

Critical threshold for regular graphs

Ishaan Bhadoo

Abstract

In this article, we study the critical percolation threshold p_c for d -regular graphs. It is well-known that $p_c \geq \frac{1}{d-1}$ for such graphs, with equality holding for the d -regular tree. We prove that among all quasi-transitive d -regular graphs, the equality $p_c(G) = \frac{1}{d-1}$ holds if and only if G is a tree. Furthermore, we provide counterexamples that illustrate the necessity of the quasi-transitive assumption.

1 Introduction

Consider independent (Bernoulli) bond¹ percolation on a locally finite, connected, infinite simple graph G (all graphs are assumed to satisfy these conditions unless stated otherwise), i.e. we retain edges with probability p and throw them away with probability $1 - p$.

We use \mathbb{P}_p to denote the corresponding percolation measure. An important function to consider in the context of percolation is, $\psi(p) = \mathbb{P}_p(\exists \text{ an infinite connected component})$. This leads to the definition of the critical parameter:

$$p_c := \sup\{p : \psi(p) = 0\}$$

Determining the exact value of p_c is challenging for most graphs; however for d -regular trees, one can show that $p_c = \frac{1}{d-1}$. The proof follows two steps: First, by a first-moment argument one can show that a graph G with maximal degree $d < \infty$ satisfies $p_c(G) \geq \frac{1}{d-1}$. Second, for trees with degree d , by a dual second moment upper bound we can get $p_c \leq \frac{1}{d-1}$, implying $p_c = \frac{1}{d-1}$ (see [Roc24, Claim 2.3.9] for details).

This leads to the following question: consider percolation on a d -regular graph G , are trees the only graphs with $p_c = \frac{1}{d-1}$?

The goal of this article is to show that trees are the only graphs with $p_c = \frac{1}{d-1}$ in the space of all d -regular quasi-transitive graphs. We start with some definitions. For a graph G , let $\text{AUT}(G)$ be the group of all automorphisms (adjacency preserving bijections) of G .

Definition 1. *A graph G is called quasi-transitive if the number of orbits for the action of $\text{AUT}(G)$ on G is finite. It is called transitive if there is only one orbit.*

Under the assumption of quasi-transitivity we have the following theorem:

Theorem 2. *Let G be a quasi-transitive d -regular graph. Then $p_c(G) \geq \frac{1}{d-1}$ and equality holds if and only if G is a tree.*

It is important to note that being quasi-transitive is essential. In Section 2, using the general theory for percolation on trees we give a counterexample (for each $d \geq 3$) when one drops this assumption. Next, we show the above theorem by constructing a covering of every quasi-transitive d -regular graph using regular trees and then use the strict monotonicity result of

¹Although we work with bond percolation, the same methods apply to site percolation.

[MS19]. The main tools we use are from [MS19] and [LP17]. For completeness, we cover the required background for percolation on trees and some techniques from the theory of coverings, in an effort to make this article self-contained.

1.1 Connection to the connective constant

A self-avoiding walk is a path that visits no vertex more than once. To define the connective constant, fix a starting vertex o , the set of all self-avoiding walks of length n starting at o is denoted as SAW_n . The connective constant $\mu(G)$ of a graph G is then defined as

$$\mu(G) := \lim_{n \rightarrow \infty} |\text{SAW}_n|^{\frac{1}{n}}$$

By Fekete's lemma, it can be checked that this limit exists. The connective constant is closely related to the critical threshold by the following standard lemma (see [LP17]).

Lemma 3. *For any connected infinite graph G , $p_c(G) \geq \frac{1}{\mu(G)^2}$.*

Proof. Let $\mathcal{C}(o)$ denote the connected component of o in Bernoulli percolation with parameter p . Define $S_n(o)$ as the set of self-avoiding walks of length n within $\mathcal{C}(o)$. If $\mathcal{C}(o)$ is infinite, then $S_n(o) \neq \emptyset$ for all n . From this, we deduce:

$$\mathbb{P}_p(o \leftrightarrow \infty) \leq \mathbb{P}_p[S_n(o) \neq \emptyset] \stackrel{\text{(Markov's Ineq)}}{\leq} \mathbb{E}_p[|S_n(o)|] = |\text{SAW}_n| p^n.$$

By taking n -th roots we get, $1 \leq \mu(G)p$ whenever $\mathbb{P}_p(o \leftrightarrow \infty) > 0$. In particular, this holds for $p > p_c$. \square

An analogous statement to Theorem 2 regarding the connective constant was previously shown by Grimmett and Li [GL15, Thm 4.2].

