ABSTRACT

Triple star systems are critical for understanding stellar dynamics and compact objects in astrophysics, yet confirmed hierarchical triples identified via spectroscopy remain limited. In this study, we identified 23 triple systems by cross-matching the Gaia DR3 non-single star catalog with LAMOST DR10 spectroscopic data, 18 of them are new discoveries. For two well-observed triples, we performed radial velocity curve fitting and light curve analysis to determine their orbital parameters, with inner and outer periods of 1.26 days and 656 days for one triple, and 3.42 days and 422 days for the other. And we compared the results with other studies. We also analyzed the radial velocities (RVs) of these 23 triples, revealing a range of ΔV from approximately 40 km/s to 210 km/s. Due to spectral resolution and detection limitations, velocity differences below 45 km/s in binaries and below 90 km/s in the inner binaries of triple systems are challenging to detect. Consequently, our detection range for inner orbital periods is restricted to 0.2–20 days, with the highest efficiency for periods under 10 days. These findings underscore the advantage of spectroscopic observations for identifying triple systems with short inner orbital periods.

Keywords: Triple stars (1714); Multiple stars (1081); Radial velocity (1332); Eclipsing binary stars(444); Light curves(918)

1. INTRODUCTION

Nearly half of the stars in the Milky Way are part of binary, triple, or higher-order systems. These multi-star systems are essential for researching stellar formation, evolution, and galactic dynamics. By analysing period distributions, mass ratios and other characteristics of triple systems, we can better understand the processes behind star formation and evolutionary processes. Studying these systems also sheds light on the internal dynamics and interactions within multi-star systems, offering key insights into the formation of more complex stellar configurations (Eggleton & Tokovinin 2008; He et al. 2023).

Hierarchical triple star systems typically consist of a close binary pair with a third star orbiting the binary’s center of mass at a large distance. This configuration minimizes the gravitational perturbation from the third star on the inner binary, thus organizing the system in a hierarchical manner (Czavalinga et al. 2023). Such an arrangement allows the system to be approximated as a large orbit (the third star around the center of mass of the inner binary) encompassing a smaller orbit (the inner binary itself), facilitating the application of *Kepler’s* laws (He et al. 2023).

In addition to their unique dynamical structure, hierarchical triple systems offer new insights into several longstanding problems in stellar astrophysics. For example, they may show the origin of blue stragglers (Perets & Fabrycky 2009), help to explain the formation of Thorne–Zytkov objects (Podsiadlowski 2021), and clarify the mechanisms behind recurrent nova outbursts (Knigge et al. 2022).

Hierarchical triple systems can remain stable under certain conditions, ensuring that gravitational interactions between the stars do not lead to system disruption. Key factors for the stability of triple star systems include the hierarchical configuration, significant orbital separation, low orbital eccentricities, appropriate mass ratios, dynamical interactions such as the Kozai-Lidov mechanism and tidal forces (Eggleton & Kiseleva 1995; Toonen et al. 2016; Tokovinin & Moe 2020; Czavalinga et al. 2023; Gaia Collaboration et al. 2023a). The primary stability criterion involves the period ratio of the outer orbit to the inner orbit, which should exceed a threshold value (around 5) derived from numerical analysis (Eggleton & Kiseleva 1995). This ratio ensures that the gravitational influence of the outer star does not destabilize the inner binary. The stability conditions are described by equations that involve the critical initial period ratio ($X_{0\min}$) and the critical initial ratio between the outer orbit's periastron distance and the inner orbit's apastron distance ($Y_{0\min}$):

$$(X_0^{\min})^{2/3} = \left(\frac{1}{1 + q_{\text{out}}} \right)^{1/3} \frac{1 + e_{\text{in}}}{1 - e_{\text{out}}} Y_0^{\min} \quad (1)$$

$$Y_0^{\min} \approx 1 + \frac{3.7}{q_{\text{out}}^{-1/3}} + \frac{2.2}{1 + q_{\text{out}}^{-1/3}} + \frac{1.4}{q_{\text{in}}^{-1/3}} \frac{q_{\text{out}}^{-1/3} - 1}{q_{\text{out}}^{-1/3} + 1} \quad (2)$$

Where e_{in} and e_{out} are the eccentricities of the inner and outer orbits, respectively, and $q_{\text{in}} = \frac{M_2}{M_1}$ and $q_{\text{out}} = \frac{M_3}{M_1 + M_2}$ are the mass ratios of the inner and outer orbits. Here, M_1 and M_2 are the masses of the inner binary, and M_3 is the mass of the third star.

To better understand triple star systems, it is important to accumulate a sufficient sample of systems with orbital parameters. Detecting these systems requires the use of various observational techniques, each methods offering valuable insights into their characteristics and dynamics. Detecting triple star systems can be achieved through various observational techniques, each providing unique insights into the characteristics and dynamics of these systems. Spectroscopic methods, such as radial velocity (RV) measurements and spectral line analysis, can detect the periodic velocity changes due to mutual orbits, revealing the presence of multiple gravitationally bound stars (Raghavan et al. 2010). Tokovinin et al. (2006) found that photometric methods, including eclipsing systems and variability studies, can indicate the presence of multiple stars through characteristic dips in brightness or system luminosity variations due to mutual eclipses and stellar activity. As noted by Halbwachs et al. (2023), astrometric techniques, including proper motion and parallax measurements, can reveal deviations in the expected trajectory caused by the presence of additional stars in the system. In addition, high-precision observations and interferometry can directly resolve multiple stars in a triple system if the distances between them are sufficiently large (Kraus & Hillenbrand 2009; Merkle 1988; Duchêne & Kraus 2013; Duchêne & Kraus 2013). While gravitational wave observations are primarily associated with binary systems, Antonini et al. (2017) and Silsbee & Tremaine (2017) indicate that they can also provide indirect insights into the dynamics and masses of stars in triple systems by studying mergers of compact objects or orbital perturbations caused by additional companions. However, unlike direct observational techniques such as spectroscopy or photometry, gravitational waves have not yet offered direct evidence for the existence of a third body in these systems.

