ABSTRACT

Context. Recent high-redshift ($z > 4$) spatially resolved observations with the James Webb Space Telescope have shown the evolution of the star formation rate (SFR) surface density (Σ_{SFR}) and its main sequence in the $\Sigma_{\text{SFR}}-M_*$ diagram ($\Sigma_{\text{SFR}}\text{MS}$). The $\Sigma_{\text{SFR}}\text{MS}$ is already observed at cosmic morning ($z \sim 7.5$). The use of Σ_{SFR} is physically motivated because it is normalized by the area in which the star formation occurs, and this indirectly considers the gas density. The $\Sigma_{\text{SFR}}-M_*$ diagram has been shown to complement the widely used (specific) SFR- M_* , particularly when selecting passive galaxies.

Aims. We establish the Σ_{SFR} evolution since $z = 12$ in the framework of the L-GALAXIES2020 semi-analytical model (SAM), and we interpret recent observations.

Methods. We estimated $\Sigma_{\text{SFR}}(-M_*)$ and the cosmic star formation rate density (CSFRD) for the simulated galaxy population and for the subsamples, which were divided into stellar mass bins in the given redshift.

Results. The simulated Σ_{SFR} decreases by ~ 3.5 dex from $z = 12$ to $z = 0$. We show that galaxies with different stellar masses have different paths of Σ_{SFR} evolution. We find that $\Sigma_{\text{SFR}}\text{MS}$ is already observed at $z \sim 11$. The simulated $\Sigma_{\text{SFR}}\text{MS}$ agrees with the observed one at $z = 0, 1, 2, 5$, and 7.5 and with individual galaxies at $z > 10$. We show that the highest $\Sigma_{\text{SFR}}\text{MS}$ slope of 0.709 ± 0.005 is at $z \sim 3$ and decreases to $\sim 0.085 \pm 0.003$ at $z = 0$. This is mostly driven by a rapid decrease in SFR with an additional size increase for the most massive galaxies in this redshift range. This coincides with the dominance of the most massive galaxies in the CSFRD from the SAM. Observations show the same picture, in which the Σ_{SFR} evolutionary path depends on the stellar mass, that is, more massive galaxies have higher Σ_{SFR} at all redshifts. Finally, using the slope and normalization evolution, we derived the simulated $\Sigma_{\text{SFR}}\text{MS}$ as a function of stellar mass and redshift.

Key words. Galaxies; Galaxies: evolution; Galaxies: fundamental parameters; Galaxies: high-redshift

1. Introduction

The rate at which a galaxy forms stars is one of the most fundamental parameters providing insight into the assembly history of cosmic mass. The Schmidt-Kennicutt law (Schmidt 1959; Kennicutt 1998) shows a correlation of the star formation rate (SFR) with the density of the gas that is used to form stars, from which the SFR-stellar mass M_* correlation follows. Many studies showed a tight sequence in the SFR- M_* diagram that is called star formation main sequence (SFMS) in optically selected star-forming galaxies (SFGs; Brinchmann et al. 2004; Noeske et al. 2007; Speagle et al. 2014; Nadolny et al. 2023), in very low-mass SFGs (Nadolny et al. 2020), or in infrared selected SFGs (Michałowski et al. 2012, 2017; Koprowski et al. 2014, 2016; González-Otero et al. 2024). Another way of expressing the star formation activity is via the specific SFR (sSFR), which is the SFR normalized by the stellar mass. The sSFR- M_* relation indicates the recent level of SF (including quenched SF), and similarly to the SFMS, it also evolves with cosmic time. The overall

cosmic SFR density (CSFRD; Madau & Dickinson 2014; Zavala et al. 2021) has also been shown to evolve and to reach its maximum at $z \sim 2$, with a steady decay with increasing redshift (Bouwens et al. 2022; Donnan et al. 2024).

In recent years, another more physically motivated parameter related to SF emerged (Wuyts et al. 2011; Salim et al. 2023; Calabrò et al. 2024). This is the SFR surface density, which is defined as $\Sigma_{\text{SFR}} = \text{SFR}/(2\pi R_e^2)[M_\odot/\text{yr}/\text{kpc}^2]$, where R_e is the radius of a galaxy (half-light radius in this work). This parameter is more fundamental than other SF tracers because it is normalized by the extent of the star-forming region. Salim et al. (2023) showed that Σ_{SFR} complements the sSFR, particularly when passive galaxies are selected (because a galaxy with a constant SFR decreases in sSFR by definition). Its relation to the molecular gas density and the effectiveness of stellar feedback (Salim et al. 2023) also has a much deeper physical justification. The Σ_{SFR} has been found to increase by almost four orders of magnitude between $z = 0$ and 10 (Wuyts et al. 2011; Calabrò et al. 2024).

