOIN_{DC}, neither dominates the other in terms of PCS. In the scenarios where the target is a higher dose (e.g., scenarios 1, 2), TITE-DC has a higher PCS, while in the scenarios where the target is a lower dose (e.g., scenarios 3,4), TITE-BOIN_{DC} achieves a higher PCS. In terms of safety, TITE-BOIN_{DC} outperforms TITE-DC in 6 out of 7 scenarios, with a lower percentage of overdosed patients. For example, in scenario 2, TITE-DC treated 11.9% of patients at doses above the MTD, whereas TITE-BOIN_{DC} treated only 4.3% of patients at doses above the MTD.

Scenarios 8-9 consider cases where the target dose is driven by DLT, which favors the DLT-based BOIN design. The PCS of TITE-DC and TITE-BOIN_{DC} remain competitive. Specifically, the PCS of TITE-DC is slightly lower than that of BOIN, while the PCS of TITE-BOIN_{DC} is comparable to that of BOIN. The PCS of TITE-DC and TITE-BOIN_{DC} are similar to DC and BOIN_{DC}, demonstrating high efficiency in handling pending data. Between TITE-DC and TITE-BOIN_{DC}, TITE-BOIN_{DC} appears safer with a higher PCS.

Scenarios 10-11 consider cases where the MTD is driven by both DLT and intolerance. In these scenarios, TITE-DC and TITE-BOIN_{DC} both achieve higher PCS compared to BOIN. This demonstrates an additional benefit of utilizing dual-criterion when both DLT and intolerance indicate the same dose as the MTD.

3.3 Sensitivity Analysis

One critical assumption used by TITE-DC and TITE-BOIN_{DC} to handle pending Y_T and Y_R is that X_T and X_R are uniformly distributed over $(0, T_T)$ and $(0, T_R)$, respectively. We evaluate the sensitivity of TITE-DC and TITE-BOIN_{DC} to this assumption by simulating X_R from a piecewise uniform distribution, where each treatment cycle has different probabilities of intolerance. Within each cycle, the probability of intolerance is uniformly distributed. Let (w_1, w_2, w_3) denote probabilities of intolerance in cycles 1 to 3. We consider four different piecewise uniform distributions for X_R with $(w_1, w_2, w_3) = (1/3, 1/3, 1/3), (1/7, 2/7, 4/7), (1/10, 1/10, 8/10), (8/10, 1/10, 1/10)$. The first distribution corresponds to a uniform distribution over the assessment window; the second distribution places higher weights towards later cycles; and the third and fourth distributions place most of the weight in cycles 3 and 1, respectively. We selected scenario 2 from Table 1 to evaluate model sensitivity. Figure 1 depicts the operating characteristics of TITE-DC and TITE-BOIN_{DC}, demonstrating the robustness of TITE-DC and TITE-BOIN_{DC} to the violation of the uniform time-to-event assumption. The PCS, the number of patients allocated to the MTD, and trial duration are comparable across the four distributions. The percentage of overdoses is higher in the second and third distributions due to more delayed events in these two cases compared to the first and fourth distributions.

We also evaluated the sensitivity of TITE-DC and TITE-BOIN_{DC} to the accrual rate. As noted by Yuan et al. (2018), the percentage of pending patients is determined by the ratio of the accrual rate to the assessment window. There is a one-to-one correspondence between varying the accrual rate with a fixed assessment window and varying the assessment window with a fixed accrual rate. Therefore, our simulation results are applicable to varying assessment windows. Figure 2 depicts the operating characteristics of TITE-DC and TITE-BOIN_{DC} under varying accrual rates, which are generally similar and not sensitive to the accrual rate except the trial duration. The trial duration is expected to increase with slower accrual.

4 Discussion

We have proposed dual-criterion dose-finding designs that determine the MTD based on both DLT and intolerance caused by non-DLT events. We considered both the model-based TITE-DC design and the model-assisted TITE-BOIN_{DC} design. Simulation studies show that both designs outperform DLT-based dose-finding designs and can efficiently handle pending data caused by the potentially long assessment window for DLT and intolerance. TITE-BOIN_{DC} is generally safer than TITE-DC. Consistent with this, TITE-BOIN_{DC} has a higher probability of identifying the MTD when it is located at a lower dose, whereas TITE-DC has a higher probability of identifying the MTD when it is located at a higher dose.

In this paper, we focus on determining the MTD. As the paradigm of dose-finding shifts from the identification of the MTD to the optimal biological dose (OBD), different extensions can be considered. One approach takes a two-stage design strategy: after establishing the MTD based on TITE-DC or TITE-BOIN_{DC} designs, we randomize patients into the MTD and a dose lower than the MTD to collect additional data to determine the OBD. The other approach is the efficacy-integrated strategy (Yuan et al., 2024), where we simultaneously consider efficacy, toxicity, and tolerability to guide dose finding. For the model-based approach, we can introduce an efficacy endpoint and accommodate it using a trivariate normal latent-variable model to account for efficacy, DLT, and intolerance. For the model-assisted design, we can apply BOIN boundaries to the efficacy endpoint and incorporate it into the dose-finding algorithm,

or model the risk-benefit tradeoff as in the BOIN12 design (Lin et al., 2020).

When treatment is administered over multiple cycles, the likelihood that patients drop out of the study increases. For example, patients may be off the study due to disease progression, resulting in missing data. Incorporating the missing data into our design is a topic of interest. Methods have been developed to incorporate partial information in the context of patient dropout (Guo and Yuan, 2015), which may be adapted to our designs.