With advancements of observational techniques, the number of known triple star systems has steadily increased. Tokovinin (2018) identified 201 compact hierarchical triple (CHT) systems with outer orbital periods shorter than 1000 days, and Eggleton & Tokovinin (2008) compiled a catalog of multiple star systems. Studies also indicate that about 10% of low-mass stars are part of triple systems, with this fraction rising to nearly 50% for B-type stars (Eggleton & Tokovinin 2008, 2010; Tokovinin 2014; Sana & Evans 2011; Sana et al. 2012; Toonen et al. 2022).

The *Gaia* mission, especially its third data release (DR3), has enhanced our capacity to discover and study multiple star systems. *Gaia* DR3 provides highly accurate astrometric data for over a billion stars, including their positions, parallaxes, and proper motions. These data help identify potential multiple star systems by detecting subtle motion patterns indicative of gravitational interactions (Gaia Collaboration et al. 2023a). Among the data, a catalog of 135,760 objects with Keplerian orbital solutions has been compiled from detailed astrometric measurements. These findings, along with their related parameters, are documented in the *Gaia* DR3 non-single star (NSS) catalog, accessible through the Vizier database (Gaia Collaboration et al. 2023b). Although the NSS catalog predominantly focuses on binary systems, it can also uncover higher-order systems, like triple star systems. The *Gaia* DR3 NSS catalog not only includes multiple systems detected through astrometry, but also incorporates photometric and spectroscopic data.

In recent years, NASA’s Transiting Exoplanet Survey Satellite (*TESS*) has become instrumental in the identification and examination of triple star systems. *TESS*, initially designed to discover exoplanets, is capable of detecting photometric variations indicative of multiple star systems. The precise light curves generated by *TESS* are useful in recognizing potential triple star systems, which exhibit periodic brightness fluctuations due to stellar interactions or eclipses, providing a basis for further investigation (Ricker et al. 2015; Sullivan et al. 2015).

The Large Sky Area Multi-Object Fibre Spectroscopic Telescope (LAMOST) has conducted extensive spectroscopic observations of the northern sky. Its Medium-Resolution Spectroscopy Data Release 10 (DR10) offers a wealth of spectral information, including RVs and other stellar parameters for millions of stars (Cui et al. 2012; Luo et al. 2015; Zhao et al. 2012). By processing these spectral data in bulk, we can efficiently identify triple star systems and obtain their RV information. This process not only accelerates the detection of multiple star systems but also enhances our understanding of their dynamic characteristics.

In this study, we combined the *Gaia* DR3 NSS star catalog with the complete LAMOST-MRS-DR10 dataset to efficiently search for triple star systems. And we used *TESS* light curve data to derive the parameters for two of these 23 identified hierarchical triple systems. We also analyzed the radial velocities (RVs) for 23 triple systems, as well as the j03 triple system. Our paper is structured as follows: In Section 2, we analyze the samples obtained from matching the *Gaia* DR3 NSS catalog with LAMOST DR10 data, using spectral template matching to search for triple star systems. In Section 3, we confirm 23 triple star systems, 18 of which are newly identified. In Section 4, we perform cross-correlation function (CCF) spectral analysis, RV fitting, and light curve analysis for the identified triple systems to determine two triple’s parameters. Section 5 examines the discussion of RVs for the 23 triple systems from LAMOST and the j03 triple system. Finally, section 6 provides summary and conclusion.

2. LAMOST DATA AND TEMPLATE MATCHING METHODOLOGY

LAMOST is a 4-meter quasi-meridian reflecting Schmidt telescope situated in Hebei, China. It features a 5° field of view equipped with 4,000 optical fibers, enabling simultaneous observations of up to 4,000 targets within a 20 square degree area. The LAMOST-MRS has two arms, with the red arm covering wavelengths from 6300 to 6800 Å and the blue arm spanning 4950 to 5350 Å. We focused on the blue arm spectra to identify candidate triple star systems and measure their RVs, as it offers a greater number of absorption lines (Li et al. 2021, 2022).

Our method involves cross-matching samples from the *Gaia* NSS catalog with all LAMOST-MRS-DR10 spectra to identify a set of non-single star candidates. We then performed cross-correlation function (CCF) fitting on the spectra of the initially obtained 32,305 non-single star candidates to validate triple-star systems.

The classical definition of the CCF for stellar spectra is given by:

$$\text{CCF}(h) = \int_{-\infty}^{+\infty} f(x)g(x+h) dx \quad (3)$$

where f is the normalized spectrum, g is the normalized template spectrum, and h is the lag in km/s (Merle et al. 2017). The CCF is normalized to range from -1 to +1, where +1 indicates perfect correlation and -1 indicates complete anti-correlation. The CCF method is used in spectroscopy to detect and analyze multiple spectral lines. For example, Merle et al. (2017) first proposed this method and detected 11 triple candidates. This method has also been applied in studies such as Li et al. (2021, 2022); He et al. (2023).