Similar to the SFMS, a tight relation (or main sequences) in the $\Sigma_{\text{SFR}}-M_*$ diagram was found for SFGs ($\Sigma_{\text{SFR}}\text{MS}$). Several works (Wuyts et al. 2011; Salim et al. 2023; Calabrò et al. 2024) showed the increasing normalization of $\Sigma_{\text{SFR}}\text{MS}$. Salim et al. (2023) reported an increasing slope at $z = 1$ and 2 caused by the fast bulge-mass build-up in the most massive galaxies, while Calabrò et al. (2024) observed the $\Sigma_{\text{SFR}}\text{MS}$ at $z \sim 5$ and 7.5. The Σ_{SFR} measurement of high- z compact star-forming nitrogen-rich galaxy (Schaerer et al. 2024) suggests that it may be useful to select this rare galaxy population.

Recent works on magnetohydrodynamics simulations (e.g. Girma & Teysier 2024) reproduced the observed Σ_{SFR} at the high spatial resolution (tens of parsecs) in striking exactitude. These simulations lacked the volume needed to provide a statistically significant evolution of Σ_{SFR} , however.

The successes of L-GALAXIES2020 semi-analytic models (SAMs) in predicting many observables (Henriques et al. 2020; Parente et al. 2023, 2024; Nadolny et al. 2024; Wang & Peng 2024) showed that the combination of resolution and statistical completeness of these simulations are adequate for drawing important conclusions about the evolution of Σ_{SFR} . This is the first study of Σ_{SFR} and the $\Sigma_{\text{SFR}}\text{MS}$ evolution of galaxies divided by their stellar mass using an SAM.

We probed the evolution of Σ_{SFR} and $\Sigma_{\text{SFR}}\text{MS}$ since cosmic dawn from $z = 12$ to $z = 0$ using SAM L-GALAXIES2020, which places low-, intermediate, and (very) high- z (up to 14) observations in perspective. In particular, we investigated the Σ_{SFR} evolution of galaxies divided into stellar mass bins, following the analysis of the $\Sigma_{\text{SFR}}\text{MS}$ evolution. We explored the possible physical causes of the slope increase in $\Sigma_{\text{SFR}}\text{MS}$ observed at z between 4 and 1. We show that the stellar mass and SFR are the fundamental parameters that define the different evolutionary paths of the simulated galaxy population.

This paper is organized as follows. Section 2 describes the data from the literature and the SAM. In Section 3 we present our results. Section 4 presents the discussion and conclusions of this work. Throughout this paper, we use a cosmological model with $h = 0.673$, $\Omega_\Lambda = 0.685$, $\Omega_m = 0.315$ (Planck Collaboration et al. 2014), and the Chabrier (2003) initial mass function (IMF), as assumed in the applied SAM.

2. Data

2.1. L-GALAXIES2020 semi-analytic model

We used the L-GALAXIES2020 SAM presented in Parente et al. (2023), which is an extended version of the latest public release of the Munich SAM for galaxy evolution (Henriques et al. 2015, 2020). This SAM accounts for a detailed dust production and evolution, and it includes an updated treatment of disk instabilities. The L-GALAXIES2020 model starts from the dark matter (DM) halo merger trees of the MILLENNIUM simulation (Springel et al. 2005) and populates them with baryons according to a number of important physical processes. Among these are gas infall into DM halos, gas cooling, disk and bulge formation, star formation, merger-driven starbursts, chemical enrichment, energetic feedback from stars and supermassive black holes (SMBHs), and environmental processes such as ram pressure and tidal stripping. We refer to the supplementary material of Henriques et al. (2020) and to Parente et al. (2023) for a detailed description of this SAM.

We used StellarHalfLightRadius as the effective radius R_e . The implemented star formation law is based on the H_2 sur-

face density (Bigiel et al. 2011; Leroy et al. 2013) and a Chabrier (2003) IMF was adopted.

2.2. L-GALAXIES2020 sample selection

To analyze Σ_{SFR} and $\Sigma_{\text{SFR}}\text{MS}$ from $z \sim 12$ to $z = 0$, we used the whole simulated galaxy population with $M_* > 10^8 M_\odot$. This is a statistically significant sample at all redshifts (the sample size in each snapshot is given in Tab. 2). Additionally, we divided the galaxies into stellar masses bins: between 8 and 9, 9 and 10, and above 10 in $\log(M_*/M_\odot)$.

