Abstract. Stellar-mass black-hole binaries are the most numerous gravitational-wave sources observed to date. Their properties make them suitable for observation both by ground- and space-based detectors. Starting from synthetic catalogues constructed based on observational constraints from ground-based detectors, we explore the detection rates and the characteristic parameters of the stellar-mass black-hole binaries observable by LISA during their inspiral, using signal-to-noise ratio thresholds as a detection criterion. We find that only a handful of these sources will be detectable with signal-to-noise ratio larger than 8: about 5 sources on average in 4 years of mission duration, among which only one or two are multiband ones (i.e. merging in less than 15 years). We find that detectable sources have chirp mass $10 M_{\odot} \lesssim \mathcal{M}_c \lesssim 100 M_{\odot}$, residual time-to-coalescence $4\text{yr} \lesssim \tau_c \lesssim 100\text{yr}$, and redshift $z \lesssim 0.1$, much closer than those observed up to now by ground-based detectors. We also explore correlations between the number of LISA detectable sources and the parameters of the population, suggesting that a joint measurement with the stochastic signal might be informative of the population characteristics. By performing parameter estimation on a subset of sources from the catalogues, we conclude that, even if LISA measurements will not be directly informative on the population due to the low number of resolvable sources, it will characterise a few, low-redshift candidates with great precision. Furthermore, we construct for the first time the LISA waterfall plot for low chirp mass, and demonstrate that LISA will also be able to discriminate and characterize, through very precise parameter estimation, a population of binaries with higher masses, $\mathcal{M}_c \sim \mathcal{O}(10^3)M_{\odot}$, if it exists.

1 Introduction

During their lifetime from formation to coalescence, stellar-mass black-hole binaries (sBHBs) emit gravitational waves (GWs) over a broad frequency range, crossing both LISA and ground-based interferometer sensitivities [1]. However, unlike ground-based interferometers probing sBHBs at merger [2], LISA will detect sBHBs during the inspiralling phase, with GW signals behaving differently depending on the source chirp mass and orbital period at the start of LISA observations. Within the mission lifetime, most sBHBs will produce quasi-monochromatic GW signals, while a minority will show a slow, positive frequency drift, either crossing a significant portion of the LISA band or eventually moving out of it. These latter are the sources with higher signal-to-noise ratio (SNR), and can transition into the ground-based detector band over a timescale short enough to allow for multiband detection [1, 3–5].

In this paper, we investigate what LISA can reveal about the sBHB population. The vast majority of sBHBs have too low SNR to be individually resolvable by LISA, and contribute to a stochastic GW background, which we characterised in [6]. Here we work on the same assumptions and simulation framework of Ref. [6], but instead of focusing on the stochastic background component, we focus on the individual sBHBs detected by LISA: we estimate their number, describe their properties, compare them with those of the sBHBs detected so far by LIGO/Virgo/KAGRA (LVK), and perform a few example parameter estimations to characterise LISA capabilities.

In Section 2.1, we summarise the population simulation framework that we developed in [6] to construct the sBHB catalogues. In particular, we adopt the POWER LAW + PEAK LVK model of the sBHB population [2] based on the analysis of the GWTC-3 catalogue [7], further supplemented with an extension of the merger-rate redshift going beyond a single power law, based on the star formation rate of [8]. Besides the merger rate, we disregard any possible redshift dependence of other population parameters, and adopt a uniform distribution for the residual time-to-coalescence evaluated at the start of the LISA mission and in the detector frame. The criterion we adopt to select, out of the synthetic catalogues, the sBHBs detectable by LISA is solely based on SNR, which we detail in Section 2.2. To compute it, we further assume that all binaries are circular. In Section 2.3, we present the number

density distributions of the sBHBs detectable by LISA for three values of detection threshold, as a function of the residual time-to-coalescence, chirp mass, redshift, and mass ratio. We predict a median value of 5 resolvable sources with $\text{SNR} \geq 8$, increasing to about 40 for $\text{SNR} \geq 4$, a threshold value compatible with archival searches [5, 9]. These numbers are in broad agreement with previous analyses [10–12] (see Section 2.3). According to our results, most resolvable sources have residual time-to-coalescence $4 \text{ yr} \lesssim \tau_c \lesssim 100 \text{ yr}$, with a median of only one or two suitable for multiband detection, i.e. with $\tau_c \leq 15 \text{ yr}$. Their chirp mass distribution peaks between $10 M_\odot \lesssim \mathcal{M}_c \lesssim 50 M_\odot$ with a tail up to $\mathcal{M}_c \sim 100 M_\odot$, and they are characterised by low redshift $z \lesssim 0.1$, a requisite to yield sufficiently high SNR in LISA. We further find that the catalogues providing the highest number of events contain sources that are chirping and appear at relatively low frequency in the LISA band: regardless of the actual population model, these would be the two features that need to be fulfilled in the real Universe realisation to maximise the number of resolvable sources with LISA.

In Section 2.4, we analyse how the number of resolved sBHBs depends on the population parameters. We find that the strongest correlation is with the index κ of the merger rate power-law dependence with redshift, while weaker correlations appear with the index α of the power-law distribution of the primary component mass, and with the mixture parameter λ_{peak} of its high-mass peak. We further analyse the role of a possible time delay t_d between the binary formation and its merger, finding that dependence of the number of resolved LISA sources on the time delay is negligible, since it is dominated by the population posterior variance.

In Section 3 we perform a comparison between the sources in LVK GWTC-3 and those detectable by LISA *if the sBHB population obeys the LVK-inferred model POWER LAW + PEAK*. We find that statistically LISA is only sensitive to very close-by sBHBs with $z \lesssim 0.1$, in the low-redshift tail of the sources’ distribution, where LVK has observed no events, yet. While seemingly contradictory, we argue this is to be expected (see discussion in Section 2.3). Regarding their chirp mass and mass ratio, the sample of sBHBs detectable by LISA is distributed similarly to the LVK events. This indicates that LISA parameter reach does not extend beyond that of LVK if the POWER LAW + PEAK population model is confirmed.¹ On the other hand, if the characteristic chirp masses extend beyond $10^2 M_\odot$ (see e.g. the population of beyond-gap binaries of [16]), a fraction of the population gradually exits the LVK detection region while remaining within the LISA one. We demonstrate this by producing, for the first time, the LISA waterfall plot in the chirp-mass range $1 M_\odot \lesssim \mathcal{M}_c \lesssim 5 \times 10^3 M_\odot$. Due to the peculiar shape of the LISA sensitivity curve combined with the presence of the Galactic foreground [17, 18], the waterfall plot peaks in redshift at around $100 M_\odot$, decreases, and then grows again for chirp masses higher than $10^3 M_\odot$. We show that this is a feature specific to sources with merger times larger than the LISA observation time.

In Section 4 we perform parameter estimation on a subset of 12 sources extracted from the catalogues with the restriction that they have an SNR larger than 8 and will merge in less than 15 yr from the start of LISA observations. Both of these restrictions place such sources at $z \leq 0.1$. We find that LISA can characterise these sources very well, with $\sim 10^{-4}$ relative uncertainty on the chirp mass and on the residual time-to-coalescence, 20 – 30% relative uncertainty on the redshift, and $\sim 10^{-6}$ relative uncertainty on the initial frequency of entrance in the LISA band. In addition, we perform parameter estimation on three sources

¹We remind that even if LVK and LISA probe similar statistical samples of the sBHB population, observing them at both the inspiral and merger stages would constrain important features of the sBHB evolution (e.g. eccentricity) [13] as well as cosmological and general relativity observables [14, 15].

with $\mathcal{O}(10^3) M_\odot$. Even though they are well beyond the higher mass cutoff imposed within the POWER LAW + PEAK model, we nevertheless consider them to confirm what is hinted by the waterfall plot, i.e. that LISA will be able to detect and characterise such a population of high mass sources, if it exists. The parameters of these sources are also very well measured, featuring $\sim 10^{-6}$ relative uncertainty on the chirp mass and 10% on the redshift, for the highest mass source with redshifted $\mathcal{M}_c = 1800 M_\odot$. Finally, in Section 5 we present our conclusions.

2 Expected sources

In this section we detail the sBHB astrophysical population model of our catalogues, and revise our procedure to extract the sBHBs detectable by LISA. We then analyze the statistical properties of the resolvable-source catalogues, provide the sources number density distribution, and describe their distribution in redshift, chirp mass, and residual time-to-coalescence. We conclude by exploring how these properties depend on the choice of population model and its posterior.

2.1 sBHB population model

Our analysis is based on the sBHB population synthesis approach presented in Ref. [6], which assumes the fiducial sBHB population model inferred by the LVK Collaboration [2]. Even though this model might be subject to changes as the number and accuracy of LVK detections increase, it currently yields the largest evidence, hence we adopt it as the fiducial one.

The procedure detailed in [6] to produce synthetic sBHB catalogues involves several assumptions, which we summarise in what follows. Previous studies [2, 19, 20] have found no evidence of redshift dependence in the sBHB population parameters (though other works mildly hint towards such an effect [21–23]). Including redshift dependency in our analysis would come at much higher computational cost, since we could not take advantage of the factorization of parts of the number density distribution to generate the corresponding source parameters independently. Therefore, here we neglect any potential dependence on redshift in the distribution of the population parameters.² Moreover, we assume that binary formation and evolution are in a steady state for the range of residual time-to-coalescence relevant to the LISA band ($\lesssim 10^5$ yr), meaning the rate of binaries merging or emitting at any allowed frequency is statistically constant; equivalently, τ_c , the residual time-to-coalescence in the source frame is uniformly distributed across the sBHB population. Note that this steady-state assumption would hold even in the case of a redshift dependence in the distribution of the population properties, since that dependency would not have a significant effect across such a short time span.