Theorem 4 (G. Grimmett, Z. Li, [GL15]). *Let $G = (V, E)$ be a d -regular quasi-transitive graph and let $d \geq 3$. We have that $\mu(G) < d - 1$ if G has cycles.*

By using Lemma 3, Theorem 2 follows. However, the techniques used in the proof of Theorem 4 are entirely combinatorial and therefore differ from our method.

2 Percolation on trees

In this section for $d \geq 3$ we give an example of a d -regular graph with cycles such that $p_c = \frac{1}{d-1}$ (such an example cannot exist for $d = 2$). To do this we use the theory of percolation on locally finite trees. We start by defining the branching number of a locally finite tree.

2.1 Branching number and the critical point for trees

Suppose $T = (V, E)$ is an infinite locally finite tree with root O . We imagine the tree T as growing downward from the root O . For $x, y \in V$, we write $x \leq y$ if x is on the shortest path from O to y ; and T_x for the subtree of T containing all the vertices y with $y \geq x$. For a vertex $x \in V$ we denote by $d(x, O)$ the graph distance from O to x . We want to understand the critical point for a tree, motivated by the comparison from Galton-Watson branching processes this naturally leads us to the study of the average number of branches coming out of a vertex which is called the branching number of a tree. To rigorously define this we use conductances and

²This also shows $p_c(G) \geq \frac{1}{d-1}$ for a graph with maximum degree d .

flows on trees. For each edge e we define the conductance of an edge to be $c(e) := \lambda^{-|e|}$, where $|e|$ denotes the distance of the edge e from the root O . It is natural to define conductances decreasing exponentially with the distance since trees grow exponentially.

If λ is very small then due to large conductances there is a non-zero flow on the tree satisfying $0 \leq \theta(e) \leq \lambda^{-|e|}$. While increasing the value of λ we observe a critical value λ_c above which such a flow does not exist. This is precisely the branching number. Specifically,

$$br(T) := \sup\{\lambda : \exists \text{ a non-zero flow } \theta \text{ on } T \text{ such that } 0 \leq \theta(e) \leq \lambda^{-|e|} \forall e \in T\}$$

By using the max-flow min-cut theorem we get that,

$$br(T) = \sup\{\lambda : \inf_{\pi} \sum_{e \in \pi} \lambda^{-|e|} > 0\}$$

Where the infimum is over all cutsets π separating O from ∞ . Using this as the definition it is easy to see that $p_c \geq \frac{1}{br(T)}$, indeed by using a first moment bound at $\lambda = \frac{1}{p}$ for $p > p_c$. By using a (weighted) second-moment method it can be shown that the reverse inequality also holds. In particular, we have the following result of Lyons.

Theorem 5 (R. Lyons, [Lyo90]). *Let T be a locally finite, infinite tree then, $p_c(T) = \frac{1}{br(T)}$ where $br(T)$ is the branching number of the tree.*

Proof: The proof essentially uses a lower bound on being connected to infinity in terms of conductances [Lyo92]. See [LP17] for the proof.

Thus, to find the critical threshold for a tree one needs to know how to compute its branching number. However, the definition of the branching number makes this in general hard, thankfully, for sub-periodic trees (defined below) we have a significantly easier method of calculating the branching number.

2.2 Superperiodic trees

For a tree T we define its upper exponential growth rate as

$$\overline{grT} := \limsup_{n \rightarrow \infty} |T_n|^{\frac{1}{n}}$$

where T_n is the number of vertices at a distance n from O . Similarly one can define the lower exponential growth rate as

$$\underline{grT} := \liminf_{n \rightarrow \infty} |T_n|^{\frac{1}{n}}$$

We say that the exponential growth rate exists if $\overline{grT} = \underline{grT}$.

We now recall the definition of subperiodic trees from [LP17]. Fix a $N \geq 0$. An infinite tree T is called N - **subperiodic** if $\forall x \in T$ there exists an adjacency preserving injection $f : T_x \rightarrow T_{f(x)}$ with $|f(x)| \leq N$ (where $|\cdot|$ is the distance from O). A tree is called **subperiodic** if there exists a N for which it is N -subperiodic. Since in general the growth rate is easier to calculate, the following theorem is the key to calculating p_c for subperiodic trees.