2.3. Observational data

We used a compilation of the high- z JWST data from the CEERS (Finkelstein et al. 2023) and GLASS (Treu et al. 2022) surveys presented in Calabrò et al. (2024); massive dusty star-forming galaxies from RUBIES (de Graaff et al. 2024); massive ($M_* > 10^{11} M_\odot$) extended red dots (Gentile et al. 2024) from COSMOS-Web (Casey et al. 2023); and the SFG (Lines et al. 2024) from the CRISTAL-ALMA survey (PI: Rodrigo Herrera-Camus). We also included low- z mean values from the GAMA survey (Smith et al. 2011; Driver et al. 2011, 2016; Baldry et al. 2018), from the COSMOS survey (Scoville et al. 2007; Weaver et al. 2022), and from the low-mass [OII] emitters at $z = 1.4$ (Cedr es et al. 2021) from the OTELO survey (Bongiovanni et al. 2019). We also included observations of intermediate- z objects from Williams et al. (2021) and Rupke et al. (2023). Finally, we also used the $\Sigma_{\text{SFR}}\text{MS}$ estimated by Salim et al. (2023) at $z = 0, 1$, and 2. Regarding very high- z (> 10), we show galaxies from JADES (Eisenstein et al. 2023), in particular, GS-z14-0 (Carniani et al. 2024), GHZ2 (Castellano et al. 2024), and GNz11 (Tacchella et al. 2023) at $z \sim 14, 12$, and 11, respectively.

We estimated Σ_{SFR} consistently (i.e., using the half-light radius R_e and the SFR based on the same IMF) in the SAM, the GAMA survey, and in the data from Williams et al. (2021), Gentile et al. (2024), Carniani et al. (2024) and Tacchella et al. (2023). The remaining works give estimates of Σ_{SFR} using the same IMF and size estimates (half-light radii R_e ; see Salim et al. 2023 for a discussion of the differences between the use of R_e and isophotal size). While the $\Sigma_{\text{SFR}}\text{MS}$ normalization changes for different size estimates and the scatter increases for R_e , the slopes of the obtained $\Sigma_{\text{SFR}}\text{MS}$ are consistent in a given redshift (Salim et al. 2023). This does not influence our conclusions, however, because we consistently used the same size estimates in the simulated data and observational results from the literature. Finally, we used the same stellar mass bins as for the simulated sample.

3. Results

3.1. SFR surface density in stellar mass bins

The evolution of Σ_{SFR} with the redshift of the L-GALAXIES2020 subsamples divided into stellar mass bins is shown in Figure 1 (bins with more than ten objects are shown). The overall Σ_{SFR} decreases from $\sim 60 M_\odot/\text{yr}/\text{kpc}^2$ at $z = 12$ to ~ 0.05 at $z = 0$. The intermediate-mass and massive (blue and red squares) simulated galaxies follow a similar trend as the overall L-GALAXIES2020 sample (black squares) up to $z \sim 4$. Above this redshift, the Σ_{SFR} of the most massive galaxies continue to increase and reach values of $\sim 40 M_\odot/\text{yr}/\text{kpc}^2$ (at $z \sim 7$); this is ~ 1 dex above the overall galaxy sample. The intermediate-mass subsample is also above the overall sample (~ 0.5 dex) and shows a milder increase