Additionally, we work under the assumption of sBHB with negligible eccentricity. It is well-established that LISA has significantly greater potential to infer sources’ eccentricities than LVK-like detectors. The reason is two-fold: circularization naturally reduces the eccentricity when a system approaches its merger [24], and the large number of waveform cycles observable by LISA makes it highly sensitive to the source eccentricity in its early inspiral [25]. However, by assuming no eccentricity, we reduce the computational cost and focus on other sets of population parameters that LISA can characterize complementarily to LVK.

²Our analysis of the sBHB confusion noise in [6] requires this assumption to hold up to $z \approx 5$, while in the present analysis, as we will prove, it is enough that it holds up to $z \approx 0.5$, since the likelihood of LISA resolving a source at $z > 0.1$ is very low.

Furthermore, since eccentricity is not constrained by current observations, results would be heavily dependent on our prior model assumptions.

Within the aforementioned assumptions the differential number of sBHBs with parameters ξ at redshift z merging after a time τ_c (in the source frame) reads [6]

$$\frac{d^3N(z, \tau_c, \xi, \Lambda)}{d\xi dz d\tau_c} = R(z, \tau_c) \left[\frac{dV_c}{dz}(z) \right] p(\xi|\Lambda). \quad (2.1)$$

Here, the dependencies on the population model are enclosed in the sBHB merger rate $R(z, \tau_c)$, and in the probability density function $p(\xi|\Lambda)$ of the source parameters ξ , both intrinsic (masses, spins, polarisations, orbital phase and frequency) and extrinsic (sky position, inclination, distance), as a function of the parameters Λ describing the population model. The cosmology is instead accounted for in the Universe comoving volume dependence on redshift, dV_c/dz . For consistency with LVK and [6], we use the best-fit Λ CDM cosmological model inferred from the ‘‘Planck 2015 + external’’ data combination of [26]. Note that in Eq. (2.1) we can use the merger rate density in the form that LVK is constraining [2] because within our assumptions, all values of τ_c are equally likely at any z , and thus the time interval $d\tau_c$ is equivalent to a generic time interval dt (see discussion in [6]).

The choice of the functional forms on the right-hand side of Eq. (2.1) sets our population model. As in [6], for the distribution $p(\xi|\Lambda)$ of source parameters we follow the nowadays standard [2] combination of a POWER LAW + PEAK model for the mass distributions, a tapered inverse power-law for the mass ratio, and independent Beta distributions for the spin amplitudes and isotropic plus truncated Gaussian mixtures for the tilts. The extrinsic source characteristics are drawn from uniform and isotropic distributions.

Finally, our $R(z, \tau_c)$ follows the functional form of the Madau-Fragos star-formation rate (SFR) R_{SFR} [8], with the modifications described in App. A of [6]. At redshifts $z \lesssim 1.5$, this is equivalent to the power-law-like merger rate adopted by LVK [2]. Since, as we will confirm later, LISA does not individually resolve sBHBs at $z \gg 0.5$, for all practical purposes we use in our analyses a rate $R(z) = R_0(1+z)^\kappa$, with parameters R_0 and κ matching those inferred by LVK. The importance of this choice will be discussed in Section 2.4.

2.2 Rapid population simulation

Our goal is to investigate within the population model described above the number and properties of the sBHBs that LISA is expected to detect individually in its nominal 4-year mission duration [17, 18]. We study the distribution of the properties of these individually resolvable compact binaries across population parameters compatible with the posterior inferred from GWTC-3 [2]. To do so, we would have to generate a large number of synthetic catalogues of sBHBs emitting in the LISA frequency band, varying the population parameters. These catalogues contain tens to hundreds of millions of events. Though we make use of the fast EXTRAPOPS simulation³ code [27],⁴ which can produce millions of events per second and CPU core, the cost in terms of CPU time and storage of this direct approach would be prohibitive. We therefore aim to restrict the simulation to events above a minimum SNR. Parameter inference analyses simulating the LISA data analysis pipeline [4, 5] have established that an

³Here we use the term *simulation* to refer to the generation of synthetic populations from a probability distribution for the source parameters, as opposed to the term *synthesis*, which in the literature usually refers to the creation of synthetic populations from astrophysical simulation codes, involving e.g. stellar formation and evolution.

⁴Available at <https://github.com/JesusTorrado/extrapops>

SNR of 8 is a viable detection threshold. In order to extend our study to sources susceptible to be identified via archival searches in LISA data (i.e. using the detection of the post-LISA signal at ground-based interferometers), we consider also SNRs down to 6 and 4 [5, 9], paying special attention to sources with a residual time-to-coalescence smaller than 15 years after the start of LISA observation, which could be suitable for multiband detection.

Only a very small fraction of the sources of each synthetic population, consisting of all sBHB emitting in the LISA band, survive these SNR cuts. Therefore, imposing them when generating synthetic populations greatly reduces computational costs. However, calculations of realistic SNRs are expensive. To impose this cut, we therefore first use an analytic, approximate SNR calculation, based on the leading-order Stationary Phase Approximation waveform for inspiralling compact binaries. In addition, for this calculation, we assume sources to be optimally-oriented (*face-on*, i.e. cosine-inclination $\cos \iota = 1$), in order to minimize the chances that we miss an event for which the approximate SNR would be underestimated. Following [28], averaging over polarization and sky position, the approximate SNR squared reads:

$$\langle \text{SNR}^2 \rangle_{\cos \iota = 1} = 2 \frac{16}{c^3} \left(\frac{\sqrt{\frac{5}{24}} G^{5/6} \mathcal{M}_c^{5/6}}{\pi^{2/3} d_L} \right)^2 \int_{f_{\min}}^{f_{\max}} \frac{f^{-7/3}}{S_{h,X}(f)} df, \quad (2.2)$$

with \mathcal{M}_c being the chirp mass of the source, d_L its luminosity distance, and $S_{h,X}$ the LISA detector sensitivity in the long-wavelength limit for a single TDI 1.5 channel (Eq. (56) in [28]), with the factor 2 in front of Eq. (2.2) accounting for the two effective TDI channels of LISA in this approximation. At this stage, we do not include the effect of the confusion noise coming from unresolved population members, because it is at sub-percent level with respect to the noise sensitivity [6]. The integration is performed over the intersection between the LISA frequency band and the span of frequencies over which the source has drifted during the 4 years of observation time.

Since in our catalogues we want to capture all sources with realistic SNR above 4, for robustness the cut we impose is rather $(\langle \text{SNR}^2 \rangle_{\cos \iota = 1})^{1/2} = 2$ from Eq. (2.2). Furthermore, we achieve even faster simulation by imposing that the sources in the catalogues have redshift smaller than 1 and residual times to coalescence shorter than 2000 yr. Outside these limits it is extremely unlikely to find sources with realistic SNR above 4.

Within these restrictions, using EXTRAPOPS, we generate one population realisation for each of the approximately 11 thousand equal-weight posterior samples from the publicly available GWTC-3 catalogue [29] for the fiducial population model described in Section 2.1 [2]. For each realisation, we re-compute the SNR of each source using the simulated instrument data analysis pipeline presented in [30], which provides a more realistic evaluation of the SNR in LISA than Eq. (2.2). This pipeline is based on an iterative process, where the stochastic signal plus instrumental noise is directly computed from the power spectral density (PSD) of the data. Then, any source with SNR higher than a given threshold is classified as resolvable, and thus is subtracted from the data. The noise levels are estimated again and the loud sources are subtracted in the same manner as before. The procedure stops when either convergence is reached at the noise PSD, or there are no more sources left to subtract. In this evaluation, we add to the LISA instrumental noise the confusion noise due to unresolved members from the corresponding population, computed as described in [6] – despite this only having a small effect on the final SNR. We finally group the sources taking 4, 6 and 8 as SNR thresholds, according to the realistic SNR computation, and discard the rest. The full set of

synthetic populations, together with a Python notebook demonstrating parts of the present analysis, is available at <https://zenodo.org/records/13974091> [31].

2.3 Sources distribution

As explained in the previous section, we have simulated at least one population per equally weighted sample from the GWTC-3 posterior, and computed the number of detectable sources N_{det} for each of the SNR threshold considered: $\rho_0 = 4, 6$ and 8 . With Λ being the population parameters referred to in Eq. (2.1) (here also including the ones defining the merger rate), the resulting set of tuples $(N_{\text{det}}, \Lambda)$ represents a fair sample from the joint distribution $p(N_{\text{det}}, \Lambda | \rho_0, \text{LVK})$, where the condition “LVK” denotes the GWTC-3 population posterior. We construct the expected distribution for the number of sBHBs resolvable by LISA and compatible with the GWTC-3 observations by marginalizing $p(N_{\text{det}}, \Lambda | \rho_0, \text{LVK})$ over the population parameter space Ω_Λ , or, equivalently, taking the expected value of the number of observable sources conditioned to the population parameters over the posterior $p(\Lambda | \text{LVK})$ from GWTC-3:

$$p(N_{\text{det}} | \rho_0, \text{LVK}) = \int_{\Omega_\Lambda} p(N_{\text{det}} | \Lambda, \rho_0) p(\Lambda | \text{LVK}) d\Lambda. \quad (2.3)$$

Numerically, this operation amounts to simply dropping the population parameters from the $(N_{\text{det}}, \Lambda)$ tuples constructed as described above.

The resulting distribution for N_{det} is shown in Fig. 1. The number of expected resolvable sources with SNR threshold $\rho_0 = 8$, has a median value around 5, having a $\sim 2\%$ probability for no sources being resolved, and a 10% probability for more than 10 sources being resolved. We compare our findings with previous results in the literature: using a similar merger rate and an ad-hoc chirp mass distribution based on the sBHB masses in GWTC-3, Ref. [10] finds an analytical point estimate of approximately 4 detectable sources; Using the population model that we analyze here, Ref. [11] obtains 6_{-2}^{+3} detectable sBHBs taking into account the 90% confidence interval of the merger rate at $z = 0.2$ under GWTC-3, and fixing the rest of the parameters, capturing roughly half of the full posterior uncertainty of 5_{-4}^{+6} shown in our study. When the detection threshold is lowered to values suitable for archival searches, we expect a number of sources of the order of 10 and 50 for SNR threshold of 6 and 4, respectively.