Our data is derived from the blue arm spectra of LAMOST-DR10, as the blue end contains more absorption lines, making it suitable for detecting multiple candidate lines and measuring their radial velocities (RV). To address the challenge of detecting SB (spectroscopic binary) and ST (spectroscopic triple) in spectra with low signal-to-noise ratios (S/N), we selected data with an S/N greater than 20 (Fernandez et al. 2017; Li et al. 2021).

2.1. The improvement of template matching method

In most studies, the template spectrum used for CCF analysis is the solar spectrum (Li et al. 2021, 2022; He et al. 2023). We made improvements to this approach. We selected template spectra of different temperatures to match the observed spectra corresponding to various stellar temperatures.

As shown in figure 1, using only the solar template spectrum for different types of stellar spectra can result in lower CCF peak values. The figure illustrates the spectrum of a triple-star with a temperature of 7,862K, where the CCF peak obtained with the solar template spectrum is significantly lower than that obtained with a 7,850K template spectrum. We utilized the *iSpec* software to construct template spectra from LAMOST with wavelengths ranging from

4,900 to 5,300 Å, and temperatures spanning from 4,000K to 8,000K in 50K intervals, while reducing the resolution to 7,500 (Blanco-Cuaresma et al. 2014; Blanco-Cuaresma 2019). This generated a series of template spectra.

Subsequently, we performed CCF fitting using different template spectra based on the stellar temperatures to improve the accuracy of the results. As mentioned in Li et al. (2021), a constraint was set to disregard spectra with CCF values less than 0.2. For the SB3 spectra, we retained a purer sample that exhibits clear SB3 characteristics in two or more observations¹.

Figure 1. Comparison of the CCF peak values for *Gaia* DR3 2077667962475652864 using different template spectra. In the upper part of the figure shows the normalized spectra. In the lower part of the figure, we present the generated CCF, $A_1 = 0.53$, $V_1 = -131$ km/s, $A_2 = 0.48$, $V_2 = 134$ km/s, and $A_3 = 0.41$, $V_3 = 19$ km/s. The black solid line represents a template spectrum with a temperature of 7862 K, while the grey dashed line represents a CCF generated using a conventional solar spectrum template.

3. IDENTIFYING 23 TRIPLES FROM LAMOST

In section 2, we cross-matched *Gaia* NSS samples with LAMOST-MRS-DR10 spectra and performed cross-correlation function (CCF) fitting on non-single star candidates, identifying 23 triple star systems. Five triples had already been identified as SB3 systems (*Gaia* DR3 508947512847441792, *Gaia* DR3 3449039200333957248, *Gaia* DR3 798566091141562240, *Gaia* DR3 4577886588616414464, *Gaia* DR3 2077667962475652864) (Li et al. 2021).

The color-magnitude diagram for the 23 triples is shown in figure 2, where the blue dots represent all stars detected with LAMOST medium-resolution spectroscopic (MRS) data, and the red stars indicate the samples we filtered. The plot reveals that the 23 triples are situated close to the main sequence. Through the CCF analysis of the LAMOST-MRS spectra for these samples, we obtained several parameters listed in table 1, which includes the *Gaia* Source ID, Right Ascension (RA), Declination (DEC), the RV (km/s) of each component in the triple star system, and the amplitude A after CCF processing.

4. ORBITAL PARAMETERS OF TWO TRIPLE SYSTEMS

In the previous section, we identified 23 triple star systems, as summarized in table 1. In this section, we extracted spectra for triples with more than six observations. This screening resulted in two triple star systems (*Gaia* DR3 249662295687401216 and *Gaia* DR3 2077667962475652864). We discussed the two triples separately.

¹ Other samples will be discussed in next work

. All photometric data are from *Gaia* DR3.

4.1. Determination of Orbital Parameters for *Gaia* DR3 249662295687401216

4.1.1. Fitting of radial velocity (RV) curve

We used the `laspec` software package (Zhang et al. 2020, 2021a) to perform CCF analysis on the observed spectra, using the same template spectra as described previously. This method allows us to determine the RVs of each component in the triple-star systems at different BJD times, as shown in figure 3. See tables 4 in the appendix for more details.

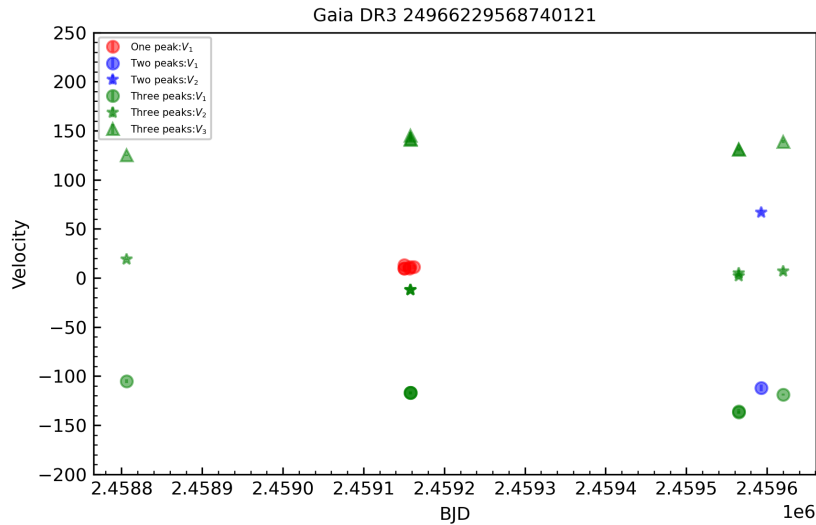

Figure 3. RV variations of the triple star system *Gaia* DR3 249662295687401216 over time. Red circles indicate spectra where CCF analysis detected only one RV. Blue circles and stars represent spectra with two detected RVs, and green circles, stars, and triangles denote spectra with three different RVs.