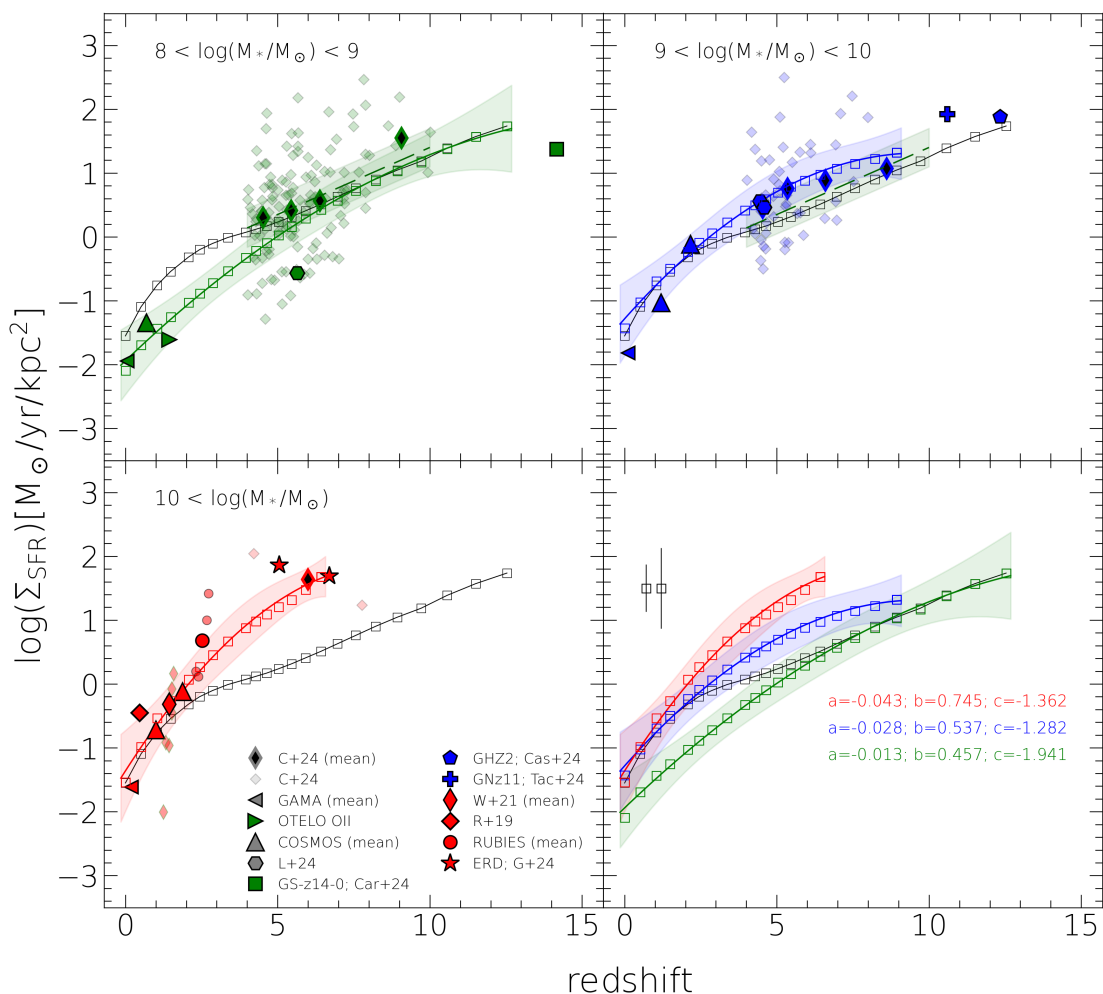

Fig. 1: Star formation rate surface density Σ_{SFR} as a function of redshift. The empty black squares show the median values for all the galaxies from L-GALAXIES2020 with $M_* > 10^8 M_\odot$. The empty green, blue and redsquares show the median values for the L-GALAXIES2020 sample divided into stellar mass bins with $\log(M_*/M_\odot)$ between 8 and 9, 9 and 10, and above 10. The lines of the same colors are the second-degree polynomial, and the coefficients are given in the bottom right panel. We show the observational data described in Section 2.3, color-coded by their stellar mass, indicated at the top of each panel. The Calabrò et al. (2024) mean values are shown in bins of stellar mass and redshift, and individual galaxies are shown as small diamonds. The dashed green line (only in the top panels) shows the fit from Calabrò et al. (2024). The values of the median of L-GALAXIES2020 SAM are given in Table 1.

than the most massive sample. The low-mass galaxies show a constant decrease in Σ_{SFR} with cosmic time since $z = 12$. They are the only subsample to reach beyond $z \sim 9$. We show second-degree fits to the subsamples with the coefficients given in Figure 1, and in Table 1 we list the median values of Σ_{SFR} for three simulated stellar mass bins.

The observational data from the literature are spread around the median values from the simulations. The fit from Calabrò et al. (2024) runs parallel to (and between) the mean L-GALAXIES2020 points for low- and medium-mass galaxies. We note that virtually all (except for two) galaxies from Calabrò et al. (2024) have stellar masses below $10^{10} M_\odot$. We further show the median values for their galaxies divided into stellar mass bins. These are found within the 2σ dispersion of the fitted function using simulated data for a particular stellar mass bin. This is also true when we consider individual galaxies (color-coded by the stellar mass). The spread is larger in this case, but the overall picture is that more massive galaxies have higher Σ_{SFR} throughout virtually the whole redshift range.