Fig. 2a shows the number density distributions as a function of the residual (log-)time-to-coalescence τ_c . The SNR of inspirals in LISA strongly depends on τ_c . On one hand, their emission amplitude increases with decreasing τ_c . On the other hand, their emission frequency also increases with decreasing τ_c , as does, in turn, the GW-driven frequency drift; this has the opposite effect: as sources spend less time in the LISA band, those with smaller τ_c have smaller accumulated SNR. As shown in Fig. 2a, the switch between these two regimes occurs at τ_c comparable to the mission duration, which we have set to 4 yr [32]. Therefore, given the large range of τ_c resulting in detectable sources for all SNR thresholds, the counts are dominated by sources that merge long after the LISA mission, with τ_c of the order of 10 – 100 yr.⁵ Most of the resolvable sBHBs are then detected as nearly monochromatic signals by LISA [10]. On the other hand, sources merging before the end of the mission, characterised by a large frequency drift, make up roughly 10% of the total, for all SNR thresholds.

We compare our findings on the number of sources merging within the mission with results in literature. In Ref. [12], the authors populated with sBHBs the star formation regions

⁵The sharp cut at $\tau_c = 2000$ yr in Fig. 2a corresponds to the limit imposed on τ_c for the generation of the catalogues, and does not affect the sources of interest.

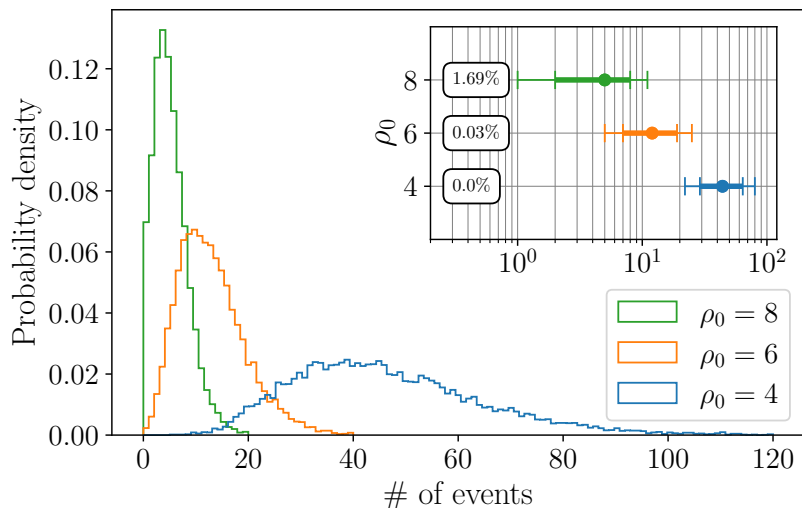

Figure 1: Histograms of the predicted distribution of number of sources resolvable by LISA, inferred from GWTC-3 observations, using synthetic catalogues generated as explained in Section 2.2. The blue (orange, green) probability density refers to an SNR threshold $\rho_0 = 4$ (6, 8). (*Inset plot*) Point estimates of the number of detectable sources: bullet markers correspond to the median of each distribution in the main plot, while thick (thin) lines denote the 68%(90%) confidence interval. Percentages in each row denote the probability of zero detectable sources for each given ρ_0 threshold.

resulting from the Illustris hydrodynamic cosmological simulation [33], using the binary star evolution code MOBSE [34] with a fiducial model approximately matching the mean merger rate recovered by GWTC-3. For sources merging before the end of the LISA mission (4 yr), they find point estimates of 2, 5 and 18 for the SNR thresholds $\rho_0 = 8, 6$ and 4. That is at least a factor of 4 greater than our result, likely due to modeling differences (e.g. greater likelihood of massive sources, a merger rate consistently greater than the mean GWTC-3 one for $z < 2$).

If LISA detects sources with a small enough residual time-to-coalescence, in our convention $\tau_c \leq 15$ yr, future ground-based GW experiments should be able to observe them as they merge. Let us now focus on these *multiband* sources, either those individually resolved by LISA ($\rho_0 = 8$), or potentially found in archival searches in the LISA data ($\rho_0 = 4, 6$). These sources account for roughly 1/3 of the total for all SNR thresholds. Fig. 2b shows the number of resolvable sources aggregated by residual time-to-coalescence intervals: for SNR detection threshold $\rho_0 = 4$ we find 16_{-11}^{+14} multiband (i.e. $\tau_c \leq 15$ yr) sources at 90% confidence interval, for $\rho_0 = 6$ the number decreases to 4_{-3}^{+6} . For $\rho_0 = 8$, we find 2_{-2}^{+3} multiband sources. Even though the posterior lower bound is compatible with zero, 79% of the catalogues yield at least one source with $\tau_c \leq 15$ and SNR above $\rho_0 = 8$. The percentages shown in Fig. 2b denote the fraction of catalogues yielding no detectable sources aggregated by τ_c ranges.

Figure 3 further illustrates the complementarity between space- and ground-based detectors. It displays the source parameter distributions across our catalogues. The 90% probability contours for the most relevant source parameters of the expected resolved events (i.e. chirp mass \mathcal{M}_c , redshift z , mass ratio q and residual time-to-coalescence τ_c) are shown as a teal solid (dotted, dashed) line for $\rho_0 = 8$ (6,4). To gauge whether LISA is complementary to

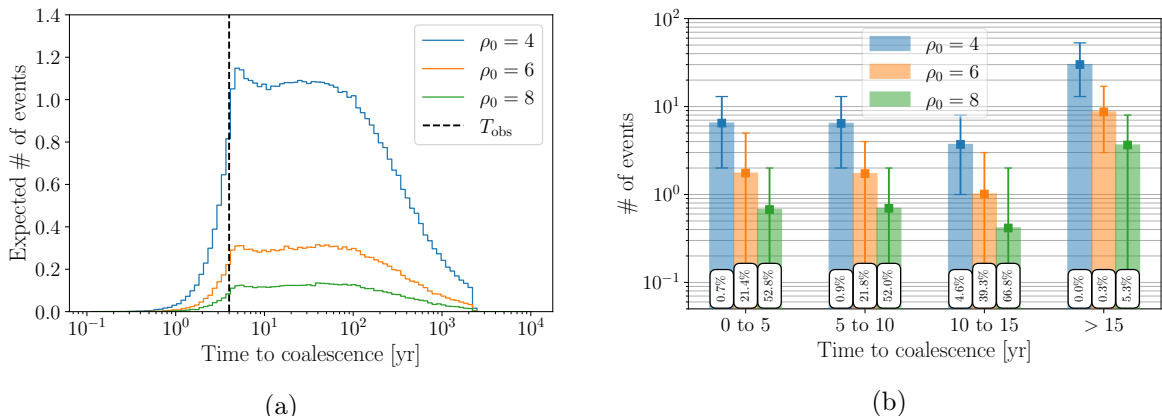

Figure 2: (a) Distribution over residual time-to-coalescence in detector frame of sources number counts across all catalogues for SNR thresholds $\rho_0 = 4$ (blue), 6 (orange), 8 (green). The dashed black line denotes the nominal mission duration $T_{\text{obs}} = 4$ yr. (b) Number of detectable events aggregated by residual time-to-coalescence intervals, including median (bar top edge) and 90% confidence intervals (thin capped lines), for SNR thresholds $\rho_0 = 4, 6, 8$ (same colours). Percentages at the bottom of each bar denote the fraction of catalogues, for each residual time-to-coalescence range and ρ_0 threshold, yielding no detectable sources. Notably, for $\rho_0 = 4$, all catalogues contain at least one source with $\tau_c > 15$ yr. Percentages do not necessarily add up to 100%, as some catalogues yield no detectable sources in multiple τ_c and ρ_0 intervals.

LVK in probing these parameters, we overplot in orange the individual events posteriors from the GWTC-3 catalogue. This allows for a straightforward comparison with LISA detection potential for sources belonging to the same population [2]. It is apparent that the LISA parameter reach is roughly within the LVK one except for the high-mass tail of the chirp mass distribution. In fact, the bulk of the LISA sources have chirp mass $10 M_\odot \lesssim \mathcal{M}_c \lesssim 50 M_\odot$, similarly to LVK, but the tail of the mass distribution extends to up to $\mathcal{M}_c \sim 100 M_\odot$. The reach of LISA is strongly limited in redshift: it is unlikely to resolve events with redshift larger than 0.1, a much smaller horizon than LVK. LISA will also be less sensitive to smaller mass ratios.

The seeming inconsistency between the observed events in GWTC-3 and the support for low redshift and masses of the population observed by LISA, illustrated by the little-to-no overlap in the (\mathcal{M}_c, z) subplot in Fig. 3, is readily explained. While the LVK network has collected data in observing mode for 393 (171) days with two (three) detectors, the detectability of sources by LISA is based solely on their emission frequency, i.e. including events merging in up to thousands of years. In other words, among the hundreds of millions of sources within that range of residual time-to-coalescence, only $\mathcal{O}(10)$ might be resolved by LISA. Sampling the same portion of the parameter space with ground-based experiments would require a number of the order of 1000 hypothetical non-simultaneous experimental runs. In Fig. 3 we also show the population of all predicted sources (solid black line), for a representative catalogue with the median population parameters from GWTC-3, but without any selection due to detectability by LISA. The black line encompasses the sources detected in GWTC-3, but not the potentially detectable ones by LISA, because they fall at the far tail of the distribution (c.f. again the (\mathcal{M}_c, z) subplot).