Given that both the outer and inner periods of the triple are known—where the outer periods are obtained from the *Gaia* NSS catalog and the inner periods are derived from *TESS* light curves (the inner and outer periods are 1.26235 days and 656.47206 days, we folded the velocity-time diagrams into phase based on these period). Figure 4 illustrates

this folding process. The black dots and red stars in figure 4 denote the velocity maps obtained after folding of the inner and outer periods, and the green points show the velocity of the inner binary’s center of mass, while the blue dashed line represents the fitted curve for the inner binary’s center of mass velocity. V_1, V_2, V_3 denote the apparent velocity profile for one period, respectively. V_1 and V_2 denote the RV curves of the primary and secondary stars in the inner binary, respectively, and V_3 represents the RV curve of the third star.

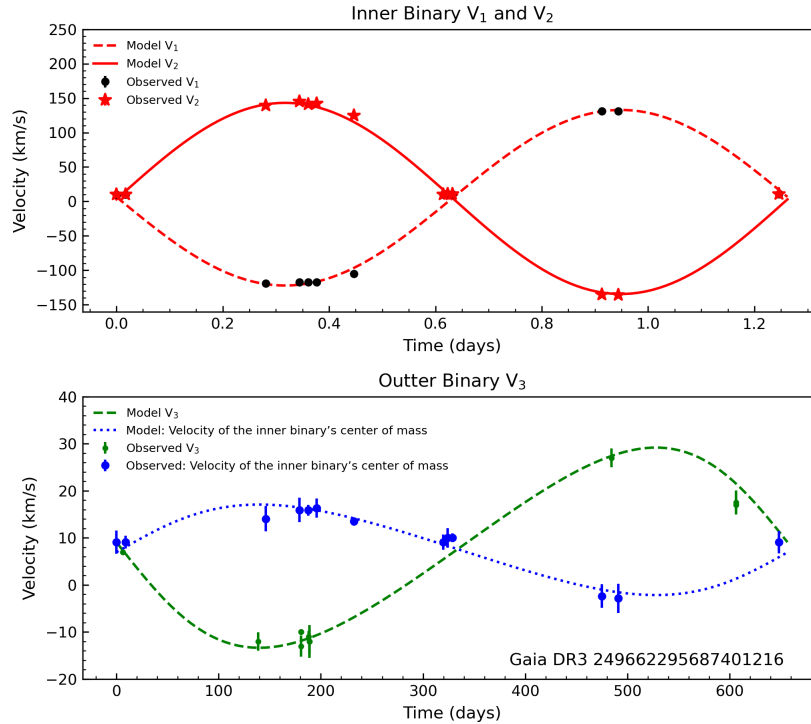

Figure 4. RV fitting for the triple star system *Gaia* DR3 249662295687401216. The black points and red stars represent the observed data after phase folding, and the red line indicates the fitted RV curve. The blue points show the velocity of the inner binary’s center of mass, while the blue dashed line represents the fitted curve for the inner binary’s center of mass velocity. The green points indicate the velocity of the tertiary star, and the green dashed line illustrates the fitted curve for the tertiary star’s velocity. V_1 and V_2 denote the RVs of the primary and secondary stars in the inner binary, respectively, and V_3 represents the RV curve of the tertiary star.

With the RV curves, we can proceed to fit these curves using the *Radvel* package (Fulton et al. 2018; Li et al. 2024) to derive various parameters. For the triple-star systems, we apply *Kepler’s* laws and classical Newtonian dynamics, treating the inner binary as a single entity due to the small ratio between the inner and outer periods. This approach allows us to calculate the orbital parameters of the center of mass of the inner binary with respect to the third star.

In the analysis, we define the likelihood function for the RV data by comparing the observed values with the model predictions. The model accounts for the contributions of each component in the triple-star system and includes an error term for each observation. Our prior distributions are as follows: for example, the RV amplitudes K_1 and K_2 of the inner binary are constrained within known ranges, the eccentricity e_2 of the outer orbit is derived from the *Gaia* NSS catalog data and its errors, and the mass ratios q_1 of the inner binary and q_2 of the third star are constrained between 0 and 1. We then use the Markov Chain Monte Carlo (MCMC; Foreman-Mackey et al. (2013)) method for parameter sampling, with 100 walkers and 50,000 iterations, where the first 5,000 iterations are designated as the burn-in phase. The initial parameter distributions are drawn from the priors. By analyzing the MCMC chains, we extract the posterior distributions of parameters such as the RV amplitudes K_b , K_c , and K_a , as well as the systemic velocity γ . We assessed the fit quality by examining the residuals between the observed data and the model predictions and calculate the logarithmic probability to ensure that the chains have thoroughly explored the parameter space and meet the constraints.