3.2. SFR surface density main sequence

We focus below on the evolution of $\Sigma_{\text{SFR}}\text{MS}$ from $z = 11$ to $z = 0$ in the stellar mass range as shown in Figure 2. The fit to the selected low- z simulated galaxies agrees with $\Sigma_{\text{SFR}}\text{MS}$ at $z = 0$ and 1 (Salim et al. 2023). As shown in Figure 2, our $\Sigma_{\text{SFR}}\text{MS}$ at $z = 0$ and 1 are within the 0.5 dex scatter of the Salim et al. (2023) $\Sigma_{\text{SFR}}\text{MS}$ with similar slopes. In the case of $\Sigma_{\text{SFR}}\text{MS}$ at $z = 2$, the slope from Salim et al. (2023) is similar to the simulated $\Sigma_{\text{SFR}}\text{MS}$ at $z = 2$, but with a lower normalization by ~ 0.5 dex. Only 15% of the $z = 2$ sample from Salim et al. (2023) have spectroscopic redshifts, which may increase the uncertainties of the estimated parameters. At the same redshift, we show four massive ($> 10^{11} M_\odot$) dusty SFGs from the RUBIES survey (Cooper et al. 2024, in green). These are above the $\Sigma_{\text{SFR}}\text{MS}$ from Salim et al. (2023), but agree with the extrapolation of $\Sigma_{\text{SFR}}\text{MS}$ derived in this work. The observed $\Sigma_{\text{SFR}}\text{MS}$ at $z = 5$ and 7.5 from Calabrò et al. (2024) both agree with the simulated $\Sigma_{\text{SFR}}\text{MS}$ at the same redshifts, except for the low-mass end at $z = 5$, where