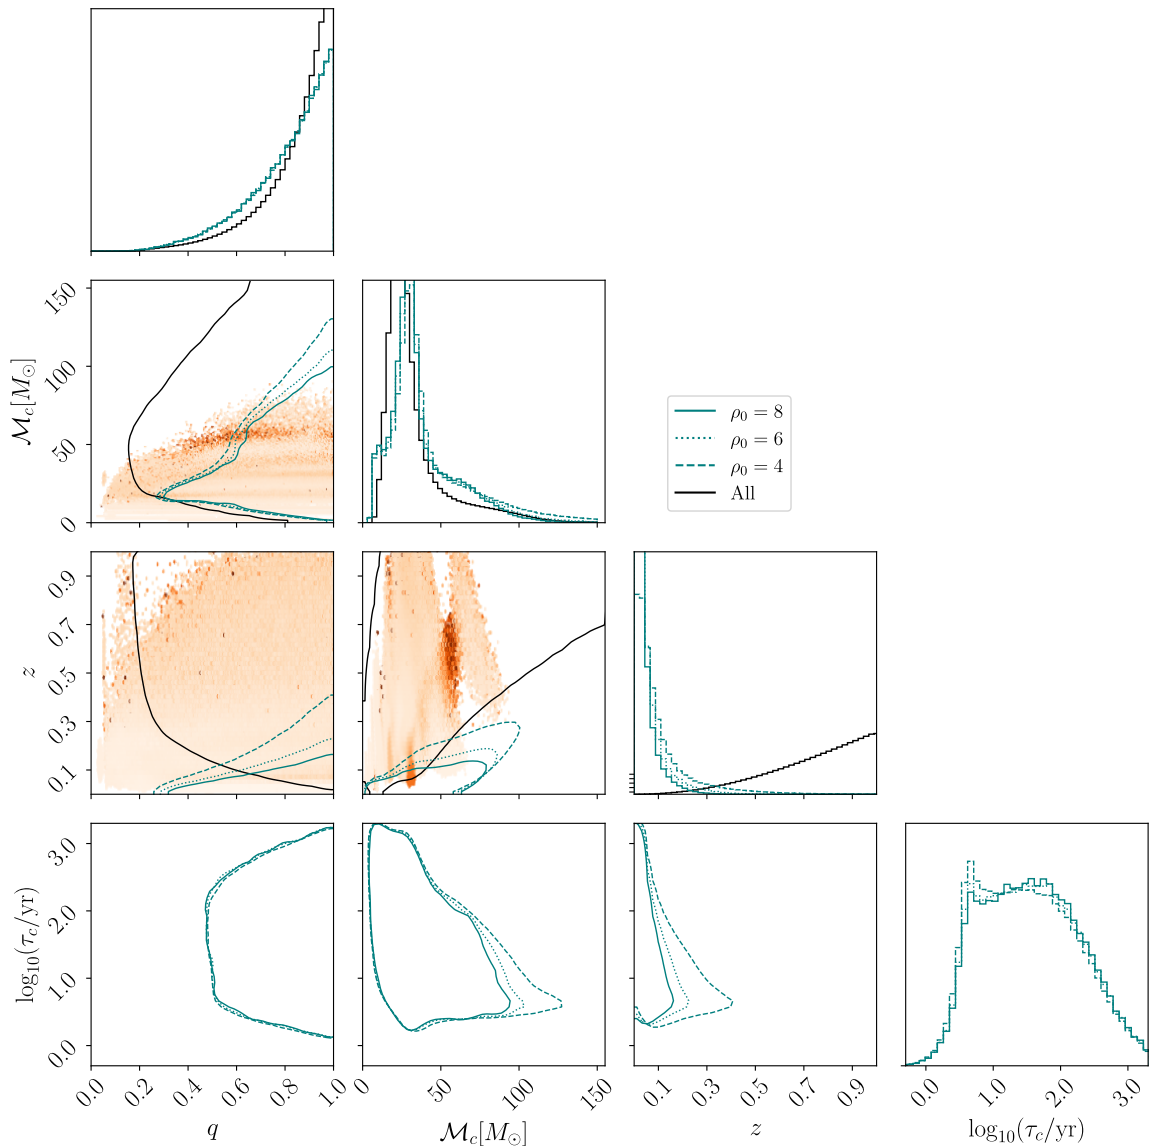

Figure 3: Predicted distribution of LISA detectable sources. Teal solid (dotted, dashed) lines enclose 90% of sources with SNR above 8 (6,4) across all catalogues. Solid black lines are the 90% contours for a full population (including unresolved sources) simulated with the median population parameters from GWTC-3. Orange shaded areas correspond to the density of posterior samples from individual events in GWTC-3.

In order to understand the features of LISA sBHB detectability, it is also useful to analyse phenomenological source parameters such as the waveform amplitude, the initial GW frequency f_0 and its derivative \dot{f} (both evaluated at the start of the LISA observation in the detector frame). In Fig. 4 we show their values for three sets of 5 catalogues, randomly sampled from those yielding 1, 5 and 10 resolvable sources, respectively. Clearly, as f_0 increases, the frequency derivative \dot{f} increases as well, as predicted by the leading-order inspiral

Figure 4: Scatter plots of individual events across catalogues, in terms of phenomenological binary parameters: the signal frequency at the start of LISA observation, its amplitude, and the frequency derivative. Circle (squares, triangles) denote parameters from 5 random catalogues with $N_{\text{det}} = 1(5, 10)$, each catalogue shown with a different shade of blue (green, red).

relation

$$\dot{f} = \frac{96}{5} \pi^{8/3} \left(\frac{G \mathcal{M}_c}{c^3} \right)^{5/3} f^{11/3}. \quad (2.4)$$

Furthermore, the sources pertaining to resolvable-source-poor catalogues tend to have smaller \dot{f} , consistently with what is expected for the whole population, which is composed mainly of slowly-evolving binaries. On the other hand, the correlation between the plus (cross) polarization amplitude \mathcal{A}_+ (\mathcal{A}_\times) and frequency, given by

$$\mathcal{A}_{\{+, \times\}} = \frac{4}{d_L} \left(\frac{G \mathcal{M}_c}{c^2} \right)^{5/3} \left(\frac{\pi f(t)}{c} \right)^{2/3} \left\{ \frac{1 + \cos^2 \iota}{2}, \cos \iota \right\}, \quad (2.5)$$

is less clear in Fig. 4, probably because other physical parameters, e.g. the luminosity distance and the inclination, play a relevant role. It is anyway appreciable from the figure that the sources with low frequency f_0 tend to cluster at low amplitude, because they stay in band longer and therefore accumulate more SNR. Fig. 4 also highlights a large variability of source properties across catalogues, so that even the catalogues with the smallest number of resolvable sBHs appear to reflect the characteristics of the whole population.

2.4 Dependency on the population parameters and time delay

In this section, we first investigate the correlation between the number of LISA-detectable sources and the population parameters as inferred from GWTC-3. We then analyse the impact of a possible time delay between the formation of the binary of stars and their evolution into sBHB systems.