Theorem 6 (Subperiodicity and Branching Number, [LP17]). *For every subperiodic infinite tree T , the exponential growth rate exists and $brT = grT$.*

Figure 1: On removing the edge e we get a sub-periodic tree T with $\text{gr}T = \text{br}T = d - 1$

2.3 Non quasi-transitive counter-examples

We are now ready to give our counterexamples. Let T be a tree with root O such that every vertex in T has degree d , except two vertices X, Y that are adjacent to the root having degree $d - 1$. Hence, $T = (V, E)$ is the graph formed by all black edges shown in Figure 1. Now define $G := T \cup \{e\} = (V, E \cup \{e\})$ to be the graph obtained after adding the red edge e . We claim that $p_c(G) = \frac{1}{d-1}$.

For the tree T , $|T_1| = d$, $|T_2| = (d - 2)(d - 1) + 2(d - 2) = (d - 2)(d + 1)$, after this point every point has $d - 1$ branches coming out, so $|T_{2+n}| = (d - 2)(d + 1)(d - 1)^n$. Therefore $\text{gr}T = d - 1$.

T is clearly subperiodic since, for all x such that $d_T(x, O) \geq 2$, we have T_x is exactly T_A , allowing us to define the function $f(v) = \phi(v)$, where ϕ is the isomorphism between T_x and T_A . Thus, T is 1-subperiodic. By Theorem 6, $\text{br}T = \text{gr}T = d - 1$. Hence, $p_c(T) = \frac{1}{d-1}$.

Since T is a subgraph of G , we have $p_c(G) \leq p_c(T) = \frac{1}{d-1}$. However, G is of degree d , so by a standard first-moment bound, $p_c(G) \geq \frac{1}{d-1}$. Combining these two observations, we conclude that $p_c(G) = \frac{1}{d-1}$. Thus, G is a d -regular graph with cycles such that $p_c(G) = \frac{1}{d-1}$. Finally, the fact that G is not quasi-transitive follows from Theorem 2.

3 Proof of the Theorem

We now show that if G is a quasi-transitive, d -regular graph then $p_c(G) > \frac{1}{d-1}$. The key idea is to cover every quasi-transitive d -regular graph (with cycles) by a d -regular tree. We start by defining what a covering map means in the context of percolation, next we use the results of Martineau and Severo [MS19] about critical thresholds under coverings.

3.1 Critical points under coverings

The question of critical points under coverings was asked by Benjamini and Schramm in their celebrated paper ‘‘Percolation beyond \mathbb{Z}^d , Many Questions and a Few Answers’’ [BS96, Ques-

tion 1]. They conjectured that if G, H are quasi-transitive graphs and G covers but is not isomorphic to H and $p_c(G) < 1$ then $p_c(G) < p_c(H)$. This conjecture was resolved by Martineau and Severo [MS19]. Following their paper we set up some definitions necessary to define a covering map.

Consider a map $\pi : V(G) \rightarrow V(H)$, we say that this map is a *strong covering map* if its 1-Lipschitz (i.e. $d_H(\pi(x), \pi(y)) \leq d_G(x, y)$) and it has the *strong lifting property*: for every $x \in V(G)$, and for every neighbour u of $\pi(x)$ there is a unique neighbour of x that maps to u . Next we say that a map $\pi : V(G) \rightarrow V(H)$ has *uniformly non-trivial fibres* ([Sev20]) if there exists R such that for all $x \in V(G)$ there exists $y \in V(G)$ such that $\pi(x) = \pi(y)$ and $0 < d_G(x, y) \leq R$. We are now ready to state the main tool:

Theorem 7 (F. Severo, S. Martineau, [MS19]). *Let G and H be graphs of bounded such that there is a map $\pi : V(G) \rightarrow V(H)$ which is a strong covering map with uniformly non-trivial fibres. Then if $p_c(G) < 1$, we have $p_c(G) < p_c(H)$.*

The above result relies on the theory of enhancements. A technique first introduced by Aizenman and Grimmett [AG91] as a recipe to prove strict inequalities between critical points of graphs, and is part of a more general idea of interpolation between percolation configurations [Sev20]. For background on the technique of enhancements see [Sev20], [BBR14]. We now show that this holds for $G = d$ -regular tree and H a d -regular quasi-transitive graph with cycles. In particular, we have the following:

Proposition 8. *Let T_d be the d -regular tree and H be a quasi-transitive d -regular graph with cycles, then there exists a strong covering map π with uniformly non-trivial fibres from $V(T_d)$ to $V(H)$.*

Proof. We start by constructing a graph X from our graph H which covers H and is isomorphic to T_d . Fix a vertex $x_0 \in V(H)$. Define the vertices of X to be the non-backtracking paths $\langle x_0, x_1, \dots, x_n \rangle$ starting at x_0 (a path $\langle x_0, x_1, \dots, x_n \rangle$ is called non-backtracking if $x_{i+2} \neq x_i \forall i$). Two paths are connected in X if one is an extension of the other by an edge (this is precisely the universal cover). We claim that for a d -regular H , X is isomorphic to T_d .