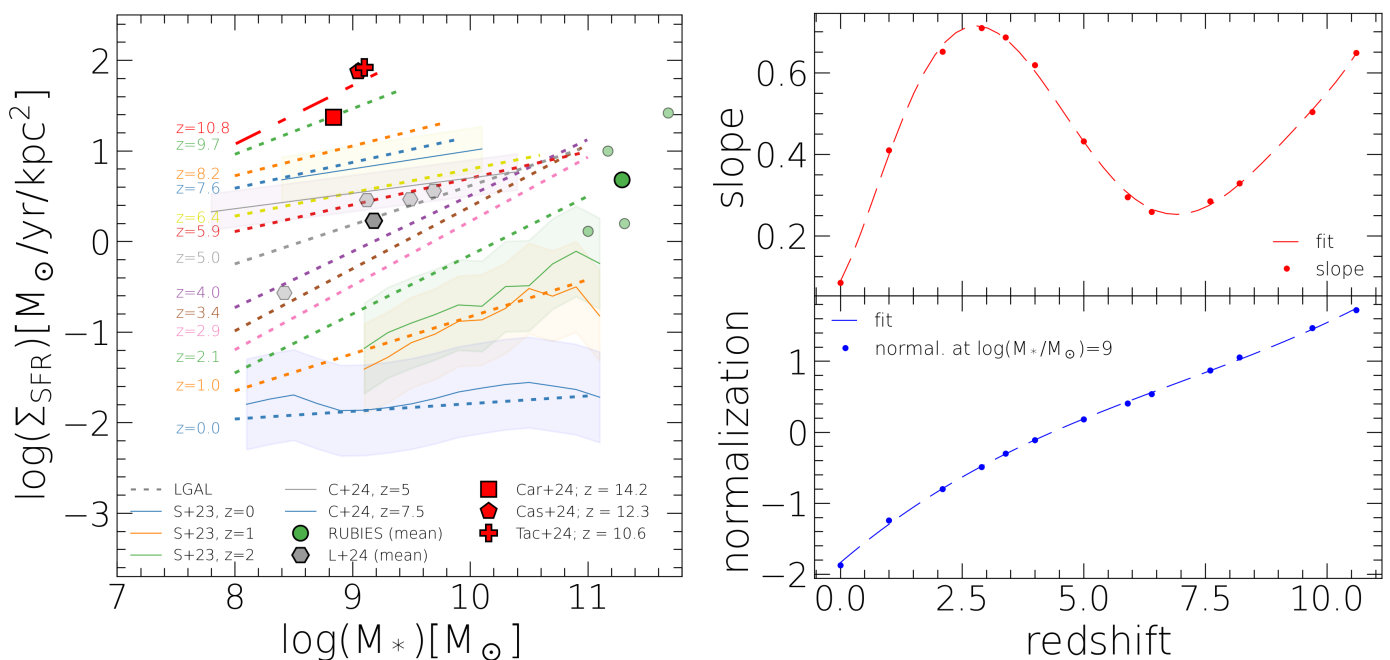

Fig. 2: Star formation surface density Σ_{SFR} main sequence (Σ_{SFRMS}). The dotted lines show Σ_{SFRMS} estimated using simulated galaxies from L-GALAXIES2020 at a given redshift from $z = 0$ up to $z \sim 10.8$ (the last dot-dashed fit includes three snapshots to increase the sample size; see Tab. 2). The colors indicate the (mean) redshift of the points corresponding to the Σ_{SFRMS} with the same color. Salim et al. (2023) Σ_{SFRMS} at $z = 0, 1, 2$, and Calabrò et al. (2024) at $z = 5$ and 7.5 are shown with solid lines in blue, orange, green, purple, and yellow with the corresponding scatter and within the stellar mass range studied in their work. The markers show individual intermediate- and high- z galaxies. Right panel: Evolution of the slope and normalization of the estimated Σ_{SFRMS} . The polynomial coefficients are given in Equations 1 and 2.

the observed Σ_{SFR} are ~ 0.5 dex higher. As noted in Calabrò et al. (2024), this may be caused by excluding the diffuse warm ionized gas and/or collisional extinction, which may contribute to the $\text{H}\alpha$ emission and lead to overestimating the SF. The data in Calabrò et al. (2024) were moreover binned over a wide range of redshifts (4 to 6, and 6 to 10), which may also cause the observed difference. A smaller range would considerably reduce the number of sources in the narrower bins. Finally, we show individual galaxies at redshift 4.5 and above 10. These are found around (within 0.4 dex) the simulated Σ_{SFRMS} at a given redshift.

The general trend of an increasing normalization in Σ_{SFRMS} with redshift is visible in L-GALAXIES2020 (right panel in Fig. 2). This increase in normalization at the most basic level is due to the overall decrease in the galaxy sizes for increasing SFRs with redshift (Fig. 3, top right, and bottom left panels). Since the Σ_{SFR} is proportional to SFR and inversely proportional to the square of the size of a galaxy, changes in these two parameters work toward increasing Σ_{SFR} with redshift.

The Σ_{SFRMS} rises rapidly between $z = 1$ and 3. This rise was pointed out by Salim et al. (2023). They suggested that the bulge build-up in more massive galaxies (or being more compact) caused this increase in the slope, up to $z = 2$ in their work. Here, the highest slope of 0.71 was found at $z = 2.9$, which roughly corresponds to the peak of the CSFRD. As shown in Figure A.1, for $z < 4.5$, the most massive galaxies begin to dominate the CSFRD (see Appendix A for more details and a comparison with observations). At the same redshift, we also find that the most massive galaxies show the fastest evolution of Σ_{SFR} (Fig. 1). All these pieces of evidence indicate that the most massive galaxies (and in particular, the drastic drop in SFR) cause the change in the slope of Σ_{SFRMS} . Stated differently, the

star-forming activity in most massive galaxies has dropped more than in less massive galaxies since $z \sim 3$. We discuss the possible cause of this slope evolution in the next section.

Using the slope and normalization evolution with redshift (see the right panel of Fig. 2), we derived the redshift-dependent Σ_{SFRMS} evolution. First, using the polynomial function, we estimated the evolution of the slope and the normalization with redshift. For the slope, we obtained a sixth-degree polynomial,

$$y_{\text{slope}} = 3.8972 \times 10^{-5} \times z^6 - 0.001401 \times z^5 + 0.01848 \times z^4 - 0.1024 \times z^3 + 0.1688 \times z^2 + 0.2272 \times z + 0.0877, \quad (1)$$

and for the normalization [evaluated at $\log(M_*/M_\odot)=9$], we obtained a third-degree polynomial,

$$y_{\text{norm.}} = 0.002315 \times z^3 - 0.04812 \times z^2 + 0.5879 \times z - 1.8406, \quad (2)$$

where z is redshift. The slope and normalization evolution are shown in the right panel of Figure 2. Finally, using these, we derived the Σ_{SFRMS} as a function of stellar mass and redshift in the form

$$\log(\Sigma_{\text{SFR}}) = y_{\text{slope}}(z) \times [\log(M_*/M_\odot) - 9] + y_{\text{norm.}}(z), \quad (3)$$

where y_{slope} and $y_{\text{norm.}}$ are the functions of redshift given in Equation 1 and 2.