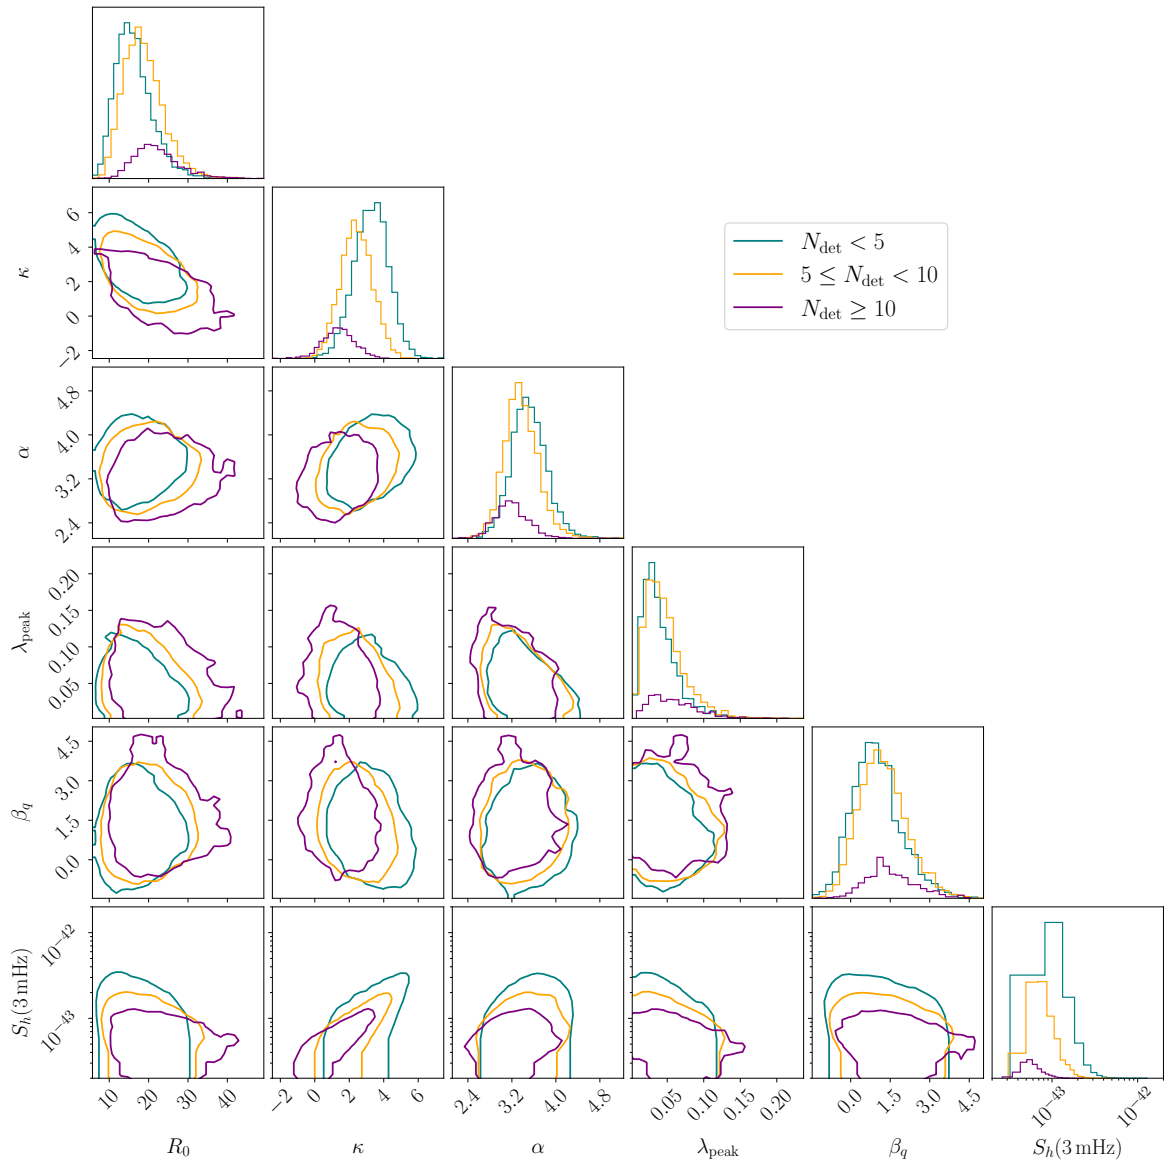

Figure 5: Distribution of some population parameters and expected SGWB power with respect to the number of detectable sources. Teal (orange, purple) contour lines denote 90% confidence intervals for population parameters of catalogues with $N_{\text{det}} < 5$ ($5 \leq N_{\text{det}} < 10$, $N_{\text{det}} \geq 10$) expected detectable sources by LISA. The one dimensional histograms along the diagonal are normalized to the number of catalogues for each chosen N_{det} , accordingly. (*Bottom row*): The expected SGWB power spectral density at a reference frequency of 3 mHz. We observe systematic anti-correlation between the number of detectable sources and the residual SGWB amplitude, and a positive correlation between the power-law index κ and the background amplitude.

Figure 5 shows the 90% confidence intervals on the population parameters for the synthetic catalogues, grouped by the number of detectable sources in each, with $N_{\text{det}} < 5$, $5 \leq N_{\text{det}} < 10$, $N_{\text{det}} \geq 10$, and assuming $\rho_0 = 8$. We find a significant negative correlation

Figure 6: (a) Effect of the negative correlation between the merger rate power-law index κ and the number of loud ($\rho_0 = 8$) sources in LISA: 50% and 90% confidence intervals of the merger rate versus redshift, $R(z)$, for catalogues with $N_{\text{det}} < 5$, $5 \leq N_{\text{det}} < 10$, $N_{\text{det}} \geq 10$. Larger number of detectable sources are associated with larger rates at redshift below $z = 0.2$, which correspond to lower values of the power-law index κ : indeed, LVK constrains best the merger rate at $z = 0.2$, which produces the anticorrelation. (b) The probability distribution of the binary primary component mass, for catalogues yielding $N_{\text{det}} < 5$, $5 < N_{\text{det}} < 10$, $N_{\text{det}} > 10$. Larger number of loud events are associated with less negative indices for the power-law component of the distribution, α , and in a smaller measure positively correlated with the relative amplitude of the Gaussian peak (given by larger values of the mixture parameter λ_{peak}) and its mean mass.

between the expected number of sources above threshold and the merger rate power-law index κ in the low-redshift regime: $R(z) \propto (1+z)^\kappa$; this effect is even greater at lower detection thresholds. This correlation is caused by the combination of (i) the merger rate being best constrained by LVK at $z = 0.2$, so that lower values of κ yield an excess of sources below that redshift, and a deficit above it; and (ii) the fact that LISA is more sensitive to sources at redshift $z \lesssim 0.2$. Figure 6a illustrates it, showing the 50% and 90% confidence intervals of the merger rate versus redshift, $R(z)$, for catalogues with $N_{\text{det}} < 5$, $5 \leq N_{\text{det}} < 10$, $N_{\text{det}} \geq 10$. The role of the pivot at $z = 0.2$ is apparent.

We further focus on the dependence on the mass distribution parameters. As stated in Section 2.1, in our analysis we assume that the mass m_1 of the primary component follows the same fiducial POWER LAW + PEAK model as in the GWTC-3 population study [2]: a mixture of a large power-law component ($m_1^{-\alpha}$), and a small, narrow Gaussian component centered at $m_1 \approx 30\text{--}40 M_\odot$, with some overall tapering at low masses. The higher sensitivity of LISA to large-mass binaries with respect to ground-based detectors produces two significant correlations: catalogues with higher number of sources tend to have a heavier-tailed power law component (smaller α) and larger a contribution from the Gaussian component (larger mixture parameter λ_{peak}), though the latter correlation is less pronounced. Fig. 6b illustrates these correlations. We point out that a small positive correlation is observed with the power-law index β_q controlling the mass ratio $q = m_2/m_1$ distribution, indicating a preference for near equal-mass binaries, as shown in Fig. 3.

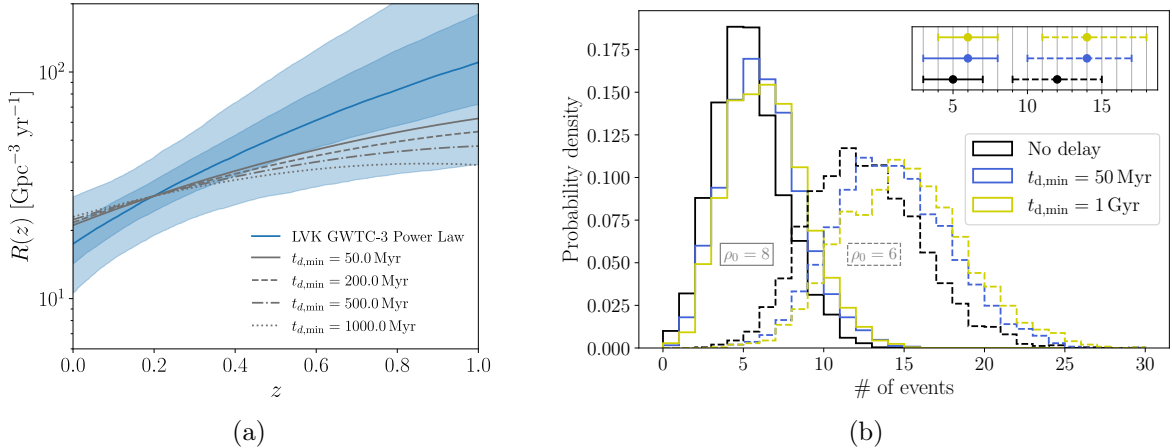

Figure 7: (a) GWTC-3 posterior for the merger rate (blue-shaded) compared to the median GWTC-3 merger rate including different minimum time-delays with the inverse-time model. (b) Dependence of the number of sources with SNR above threshold $\rho_0 = 8$ and 6 on the minimum time delay for the median of the population parameters from the GWTC-3 posterior; the effect is smaller than the posterior variance (cf. Fig. 1); the inset shows the 68% CI.

In summary, the sensitivity of LISA, favouring the detection of low-redshift, massive sources, produces correlations between the parameters describing the population and the number of detected sources. However, the expected number counts are too small to discern the effect of such correlations over Poisson noise, and therefore the detection of individual sources has limited statistical power to constrain the population model. On the other hand, the amplitude of the stochastic gravitational wave background (SGWB) due to the unresolved sBHBs presents similar correlations, but with opposite signs. This can be appreciated from the bottom row of Fig. 5 showing the amplitude of the SGWB from sBHBs at a reference frequency of 3 mHz, computed following [6]. Therefore, a potential synergy between the observation of the sBHB background and resolvable sources can be exploited to gain insight on the population model. For example, detecting a high background amplitude together with a high number of detected sources might indicate that a revision of the merger rate amplitude and power-law assumption is needed. These considerations, however, are subject to the caveat that recent confusion background estimates due to extra-galactic white dwarfs may hinder a precise determination of that from unresolved sBHBs [35].

The presence of a time delay between the formation of the stellar binary and their evolution to sBHBs can also modify the merger rate, with an effect similar to a shallower power-law index κ . As found above, the value of κ strongly influences the number of resolvable sources. We therefore investigate whether time delays can alter this number within our model. To do that, we augment the merger rate used in our study (following the functional form of the star formation rate in Madau-Fragos [8], see Section 2.1) with a time-delay log-uniform distribution, leading to [36, 37]

$$R(z) = R_{\text{ref}} \int_{t_{d,\text{min}}}^{t_{d,\text{max}}} R_{\text{SFR}}(t(z) + t_d) \frac{1}{t_d} dt_d, \quad (2.6)$$

where $R_{\text{SFR}}(z)$ is the star formation rate, and the integration is performed between a chosen minimum and a large maximum time-delay, $t_{d,\text{min}}$ and $t_{d,\text{max}}$, respectively. We fix the

normalisation of the merger rate to the median rate of the GWTC-3 posterior at $z = 0.2$, where it is best constrained. We then explore physically motivated time-delay models in the literature by considering $t_{d,\min} = 0, 50, 200, 500, 1000$ Myr (due to the $1/t_d$ dependence, we take $t_{d,\max}$ large enough such that it does not influence the integral). The resulting merger rates are presented in Fig. 7a: they are well within the blue band corresponding to the LVK posterior, and also compatible with the SGWB upper bound by LVK [2].

We assess the effect of a time-delay on the expected number of LISA detectable sources by fixing the population parameters to the median values obtained from population analyses in GWTC-3 for the fiducial model presented in Section 2.1, while replacing the merger rate with the “delayed” models, for the discrete set of $t_{d,\min}$ listed above. We follow the procedure described in Section 2.2 to evaluate the number of detectable sources with SNRs above $\rho_0 = 8$ and 6, performing 2500 simulations for each delayed model. In this context, given the large number of expensive realistic LISA SNR evaluations needed, we adopt the following procedure to speed up the source selection. Starting for the sources in our main (non-delayed) set of catalogues, for which we have *already* computed both the realistic SNR and the inclination-averaged one of Eq. (2.2), we fit a multivariate polynomial function to the ratio of both SNRs,⁶ reaching an accuracy better than a few percent. Then, for the newly-generated sources predicted by the delayed model, we compute approximate realistic LISA SNRs from the product of the fast inclination-averaged SNRs and the fitting function. Results are shown in Fig. 7b. Comparing with Fig. 1, we can see that the observed variability of the number of detections is too weak to be directly informative on the time-delay distribution, confirming what was already hinted in [11] using a simpler analysis.