The fact that X is a tree is clear since all paths are non-backtracking and start at a fix vertex x_0 . Now any point $\langle x_0, x_1, \dots, x_n \rangle$ has neighbours as $\langle x_0, x_1, \dots, x_{n-1} \rangle$ and $\langle x_0, x_1, \dots, x_n, u \rangle$ where u runs over all neighbours of x_n not equal to x_{n-1} , this shows d -regularity. Therefore $X \cong T_d$.

For the covering map we let π be the map which projects every path to its last vertex, more formally define $\pi : V(T_d) \rightarrow V(H)$ such that $\pi(\langle x_0, x_1, \dots, x_n \rangle) = x_n$ where we identify T_d with X . We now show that this is a strong covering map with uniformly non-trivial fibres.

Lipschitz property. Let $x = \langle x_0, \dots, x_n \rangle, y = \langle y_0, \dots, y_m \rangle$. We want to show that $d_H(\pi(x), \pi(y)) = d_H(x_n, y_m) \leq d_X(x, y)$. Let z be the common ancestor of x, y in X . Then $d_X(x, y) = d_X(x, z) + d_X(z, y)$. Since x is a descendant of z it is easy to see that $d_X(x, z) \geq d_H(\pi(x), \pi(z))$. Thus by the above equation $d_X(x, y) \geq d_H(\pi(x), \pi(y))$.

Uniformly non-trivial fibres. We show that there are uniformly non-trivial fibres. This is the only property that requires quasi-transitivity. Pick a $x = \langle x_0, x_1, \dots, x_n \rangle$. By quasi-transitivity, we can find a K (independent of x_n) such that there is a cycle (not necessarily simple) $C = \langle x_n, x_{n+1}, \dots, x_{n+m} = x_n \rangle$ of length $m \leq K$. If $x_{n-1} = x_{n+1}$, then $y = \langle x_0, \dots, x_{n-1}, x_{n+2}, \dots, x_{n+m} = x \rangle$ is a non-backtracking path satisfying $\pi(x) = \pi(y)$. Otherwise, consider the path $y = \langle x_0, x_1, \dots, x_{n-1}, x_n, x_{n+1}, \dots, x_n \rangle$ since $x_{n-1} \neq x_{n+1}$, this is a non-backtracking path and gets mapped $\pi(x)$.

Strong lifting property. Pick a $x = \langle x_0, x_1, \dots, x_n \rangle \in V(X)$, for any neighbour u of $\pi(x)$ we need to find a neighbour of x mapping to it. If $u = x_{n-1}$ then let that neighbour be $\langle x_0, x_1, \dots, x_{n-1} \rangle$, otherwise let it be $\langle x_0, x_1, \dots, x_n, u \rangle$.

Thus π is a strong covering map with uniformly non-trivial fibres, which shows the proposition. By our earlier comments, this also proves Theorem 2. \square

4 Concluding remarks

Even though we worked with quasi-transitive graphs, the same proof extends to graphs with *bounded local girth*. The concept of bounded local girth can be defined as follows: Consider a vertex x , define the *girth* of x as

$$L_x := \inf\{l(C) : C \text{ cycle}^3, C \ni x\}$$

where $l(C)$ is the length of the cycle C . We say that a graph G has bounded local girth if $\sup_x L_x < \infty$.

The only place where we used quasi-transitivity was to show that our map has uniformly non-trivial fibres. By bounded local girth, the same proof applies, and hence, for any d -regular graph G , we have $p_c(G) > \frac{1}{d-1}$. Therefore, trees minimize p_c in the space of all graphs with bounded local girth or no cycles.

A similar question can be asked for the uniqueness threshold p_u . Even though a theorem analogous to Theorem 7 has been established for p_u (see [MS19]), the same technique cannot be applied since $p_u(T) = 1$ for a tree T .

5 Acknowledgements

I thank Prof. Subhajit Goswami for suggesting the problem and for his guidance and comments throughout the project. This work was done as part of the Visiting Students Research Program (VSRP 2024) at the Tata Institute of Fundamental Research, Mumbai and I thank them for this opportunity.