We used MCMC to determine some orbital parameters of the triple-star systems. The parameters are as follows: for the inner binary: $q_1 = 0.919 \pm 0.006$, $K_1 = 138.798^{+0.727}_{-0.749}$, $\sqrt{e_1} \cos \omega_1 = 0$, $\sqrt{e_1} \sin \omega_1 = 0.0014 \pm 0.001$; Outer binary: $\sqrt{e_2} \cos \omega_2 = -0.008^{+0.015}_{-0.008}$, $\sqrt{e_2} \sin \omega_2 = 0.144^{+0.085}_{-0.068}$, $q_2 = 0.0427^{+0.077}_{-0.068}$, $K_3 = 21.275^{+1.752}_{-1.484}$; and the system velocity $\gamma = 7.74^{+1.038}_{-0.988}$ km/s. See figures 9 in the appendix for more details.

4.1.2. Fitting of light curve

We identified the light curve of the triple-star system from *TESS* data (Ricker et al. 2015). Lomb–Scargle periodogram analysis (VanderPlas 2017) of the light curve yielded inner periods of 1.2623 days. This is consistent with the criterion of an outer-to-inner period ratio greater than 5 for triple-star systems (Eggleton & Kiseleva 1995). Subsequently, we folded the light curves to phase, as shown in figure 5. Observational data are indicated by blue points.

We then employed the PHOEBE software (Physics of Eclipsing Binaries, PHOEBE 2.26) (Prša & Zwitter 2005; Prša et al. 2016; Jones et al. 2020) to perform parameter fitting for the light curves. PHOEBE is based on the WD code by (Wilson & Devinney 1971). The eclipsing light curves constrain the inclination angle and relative radius of the secondary star with respect to the semi-major axis (Xiong et al. 2024). Given that the light curves visually resemble those of detached binaries, we applied the detached binary model. The effective temperature and surface gravity ($\log g$) of the primary star were estimated from the spectrum at the secondary eclipse minimum, where the contribution of the secondary star to the total flux is minimal. El-Badry et al. (2018) found that typical errors in effective temperature (T_{eff}) and surface gravity ($\log g$) for unresolved binaries treated as single stars are less than 200 K and 0.1 dex, respectively, for LAMOST spectra. These systematic errors are comparable to measurement uncertainties and do not significantly affect the final results for mass and radius estimates (Xiong et al. 2023).

We employed Markov Chain Monte Carlo (MCMC; Foreman-Mackey et al. (2013)) sampling in PHOEBE to solve for all orbital parameters. The following prior information was added to constrain the MCMC sampling:

1. Orbital inclination (i): $0^\circ < i < 90^\circ$
2. Temperature ratio of the secondary to the primary star: $0 < T_2/T_1 < 1$
3. Effective radius of the primary star (R_1/a): $0 < R_1/a < 1$
4. Effective radius of the secondary star (R_2/a): $0 < R_2/a < 1$
4. Third light fraction : $0 < L_3 < 1$

We used the temperature obtained from LAMOST as the fixed parameter for the primary star and performed a search with 80 walkers for 20,000 steps. The peak of the probability distribution and the standard deviation of randomly sampled points were calculated as the best-fit parameters and their uncertainties. With these parameters, we can determine the inclination, temperature ratio of the primary and secondary stars, R_1/a , R_2/a and L_3 . We adopted the third-light model ‘with third light’ in Phoebe. Figures 5 and 8 present the results obtained by fitting the light curves of this triple system using Phoebe. From figures 5, it is evident that the blue points represent the phase-folded observational data, while the yellow solid lines indicate the fitting results. The horizontal axis denotes the phase, and the fitting residuals are shown at the bottom of the figures.

Utilizing the light curves from *TESS*, we ultimately derived the following parameters: the inclination angle i is $69.854^{+0.631}_{-0.461}$, $T_2/T_1 = 0.980^{+0.007}_{-0.009}$, $R_1/a = 0.216^{+0.009}_{-0.02}$, $R_2/a = 0.206^{+0.014}_{-0.017}$, and $L_3 = 0.443^{+0.044}_{-0.046}$.

However, R_1/a and R_2/a are only the relative radii of the two stars, and accurate values for the stellar radii cannot be obtained solely from the light curve. Therefore, we can use the RV curves and the light curves to determine the parameters of the components in the triple-star systems. Using the data in the 4.1 section, we obtained the eccentricities (e_1 , e_2) and velocity amplitudes (K_1 , K_2) for the inner and outer binary stars. Combining these with the inclination obtained from the light curve, we can determine the semi-major axis a of the inner binary star using the following formula (Xiong et al. 2023; Li et al. 2024):