3 Comparison of LISA and LVK sensitivity to sBHBs

We turn our attention to the characterization of the complementarity between ground- and space-based detectors in detecting sBHB signals, without making any assumption on the underlying population. For this purpose, we compare the sensitivity of LISA and LVK, evaluated in terms of SNR, in the (\mathcal{M}_c, z) parameter space by constructing so-called “waterfall plots”. We assume LISA operating at nominal sensitivity for 4 yr [17, 18], and the LVK network operating at design sensitivity [38].

We characterize the detectability of individual GWs as a function of source-frame chirp mass \mathcal{M}_c and redshift, see Fig. 8. As in the previous section, a GW signal is deemed detectable by LISA if its SNR is greater than 8. Similarly, we flag an event as detectable by LVK if its network SNR is greater than 14, roughly equivalent to a three-detector network threshold $\text{SNR} = 8$.

The parameters most affecting the SNR, apart from \mathcal{M}_c and z , are: (i) the source cosine inclination $\cos \iota$ with respect to the line-of-sight, which we bracket with three fiducial values: 0, 1, and $\sqrt{2}/2$; (ii) in the case of LISA, the binary’s time-to-coalescence, for which we consider the values $\tau_c = 3$ yr, $\tau_c = 10$ yr, and $\tau_c = 20$ yr. Concerning (i), it can be observed in Fig. 8 that the SNR loss as the binary orientation moves away from face-on or face-off, decreases the maximal redshift at which sources can be detected. Concerning (ii), as also shown in Fig. 8, sources close to 3 yr from the merger are detectable up to large distances if $\mathcal{M}_c \geq 100M_\odot$.

⁶The specific fitting function consists of the product of three polynomials accounting separately for the effect of the parameters most correlated with the difference between realistic and approximate SNR: one of degree 6 for the inclination, one of degree 6 for the ecliptic latitude, and one of degree 4 for the residual log-time-to-coalescence.

Figure 8: Comparison of LISA and LVK sensitivities in the (\mathcal{M}_c, z) plane. Black (purple, teal) lines denote the detectability horizon of LISA with a threshold SNR of 8 for sources with fixed residual time-to-merger of $\tau_c = 3$ yr ($\tau_c = 10$ yr, $\tau_c = 20$ yr). Solid (dotted and dashed) lines denote sources whose orbital plane is inclined at 0 deg, 45 deg, and 90 deg, respectively. The orange shaded regions denote the detectability horizon of the LVK detector network at design sensitivity, with an SNR threshold of 14, corresponding approximately to three single SNRs = 8. These orange regions are computed by omitting sources above $1000 M_\odot$ as their SNRs heavily depend on the LVK detectors’ stability at very low frequencies below 10 Hz; the Gaussian smoothing introduces the small tail visible in the figure. Black (purple, teal) stars denote three massive sources selected for parameter estimation at the boundaries of the LVK detectors design sensitivity, with source-frame chirp mass $\mathcal{M}_c = 1000 M_\odot$, redshift $z = 0.1$ (0.2, 0.8) and $\tau_c = 20$ yr (10 yr, 3 yr).

However, the horizon reduces to below $z \sim 0.6$ (0.25) if the same sources are observed at 10(20)yr from the merger. Such reduction originates from the signal frequency evolution over the mission duration for systems with masses below $\sim 1000 M_\odot$, exemplified by the colorful lines in Fig. 9 (see description below). The slow frequency evolution shortens the frequency support and lowers the resulting integrated SNR.

Furthermore, across all inclinations, we observe a peak at redshift $z \lesssim 0.6$ ($\lesssim 0.3$) for residual time-to-coalescence equal to 10(20) yr. Figure 9 helps clarify the origin of this peculiar structure. Therein, we pick a reference redshift equal to 0.3 and show the characteristic strain for sources with chirp mass between 5 and $5000 M_\odot$ and 4 initial times-to-coalescence. For systems that are far from coalescence, the presence of a minimum (corresponding to max-

Figure 9: Characteristic strain in LISA of sources with different residual time-to-coalescence and chirp mass. The blue line is the sum of the detector noise and the confusion noise from the Galaxy. Segments and points denote the inclination-averaged characteristic strain of 7 sources, all at redshift 0.3, with different detector frame chirp mass \mathcal{M}_c , according to the labels. Black (purple, teal) lines correspond to sources injected at a fixed time to merger of $\tau_c = 3$ yr ($\tau_c = 10$ yr, $\tau_c = 20$ yr); orange dots denote quasi-monochromatic sources very early in their inspiral phase, with $\tau_c = 300$ yr. The dip around 1000 solar masses in Fig. 8 corresponds to the amplitude of the Galactic confusion noise as a function of frequency, which dominates the instrumental noise at frequencies between 0.2 mHz and 3 mHz. The black lines extend out of the LISA band and reach their merger within the mission duration. For simplicity, no LISA response is applied when plotting the characteristic strain as the lines would become quite cluttered (see e.g. Fig.1 in [4]).

imal sensitivity) in the LISA noise curve at around 3 mHz induces the peak structure in the horizon distance plot in Fig. 8. While the signal amplitude (and thus its SNR) increases with \mathcal{M}_c , systems with masses between a few hundred and a few thousand solar masses, emit at frequencies between 0.5 and 3 mHz, where the confusion noise from Galactic binaries dominates over the instrumental noise. This additional noise source sharply increases the overall noise curve, strongly suppressing the SNR for these systems. Binaries with larger masses emit at even lower frequencies, where the confusion noise is negligible and the instrumental noise dominates the total noise budget, yielding an SNR that monotonically increases with the mass of the system. A similar peak is absent for $\tau_c = 3$ yr because the SNR is dominated by the part of the characteristic strain signal extending to high frequency.

Note that the LVK network horizon does not feature the same peak structure. Indeed, no equivalent of the Galactic foreground exists for LVK and, furthermore, every system entering the LVK frequency band merges in less than a few seconds (at the relevant masses) leading to a negligible signal duration compared to the total observing time. Finally, we highlight that the detectability of binary systems with hundreds up to thousands of solar masses is

highly dependent on the ground-based detectors' stability at and below 5 Hz. Therefore, the high-mass end of the LVK waterfall plot should be treated with caution. In Section 4, we expand on the parameter estimation accuracy for such sources by LISA.

4 Parameter estimation on representative sources

In order to assess how well LISA will be able to characterise individual sBHBs, we have also performed Bayesian parameter estimation on a sample of representative sources. We simulate and infer on the GW signals produced by each source using BALROG, following closely the procedure described in [4, 25], which we summarize here for completeness. We simulate the GW emission in the frequency domain and perform Bayesian inference on the three time-delay-interferometry (TDI) data streams $d = \{d_k; k = A, E, T\}$, in terms of which the noise covariance matrix is diagonal for an equal-arms constellation with equal noise levels in the six inter-satellite links [39–42]. The likelihood is parameterized by the 11 parameters describing individual binaries, each defined in the Solar System Barycenter frame: the chirp mass $\mathcal{M}_c = (m_1 m_2)^{3/5} / (m_1 + m_2)^{1/5}$, where $m_{1,2}$ are the binary component masses; the dimensionless mass difference $\delta\mu = (m_1 - m_2) / (m_1 + m_2)$ and the component spins $\chi_{1,2}$; the initial orbital frequency f_{orb}^0 . The intrinsic parameters are further completed by the extrinsic ones: the luminosity distance d_L , the cosine inclination ι of the binary orbital plane with respect to the line-of-sight, described by its (sine)ecliptic latitude $\sin b$ and longitude l . Finally, the GW signal is completely specified by choosing a polarization angle ψ and an initial orbital phase ϕ_{orb} . The likelihood therefore reads

$$\ln \mathcal{L}(d | \theta) = - \sum_k \frac{(d_k - s_k(\theta) | d_k - s_k(\theta))_k}{2} + \text{const}, \quad (4.1)$$

with $s_k(\theta)$ the TDI output associated to a GW signal $h(f; \theta)$. The inner product in Eq. (4.1) is defined as

$$(a | b)_k = 2 \int_{f_{\min}(\theta)}^{f_{\max}(\theta)} \frac{a_k(f) b_k^*(f) + a_k^*(f) b_k(f)}{S_k(f)}, \quad (4.2)$$

where the integration boundaries $f_{\min}(\theta), f_{\max}(\theta)$ denote the lower and upper end of the injected signal with parameters θ , spanned over the nominal LISA mission duration of 4yr (as in Eq. (2.2)). Our choice of parameterization is aimed to (partially) reduce correlations between parameters, hence speeding up the likelihood surface exploration. We set broad uniform priors on mildly constrained parameters (i.e. $\delta\mu, \chi_1, \chi_2, \cos \iota, \phi_{\text{orb}}, \psi$). For the remaining parameters (i.e. $\mathcal{M}_c, d_L, \sin b, l$ and f_{orb}^0) we choose priors small enough to keep the computational cost at a minimum, and sufficiently large to explore the posterior in the region dominated by the likelihood. This is motivated by the assumption that, in a realistic data analysis setup, a preliminary search for such signals will be available and provide rough initial guesses on the source parameters (see e.g. [43, 44]). Posterior samples for each source considered are obtained through nested sampling as implemented in NESSAI [45], and are distributed according to

$$p(\theta | d) = \frac{\mathcal{L}(d | \theta) \pi(\theta)}{\mathcal{Z}(d)}, \quad (4.3)$$

where $\mathcal{Z}(d)$ is a normalization constant dependent only on the fixed data.