3.3. The cause of the slope evolution

We investigated what might cause the slope decrease between $z = 4$ and 1. To verify whether the slope of the Σ_{SFRMS} changes

Table 1: $\log(\Sigma_{\text{SFR}})$ -redshift evolution for the stellar mass bins shown in Figure 1.

Notes. Σ_{SFR} is given in units of $M_{\odot}/\text{yr}/\text{kpc}^2$. The uncertainties represent the 1σ dispersion of the points in a particular redshift and stellar mass bin.

due to the bulge build-up in massive galaxies (as suggested by Salim et al. 2023), we considered the evolution of the bulge-to-total mass ratio (B/T) in stellar mass bins shown in the top left panel of Figure 3. For massive and intermediate-mass galaxies, their B/T increases similarly between $z = 4$ and 2. Later, below $z = 2$, the most massive galaxies build their bulges in a pronounced manner to $z = 0$. The low-mass galaxies have a low ($< 20\%$) bulge contribution to the total mass. The top right panel Fig. 3 shows a distinct R_e evolution for all three stellar mass bins in the same redshift range. The most massive galaxies increase their size by $\sim 200\%$ from $z = 4$ to $z = 0$, while the intermediate- and low-mass galaxies increase their sizes by $\sim 160\%$ in the same z range.

We then considered the changes in SFR (bottom left panel Fig. 3). In the same redshift range, there is a drop of $\sim 5000\%$ (1.9 dex), $\sim 2000\%$ (1.3 dex), and $\sim 1500\%$ (1.2 dex) for massive, intermediate-, and low-mass galaxies. Thus, the change in Σ_{SFR} mostly depends on the changes in SFR, at least since $z \sim 4$, while the change in R_e also increases Σ_{SFR} . The slope of $\Sigma_{\text{SFR}}\text{MS}$ at $z > 4$ is lower, and we can also observe a much slower SFR evolution in the most massive and intermediate-mass galaxies.

Thus, even if Σ_{SFR} is inversely proportional to the square of the size, the much greater changes in SFR (for the most massive galaxies in particular) drive the slope evolution with redshift between $z = 4$ and 1. The bulge build-up alone is not sufficient to explain the slope evolution.

Considering the slope increase between $z = 7.5$ and 3 (Fig. 2), we find that the appearance of the most massive highly star-forming galaxies seems to cause this. These massive galaxies with SFRs 1 dex higher than the lower-mass galaxies (at $z \sim 7$)

 Table 2: Results of the $\Sigma_{\text{SFR}}\text{MS}$ fitting.

Notes. a and b are the slope and intercept evaluated at $\log(M_*/M_{\odot}) = 9$ of the fits in the form $\log(\Sigma_{\text{SFR}}) = a \times [\log(M_*/M_{\odot}) - 9] + b$ and shown in Figure 2. To increase the sample size for the last three snapshots, from $z = 10.6$ to 12.5, they were analyzed together, and the fit coefficients are given in the last row.

drag up the high-mass end of the $\Sigma_{\text{SFR}}\text{MS}$. This increase continues until the peak of the CSFRD at $z \sim 2.5$.

4. Discussion and conclusions

We showed the evolution of Σ_{SFR} and its main sequences $\Sigma_{\text{SFR}}\text{MS}$ since $z = 12$ to $z = 0$. This sets the evolutionary sequences for this physically motivated star formation indicator.

Considering the whole L-GALAXIES2020 population in snapshots from $z = 12$ to $z = 0$, we find the evolution of Σ_{SFR} with redshift by ~ 3 dex (considering the mean values of the whole population; black squares in Fig. 1).

The observational data from JWST at $4 < z < 10$ (Calabrò et al. 2024) agree with the simulated population with stellar masses below $10^{10} M_{\odot}$. In particular, their fit runs parallel and between our low- and intermediate-mass bins with $M_* < 10^{10} M_{\odot}$. A decrease in Σ_{SFR} from ~ 25 to $\sim 1 M_{\odot}/\text{yr}/\text{kpc}^2$ is observed from $z = 10$ to 4 (see Fig. 1). This also agrees with previous investigations of the Σ_{SFR} evolution in this redshift range using simulated CEERS light cones (Yung et al. 2022). The most massive galaxies have higher Σ_{SFR} at virtually all redshifts. Furthermore, these objects show the fastest evolution of Σ_{SFR} from $z = 4$ to $z = 0$ while dominating the CSFRD in the same redshift range (see Fig. A.1).