$$K_1 = \frac{2\pi a_1 \sin i}{P_1(1 - e_1^2)^{1/2}}, \quad (4)$$

$$K_2 = \frac{2\pi a_2 \sin i}{P_1(1 - e_1^2)^{1/2}}. \quad (5)$$

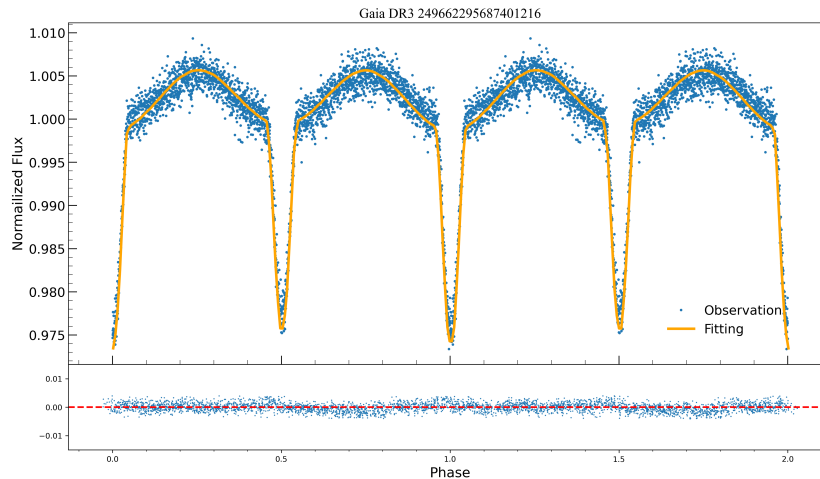

Figure 5. Light curve fitting for the triple star system *Gaia* DR3 249662295687401216. The blue dots indicate phase-folded observations, and the solid yellow line indicates the results of the fit. The horizontal axis indicates the phase, and the fitting residuals are shown at the bottom of the plot.

P_1 represents the inner period, e represents the eccentricity of the inner binary, i is the inclination of the inner binary, which can be obtained from figs. 8, and K_1 K_2 are the apparent velocity amplitudes of the inner binary, which can be obtained from Figs. 9. With the semi-major axis $a=a_1+a_2$, we can determine the radii R_1 and R_2 of the inner binary stars. Next, the masses M_1 and M_2 of the inner binary stars can be calculated using the following equations:

$$f_{\text{binary}} = \frac{M_2^3 \sin^3 i_1}{(M_1 + M_2)^2} = \frac{P_1 K_1^3 (1 - e_1^2)^{3/2}}{2\pi G} \quad (6)$$

M_1 represents the mass of the primary star in the inner binary and M_2 represents the mass of the secondary star in the inner binary. The mass of the third star can be derived from the mass ratio q_2 , and then the Roche lobe radius can be calculated using the following equation to determine whether the inner binary stars overflow their Roche lobes, and The q below represents the inner binary mass ratio M_2/M_1 :

$$\frac{R_{\text{OL}}}{a} \equiv x_{\text{OL}}(q) \approx \frac{0.49q^{2/3} + 0.27q - 0.12q^{4/3}}{0.6q^{2/3} + \ln(1 + q^{1/3})}, \quad q \leq 1, \quad (7)$$

We obtained the specific parameters for this triple, as detailed in table 2. This table presents the parameters of the hierarchical triple-star systems analyzed in this study. This system *Gaia* DR3 249662295687401216 is modeled using photometric and spectroscopic data. The parameters include the masses, temperatures, surface gravities, radii, Roche lobe radii, semi-major axes, and eccentricities for the inner and outer orbits, as well as the orbital periods.

4.2. Determination of Orbital Parameters for *Gaia* DR3 2077667962475652864

Similarly, for the *Gaia* DR3 2077667962475652864 triple system, we applied the same method by selecting the most recent spectroscopic data from the LAMOST middle-resolution spectra for analysis 4.1. Additionally, we incorporated RV data from HIDES (Helminiak et al. 2017; Pan et al. 2022). The details of the LAMOST data are provided in Table 5 in the Appendix. Using a combination of RV fitting and light curve modeling, we derived the orbital parameters of the triple system. A detailed comparison of the RV and light curve fits can be found in figures 10,11 and 12 in the Appendix. We then compared our results with Pan et al. (2022)’s work, as shown in table 3. The comparison results indicate that our findings are consistent with most aspects of previous studies. The masses values of the inner binary stars in our research are slightly higher than those reported earlier, which may be attributed to the fact that we did not apply a zero-point offset correction among the RVs (Zhang et al. 2021b).

5. DISCUSSION OF RADIAL VELOCITIES (RV) FOR THE 23 TRIPLE SYSTEMS FROM LAMOST AND THE J03 TRIPLE SYSTEM

In this section, we discussed the distribution of RVs for the 23 triple systems identified in the LAMOST dataset and discuss one triple system j03.

Table 2. Parameters of the triple star system *Gaia* DR3 249662295687401216.

Parameter	Symbol	Triple : <i>Gaia</i> DR3 249662295687401216
BJD	T_0	2450000.216 ± 0.006
Primary mass (M_\odot)	M_1	$1.844^{+0.046}_{-0.045}$
Primary temperature (K)	T_1	7862.50 ± 101.6
Primary surface gravity (log g)	$\log g_1$	$4.336^{+0.085}_{-0.078}$
Secondary mass (M_\odot)	M_2	1.694 ± 0.034
Secondary temperature (K)	T_2	7711.85 ± 122.70
Secondary surface gravity (log g)	$\log g_2$	$4.340^{+0.074}_{-0.069}$
Primary radius (R_\odot)	R_1	1.528 ± 0.14
Secondary radius (R_\odot)	R_2	$1.458^{+0.12}_{-0.12}$
Roche lobe radius (R_\odot)	R_L	2.658 ± 0.021
Semi-major axis inner (R_\odot)	a_{inner}	$7.077^{+0.036}_{-0.035}$
Inner eccentricity	e_{inner}	0.001 ± 0.0010
Tertiary mass (M_\odot)	M_3	$1.508 \pm^{+0.27}_{-0.24}$
Semi-major axis outer (R_\odot)	a_{outer}	$545.127^{+10.31}_{-9.25}$
Outer eccentricity	e_{outer}	0.144 ± 0.067
Inner period (days)	P_{in}	1.262 ± 0.0
Outer period (days)	P_{out}	656.472 ± 14.85
Inner inclination (deg)	i_{in}	69.854 ± 0.54
Outer inclination (deg)	i_{out}	89.90 ± 27.29

Table 3. Parameters of the triple *Gaia* DR3 2077667962475652864.