We select the sources on which to run parameter estimation as follows. We first filter catalogue events with SNRs between 8 and 12, to warrant detectability, and source-frame

chirp masses between $20 M_{\odot}$ and $40 M_{\odot}$, to explore the chirp-mass range where the bulk of the sBHB population probability is (see Fig. 3). We further group the selected sources by three τ_c ranges, $\tau_c \leq 5$ yr, $5 \text{ yr} < \tau_c \leq 10$ yr, and $10 \text{ yr} < \tau_c \leq 15$ yr, respectively. Though these are not the most representative values for τ_c , as we expect most sBHBs to have higher ones (see Fig. 2), we select sBHBs closer to merger because they have the highest SNR and better chances to be multiband. For each τ_c class, we select two representative sources close to face-on or face-off ($|\cos i| \simeq 1$), and two close to edge-on ($|\cos i| \simeq 0$). Among the sources available in our catalogues, we pick those that are low on the Ecliptic plane, with $\sin b < 1/2$.

Overall, we select a set of 12 sources, whose injection parameters are listed in Table 1. The SNR cut selects, among the catalogues, sources at very low redshift overall, with larger chirp masses allowing for larger redshifts at comparable SNRs. The initial orbital frequency f_{orb}^0 tends to increase for the low chirp mass sources, to maintain them drifting (see Eq. (2.4)) and thereby place them in the higher SNR region. On the other hand, the SNR cut clearly plays a minor role in constraining the source inclination (and all the remaining parameters, for which no sizable correlation with SNR is observed).

Results of individual parameter estimations are presented in Fig. 10, Table 2 and Table 3. As expected (see [18]), LISA yields individual chirp-mass (initial orbital frequencies, residual time-to-coalescence) measurements with relative precision greater than 2×10^{-4} (9×10^{-7} , 4×10^{-4}) across all sources predicted in the catalogues, and up to 2×10^{-5} (3×10^{-7} , 3×10^{-5}) for those at less than 5 yr from merger. Indeed, the intrinsic parameters of the latter are overall better determined, because of the larger drifting within the LISA band. For sources with high and intermediate τ_c , the relative errors on \mathcal{M}_c , f_{orb}^0 and τ_c decrease with decreasing \mathcal{M}_c , due to the fact that they chirp more (f_{orb}^0 increases as shown in Table 1). At low τ_c the tendency is inverted and errors decrease with increasing chirp mass (indeed, the trend in f_{orb}^0 observed for high and intermediate τ_c sources, is no longer apparent).

On the other hand, the relative redshift errors vary between 20% and 50% across all sources, both with low and high τ_c . The inclination also does not influence the parameter estimation. Figure 10 shows the selected source parameters with respect to the 90% (and 50%) of all the detectable sBHBs in the catalogues. Their chirp mass, redshift, and residual time-to-coalescence are broadly capturing the whole population distribution. However, as a consequence of SNR selection and the chirp mass cuts described previously, they have lower mass ratios as compared to the rest of the population. From this figure, one can appreciate the exquisite precision with which both the chirp mass and residual time-to-coalescence are determined, while the redshift is measured much better for close-by sources.

To explore the high-mass region of LISA sensitivity, we additionally consider three equal-mass binary systems with source-frame chirp masses $\mathcal{M}_c = 1000 M_{\odot}$ and redshifts 0.1, 0.2, 0.8, respectively. The chirp mass is explicitly chosen at the high-end of the LVK design sensitivity, where LISA has the best chances to complement LVK detections (see Fig. 8). We choose arbitrarily to set these sources as face-on, non-spinning systems and place them at the Ecliptic north pole. The three high-mass sources appear in the LISA band at much lower frequencies than the stellar-mass ones. Being more massive, they have high SNR even though they are about a factor of 10 farther away in redshift (all 12 sources considered previously have redshifts lower than $z = 0.1$). The relative measurement precision of their chirp-mass (initial orbital frequencies, residual time-to-coalescence) is 7×10^{-4} (5×10^{-6} , 2×10^{-3}) for the two closest sources, with detector-frame chirp mass of $1100 M_{\odot}$ and $1200 M_{\odot}$, and decreases to 5×10^{-6} (9×10^{-7} , 6×10^{-6}) for the most distant source, with detector-frame \mathcal{M}_c of 1800 solar masses. The increase in mass plays therefore a dominant role in the precision of LISA

parameter estimation. The relative error on the redshift also decreases from about 25% – a precision similar to that of some catalogue sources – down to 7% for the farthest one.

In summary, we find that LISA grants a much better precision on the chirp-mass measurement than LVK (see e.g. [7]), on the sBHBs that we expect it will detect. This is true within the assumptions justifying the priors we have adopted [4, 5]. The redshift, on the other hand, is determined with similar precision, but sources detectable by LVK extend up to higher redshifts, $z \lesssim 1$. The sub-per mille precision with which LISA can measure the residual time-to-coalescence of sBHBs with $\tau_c \leq 15$ yr opens up the possibility of multiband searches. While the extremely high precision in the chirp mass measurement is not expected to revolutionise our understanding of the bulk of the sBHB population observed so far, it has a great potential for signals at the low-frequency end of the LVK design sensitivity, with $\mathcal{M}_c \sim 10^3 M_\odot$. Indeed, if such a population exists, LISA will be able to observationally characterise it and distinguish it from sBHBs with lighter masses, i.e. $\mathcal{M}_c \lesssim \mathcal{O}(10^2) M_\odot$.

5 Conclusions

In this paper we have analysed the potential of LISA to characterise the population of sBHBs observed by the LVK detector network. We have constructed synthetic catalogues of circular sBHBs, based on the POWER LAW + PEAK population inferred from the GWTC-3 catalogue, as in [6]. The distribution of source parameters follows the posteriors on the chirp mass, mass ratio and spin models detailed in [2], while the extrinsic source parameters are drawn from uniform and isotropic distributions. The sources we find detectable by LISA cluster at low redshift, and therefore the dependence of their merger rate with redshift can be approximated with a single power law, for which we have also sampled over the parameter posteriors derived in [2].

While in [6] these synthetic catalogues were used to forecast the SGWB from unresolved sBHBs in the LISA band, in this paper we have re-generated the low-redshift tail of these catalogues to use the reciprocal information that can be extracted from them, i.e. the number and characteristics of the sources resolvable by LISA. As a selection criterion for detectability, we have adopted an SNR threshold ρ_0 set at 8 for direct LISA detection, or at 6 and 4 for archival searches, assuming 4 yr of LISA mission duration operating at nominal sensitivity. We have found that the number of expected resolvable sources with $\rho_0 = 8$ has a median value of about 5. With 10% probability, this number will be higher than 10; however, with 2% probability, no sources will be detected by LISA. Decreasing the SNR detection threshold increases the number of sources: the LISA data stream is expected to contain at least 20 sources with $\rho_0 = 4$ with probability above 90%, showing that archival searches will provide a relatively high number of additional sBHB detections. For $\rho_0 = 6$, at least 5 detectable sources are expected at 90% probability, and the probability of detecting zero sources is extremely small, of the order of 0.03%.

We have also analysed the subset of sources for which multiband observations can occur within the LISA mission or shortly after. It turns out that the number of sources merging within 15 yr from the time LISA starts operating, is around a third of the total population detectable by LISA, independently of the assumed SNR threshold ρ_0 . In particular, the number of multiband detectable sources by LISA alone with $\rho_0 = 8$ is compatible with 0 at 21% probability and has a median of 2. For $\rho_0 = 6$, such a number is still compatible with zero though at 10% probability only, and has a median value of 4. It instead reaches 5 with a probability above 90% for $\rho_0 = 4$. Such sources with SNR just above $\rho_0 = 4$ or 6 cannot

Table 1: Injection parameters for the selected sources as described in Section 4. Where relevant, parameter values are specified in detector frame. For simplicity, we omit introducing new symbols for each of those.