The simulated $\Sigma_{\text{SFR}}\text{MS}$ agree with the observed relations at $z \sim 0, 1, 7.5$. Considering the $z = 2$ $\Sigma_{\text{SFR}}\text{MS}$, the simulated MS have a similar slope but a 0.5 dex higher normalization than is observed. This difference may be due to a low number of objects with spectroscopic redshifts for the observed $z = 2$ sample (Salim et al. 2023). However, massive dusty star-forming galaxies from the RUBIES survey at $z \sim 2$ follow the simulated $\Sigma_{\text{SFR}}\text{MS}$ at this redshift. For the $\Sigma_{\text{SFR}}\text{MS}$ at $z = 5$, the simulated MS is steeper, and the low-mass end lies below the observed relation.

In the context of Σ_{SFR} and its main sequences, we showed very distant ($z > 10$) spectroscopically confirmed galaxies.

Fig. 3: Bulge-to-total mass ratio, effective radius, and SFR as a function of redshift, and SFR as a function of effective radius for simulated galaxies in three stellar mass bins as indicated in the legend. The redshifts in the right panel are shown for reference.

These follow (roughly) the evolution of Σ_{SFR} considering their stellar mass, and they are close to the predicted simulated Σ_{SFRMS} at a similar redshift. This shows the SAM success in predicting such high- z Σ_{SFR} .

We described the evolution of simulated Σ_{SFRMS} from $z = 12$ to $z = 0$ (see Fig. 2, and Tab. 2). The slope of the Σ_{SFRMS} decreases from 0.71 at $z = 2.9$ to 0.08 at $z = 0$. We found that this decrease in the slope is due to a dramatic decrease (by $\sim 5000\%$) in SFR in this redshift range for the most massive galaxies. This is a dominant factor considering that the changes in R_e are much smaller.

Finally, using the slope and normalization evolution (Eq. 1 and 2, and the right panel of Fig. 2), we provided the evolution of Σ_{SFRMS} as a function of stellar mass and redshift within the SAM framework (Eq. 3), up to $z = 10.8$ with the stellar mass ranges indicated in Table 2.

Appendix A: Cosmic star-formation rate density

The cosmic star-formation rate density (CSFRD) is shown in Figure A.1. The total simulated CSFRD has been shown to reproduce observations (Parente et al. 2023). Here we show the total CSFRD up to $z = 12$ together with the CSFRD for the three stellar mass bins. It is clear that at higher- z the low-mass galaxies dominate the cosmic SFRD, while at $z \sim 4$, the most massive galaxies take over the low and mid-mass galaxies leading to the peak of CSFRD at $z \sim 2$. Bouwens et al. (2022) studied obscured and unobscured CSFRD at redshift range from 2 up to 9. They showed that obscured CSFRD began to dominate the total CSFRD at $z < 4$ (see also Zavala et al. 2021), coinciding with the dominance of massive galaxies from SAM. Above that z , the obscured CSFRD drops following the mid-mass galaxies, while the unobscured CSFRD follows a milder decline, as shown by low-mass galaxies.

The total simulated CSFRD agrees with the observed SFRD from Madau & Dickinson (2014, scaled to the Chabrier 2003 IMF) up to $z = 8$. At $z > 8$ the total simulated CSFRD shows lower values compared to Madau & Dickinson (2014, already extrapolated above $z \sim 8$). The observed high- z data points from Donnan et al. (2024) show a similar drop in CSFRD below Madau & Dickinson (2014) fit. As suggested by Donnan et al. (2024), there is tentative evidence for CSFRD rapid decline at $z > 13$.

Fig. A.1: Cosmic star-formation rate density. Gray shaded region shows CSFRD from Madau & Dickinson (2014) scaled to the Chabrier (2003) IMF. Black dots and line represent a total CSFRD estimated using L-GALAXIES2020 above the stellar mass limit ($> 10^8 M_\odot$). The red, blue and green points and lines represent L-GALAXIES2020 subsamples in stellar mass bins. Diamonds show data from Bouwens et al. (2022) for total (black), unobscured (green) and obscured (red) estimates of CSFRD, with shaded regions only for visualization purposes; squares show data from Donnan et al. (2024), while the cyan square is the tentative estimates based on a scarce sample size at $z = 14.5$ from their work.