Parameter	Symbol	This work	Pan et al. (2022)'s work
Semi-amplitude of the third star's RV (km/s)	K_3	$30.001^{+0.049}_{-0.047}$	30.08 ± 0.08
RV semi-amplitude of the inner binary M_1 (km/s)	K_1	$91.971^{+0.16}_{-0.15}$	-
M_2/M_1	q_{in}	0.937 ± 0.003	0.939 ± 0.001
$M_3/(M_1 + M_2)$	q_{out}	0.393 ± 0.003	0.387 ± 0.005
Inner period (days)	P_{in}	3.421 ± 0.0006	3.421
Outer period (days)	P_{out}	422.559 ± 3.33 (fixed)	418.2 ± 0.20
Inner inclination incl (deg)	i_{in}	86.163 ± 0.75	85.34 ± 0.01
Outer inclination incl (deg)	i_{out}	89.90 ± 6.46	84.50 ± 1.90
Inner eccentricity	e_{inner}	0.008 ± 0.001	0.00
Outer eccentricity	e_{outer}	0.294 ± 0.0014	0.300 ± 0.002
Primary temperature (K)	T_1	6105.2 ± 149.2 (fixed)	6103
Secondary temperature (K)	T_2	5879.308 ± 155.1	5950 ± 100
System velocity (km/s)	γ	$4.582^{+0.023}_{-0.025}$	4.56 ± 0.04
Primary radius(R_\odot)	R_1	$1.098^{+0.12}_{-0.12}$	1.127 ± 0.008
Secondary radius (R_\odot)	R_2	$0.880^{+0.12}_{-0.12}$	0.963 ± 0.007
Semi-major axis inner(R_\odot)	a_{inner}	$12.076^{+0.029}_{-0.023}$	12.02 ± 0.01
Primary mass(M_\odot)	M_1	1.186 ± 0.013	1.0286 ± 0.0026
Secondary mass (M_\odot)	M_2	1.112 ± 0.010	0.9667 ± 0.0024
Primary surface gravity (log g)	$\log g_1$	$4.431^{+0.10}_{-0.10}$	4.35 ± 0.01
Secondary surface gravity (log g)	$\log g_2$	$4.596^{+0.13}_{-0.12}$	4.45 ± 0.01
Semi-major axis outer(R_\odot)	a_{outer}	$346.898^{+1.02}_{-0.93}$	329.73 ± 1.72
The third light	L_3	0.349 ± 0.11	0.257 ± 0.002
Tertiary mass (M_\odot)	M_3	0.904 ± 0.01	-
Roche lobe radius(R_\odot)	R_L	4.562 ± 0.013	-

Figure 6. Distribution of the number of ΔV s between any two components in the triples. The three velocities, ordered from lowest to highest, are labeled as V_1 , V_2 , and V_3 . The upper panel shows the ΔV distribution between any two components of the triple star sample from Section 3, while the lower panel shows the same for the 132 triple star candidates from Li et al. (2021). The black dashed line denotes ΔV between $V_2 - V_1$ (ΔV_{2-1}), the red dash-dotted line shows ΔV between $V_3 - V_2$ (ΔV_{3-2}), and the blue solid line indicates ΔV between $V_3 - V_1$ (ΔV_{3-1}).

We compared the RV differences (ΔV) between components in our triple stars from Section 3 with those of 132 triple candidates identified by Li et al. (2021) using LAMOST-MRS spectra. Specifically, we examined the distribution of the RV differences (ΔV) between any two components in these two samples. We designated the three velocities in ascending order as V_1 , V_2 , and V_3 . The upper panel of figure 6 shows the ΔV distribution in our triples, while the lower panel illustrates the same for the Li et al. (2021)’s sample. The black dashed line represents the velocity difference between $V_2 - V_1$ (ΔV_{2-1}), the red dash-dotted line denotes the difference between $V_3 - V_2$ (ΔV_{3-2}), and the blue solid line indicates the difference between $V_3 - V_1$ (ΔV_{3-1}). The definitions of ΔV are detailed in figure 1.

The minimum ΔV in our triples is approximately 40 km/s, aligning with the resolution of LAMOST-MRS spectra, and the maximum ΔV is around 210 km/s. These results are consistent with those from Li et al. (2021), confirming the reliability of our analysis. The ΔV results also show that components of the triple systems can be effectively resolved using the CCF method. Notably, we cannot detect velocity differences less than 45 km/s (spectral resolution constraints) in binary stars or below 90 km/s in the inner binaries of triple systems. According to figure 9 in He et al. (2023), we established the relationship between the inner periods of triple systems and detection efficiency by analyzing various orbital period ratios ($P_{\text{out}}/P_{\text{in}}$). Due to the constraints of spectral resolution and RV, our detection range for inner periods is limited to between 0.2 days and 20 days, with maximum detection efficiency for periods shorter than 10 days. This observation suggests that the spectroscopic observations method has a distinct advantage in detecting short-period triple systems.