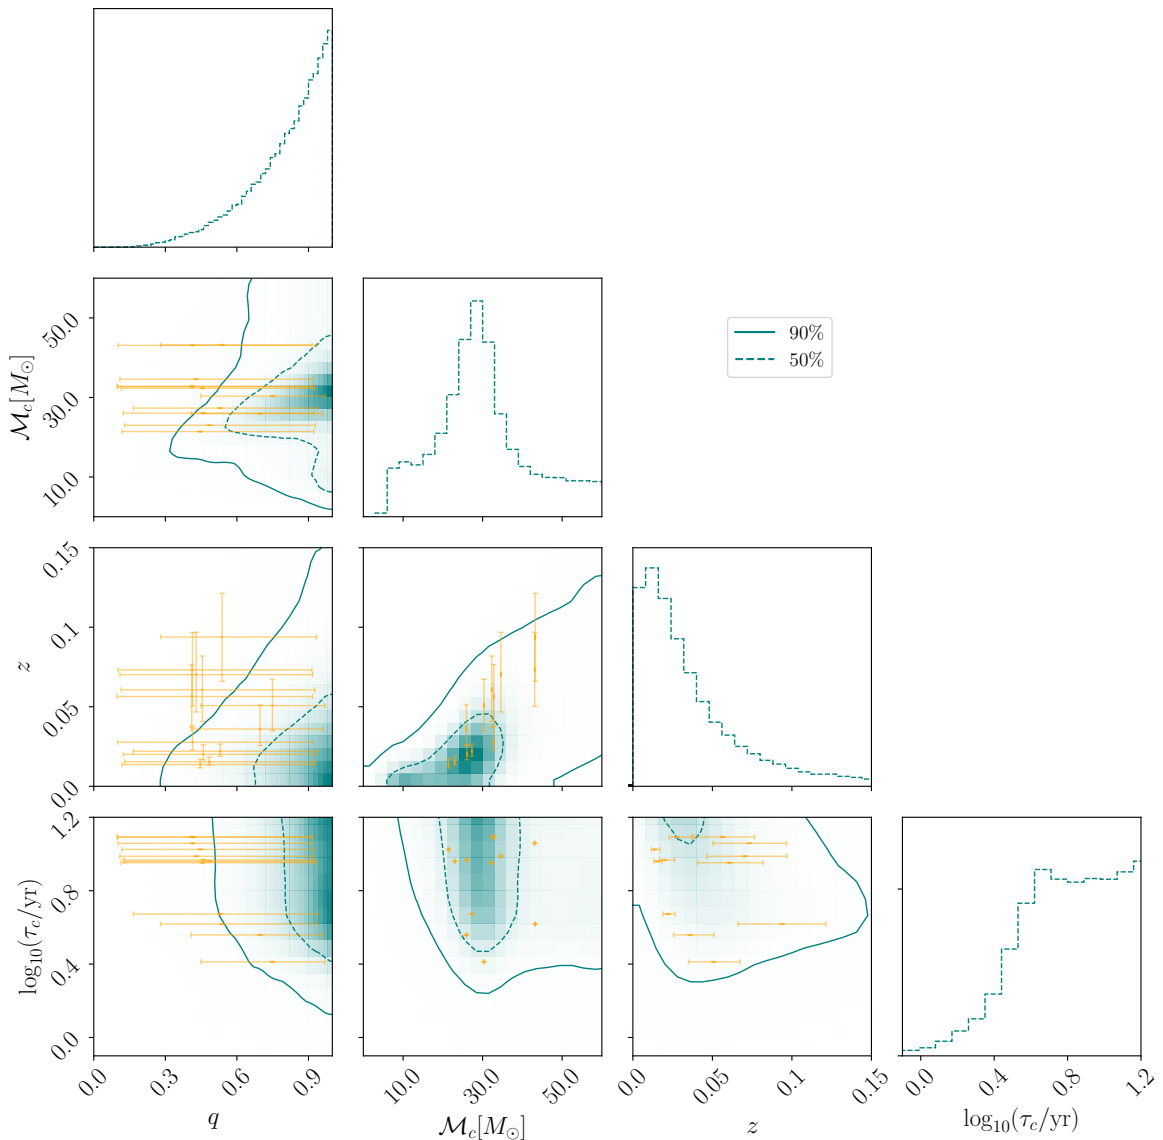

Figure 10: Results of the Bayesian parameter estimation on the set of 12 representative sources, selected from the catalogues as presented in Section 4. Yellow dots (error bars) denote the posterior median (90% confidence intervals) on each individual parameter. We focus on the best measured parameters, i.e. the chirp mass, residual time-to-coalescence, redshift, and mass ratio (see Table 2 and Table 3 for the individual parameters posterior median and uncertainties on the entire parameter set). The solid (dashed) blue lines represent the 90% (50%) contours enclosing the expected distribution of detectable sources, as in Fig. 3. The selected sources have smaller q as compared the rest of the population, due to the SNR selection and chirp-mass cuts described in Section 4. The chirp mass and residual time-to-coalescence are measured very precisely, while the redshift posterior uncertainty increases with the median redshift.

be resolved by LISA alone, but thanks to their multiband property, they are expected to be recovered through archival searches [46].

Table 2: Recovered intrinsic parameters for selected sources as discussed in Section 4. Injection parameters are listed in Table 1. Quoted fractional errors are computed as the ratio between the posterior 90% confidence intervals and corresponding median. Point estimates $m_{-\Delta l}^{+\Delta u}$ denote posterior median, upper and lower widths corresponding to 90% confidence intervals.

The number of sources itself is an important observable, though subject to large Poisson uncertainties for the highest threshold SNRs: a number of resolved signals highly inconsistent with the above predictions could hint at missing features in the sBHB population model (e.g. higher-than-expected likelihood of larger masses, local effects in the merger rate), especially when combined with the corresponding prediction for the sBHB confusion noise, which LISA should be able to measure with high precision [6] (see, however, [35]). Indeed, we have found sizable correlations between the number of detectable events in LISA and some of the population parameters, most notably a strong, negative correlation with κ , the power-law index of the merger rate dependence on redshift (a lower κ produces an excess of events at low redshift). Milder correlations appear with the power-law index of the primary mass distribution α , and with the mixture parameter λ_{peak} determining the Gaussian bump superimposed on the power law, where each of them increases the number of higher-mass sources. Remarkably, the amplitude of the sBHBs confusion noise presents similar correlations but with opposite sign, which makes a combined measurement of the number of resolvable sBHBs and their confusion noise a powerful tool to unveil the characteristics of the sBHBs population.

We have moreover shown that the subset of sBHBs detectable by LISA and compatible with GWTC-3 have chirp mass $10 M_\odot \lesssim \mathcal{M}_c \lesssim 100 M_\odot$, residual time-to-coalescence $4 \text{ yr} \lesssim \tau_c \lesssim 100 \text{ yr}$, and redshift $z \lesssim 0.1$. Hence, LISA can explore the tail of the sBHB population at very low redshift and relatively high chirp mass, towards $100 M_\odot$. Even though the number of

Table 3: Recovered extrinsic parameters for selected sources as discussed in Section 4. Quoted fractional errors are computed as the ratio between the posterior 90% confidence intervals and corresponding median. Point estimates $m_{-\Delta l}^{+\Delta u}$ denote posterior median, upper and lower widths corresponding to a 90% confidence interval.

such sources which are detectable by LISA is rather small (not surprisingly since they pertain to the tail of the distribution), their detection is still relevant and complementary to the observations available before LISA flies: LVK at design sensitivity would need an unrealistic number of observing runs to equivalently probe this region of the parameter space. This also suggests that LISA would be best equipped to characterise a population with higher chirp mass than the POWER LAW + PEAK high-mass cutoff, if it existed. To prove this, while remaining agnostic about the population, we have constructed for the first time the LISA waterfall plot for chirp mass smaller than $4 \times 10^3 M_\odot$. We found that in this range of masses it strongly depends on the residual time-to-coalescence and the source inclination. For sources remaining in band at least for the entire mission duration, as mass increases from $10 M_\odot$, SNR increases with mass, increasing in turn the reach in redshift; after a peak at $\mathcal{M}_c \sim 100 M_\odot$, the tendency inverts as the binary signal is displaced to frequencies where the Galactic foreground dominates the noise budget, reducing the source's SNR; at $\mathcal{M}_c \gtrsim 10^3 M_\odot$, the sensitivity improves again as the binary's signal mostly occur in the high-frequency part of the LISA noise curve, where the Galactic foreground is subdominant. For sources remaining in band for less than the mission duration, sensitivity grows along with chirp mass for the whole mass range, because their SNR is always dominated by the signal at high frequency. However, as already discussed, sources with such a low τ_c are extremely rare: not only they

are intrinsically less numerous, but also have smaller accumulated SNR, despite their chirping that makes detection easier.

The comparison of our LISA and LVK waterfall plots in the chirp mass region $\mathcal{O}(1) - \mathcal{O}(10^3) M_\odot$ has shown that the complementarity of the observatories mainly resides in the region $\mathcal{M}_c \gtrsim 10^3 M_\odot$, where the LVK sensitivity drops. However, by performing parameter estimation on a subset of sources selected from the catalogues (i.e. drawn from the POWER LAW + PEAK population), we have shown that LISA has great potential in characterising sBHBs with sufficiently high SNR (between 8 and 12), granting a much better precision in the parameter inference than LVK. Therefore, even if LISA measurements will not be directly informative on the population due to the very low number of resolvable sources, they can help characterising a few, low-redshift candidates with great precision.

We have reached such conclusions by performing parameter estimation on sBHBs with $\tau_c \lesssim 15$ yr and SNR above the threshold $\rho_0 = 8$. This implies the sources to be close by ($z \lesssim 0.1$) and emitting in the high-frequency part of the LISA sensitivity ($f_{\text{orb}}^0 \geq 4.4$ mHz). The selected sources turn out to be characterised with exquisite precision. As far as the chirp mass, initial orbital frequency and residual time-to-coalescence are concerned, their relative reconstruction errors are all below the per-mille level by at least one order of magnitude. For sources with $\tau_c < 10$ yr, the residual time-to-coalescence can be reconstructed with an uncertainty of a few hours, showing that multiband detection can be feasible at a sensitivity similar to current ground-based interferometers, such that not many sources are expected to be detectable over that time interval.

Additionally we explore the sensitivity of LISA to a population of sources with intermediate values of the chirp mass $\mathcal{M}_c = \mathcal{O}(10^3) M_\odot$, by analysing three representative sources with $\mathcal{M}_c = 10^3 M_\odot$ and $z = 0.1, 0.2$ and 0.8 , to which LVK is not sensitive. The outcome is that LISA can reconstruct the chirp mass and residual time-to-coalescence of these sources with relative error below the per-mille level, and down to $\mathcal{O}(10^{-6})$ for the source with $z = 0.8$, for which redshift can be determined down to a precision of 7%. Therefore, if such a population exists, LISA will be able to fully characterise it and distinguish it from the sBHBs probed by LVK.

In this paper we have restricted the analysis to the LISA nominal mission duration of 4 yr, and assumed LVK network to have design sensitivity. Nevertheless, it is certainly worth extending our analysis to longer mission times and the co-existence of Einstein Telescope and Cosmic Explorer, which are expected to be much more sensitive than LVK to the high-mass tail of the sBHB population. It would also be of great interest to revise the sBHB-related science that LISA can achieve, using our catalogues. Several tests for general relativity and cosmography with LISA have been proposed [13, 14], but their expected outcome strongly depends on the properties and number of the sBHBs that LISA can resolve. Our priority in the short-term future is to account for the next LVK sBHB population inference analysis, which may provide surprises. These are not expected to modify the qualitative conclusions of the present paper, but with small adjustments to the methods and codes described here, we can readily obtain reliable, quantitative updates.

The full set of synthetic populations generated for and used in this work, together with a Python notebook demonstrating parts of the present analysis, is available at <https://zenodo.org/records/13974091> [31].