Next, we discussed the triple system j03 (*Gaia* DR3 66913361387671424). In this system, the primary star in the inner binary and the tertiary are relatively bright, while the secondary star is much fainter. In Kovalev et al. (2024), they employed spectral disentangling to analyse the system. They precisely determined an inner period of 5.73 days, the RV semi-amplitude of one of the stars and the systemic velocity, among other parameters, and roughly estimated

the mass ratio of the inner binary as 0.63. However, due to the lack of information about the outer orbit and the fact that they could only accurately obtain the RV of one star in the inner binary, they were unable to determine the inner binary’s mass ratio from the RV amplitude.

In our approach, we employed template matching to directly obtain the RV curve of the secondary star in the inner binary. With both RV curves available, we can accurately determine the mass ratio. As shown in the figure 7, our RV curve fitting yields a precise mass ratio of $0.600^{+0.008}_{-0.009}$ (see figure 13 in the Appendix). At present, it is unclear whether these fitting residuals are due to the influence of the third star. We obtained a comparable mass ratio to previous results, which suggests that our measurements are reliable.

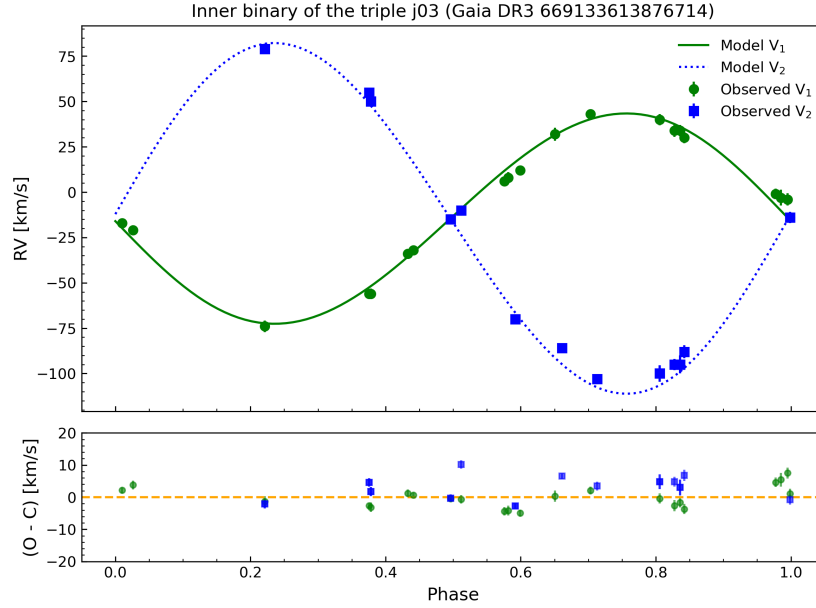

Figure 7. RV fitting of inner binaries for the triple star system j03 *Gaia* DR3 669133613876714. The green circles show the velocity of the primary star, while blue squares represent the velocity of the secondary star. V_1 and V_2 denote the RV curves of the primary and secondary stars in the inner binary.

6. SUMMARY AND CONCLUSION

In this study, we successfully identified and characterized new hierarchical triple-star systems by leveraging the synergy between *Gaia* DR3 NSS and LAMOST DR10 data. By cross-matching these datasets, we discovered 23 triple-star systems, including 18 new systems. For two triples with extensive observations, we conducted cross-correlation function (CCF) spectral analysis, RV fitting, and light curve analysis. We determined the system parameters of these triples. Our approach highlights the complementary nature of astrometry and spectroscopy in the detection and characterization of multiple star systems. *Gaia*’s astrometry is highly sensitive to long-period and wide-orbit systems, whereas LAMOST’s spectroscopy effectively reveals short-period systems. This dual approach enhances the overall efficiency of detecting and studying hierarchical triple-star systems (Gaia Collaboration et al. 2023b).

For the two triples, *Gaia* DR3 249662295687401216, and *Gaia* DR3 2077667962475652864, we utilized the Lomb-Scargle periodogram to determine their inner periods. We then phase-folded the light curves, revealing detailed periodic variations (Moharana et al. 2024). Subsequently, we modeled these triples using the PHOEBE software, obtaining key parameters such as orbital inclination, temperature ratio, relative radii, and the third light contribution. We refined these parameters precisely using MCMC sampling methods. The RV curves derived from our analysis were fitted using the Radvel package, yielding reliable orbital parameters. By combining RV data with light curves, we employed *Kepler*’s laws to calculate the semi-major axis and mass of the inner binary. This comprehensive approach allowed us to accurately determine the physical properties of the hierarchical triple-star systems, including the masses, radii, and orbital configurations of the constituent stars.

Then we analyzed the RV distributions of 23 triple systems from the LAMOST dataset. The RV differences (ΔV) in our triples ranged from about 40 km/s to 210 km/s, confirming the reliability of our findings and limiting detectable

inner periods to between 0.2 and 20 days. For the triple system j03, we utilized template matching to derive the RV curve of the secondary star in the inner binary. This differs from the spectral disentangling approach in Kovalev et al. (2024), they estimated the mass ratio of the inner orbital as approximately 0.63. Our method, which includes both RV curves, yielded a precise mass ratio of $0.6^{+0.008}_{-0.009}$, illustrating the reliability of our approach.

The study of multiple-star systems, especially triple star systems, is of significant importance in astronomy. They play a crucial role in stellar dynamics and evolution, providing valuable insights into stellar interactions and mass transfer (Tokovinin et al. 2006; Raghavan et al. 2010). Combining the strengths of astrometry and spectroscopy can provide new ways of revealing the complex structure and distribution properties of these systems, contributing to our understanding of star formation and evolution.

APPENDIX

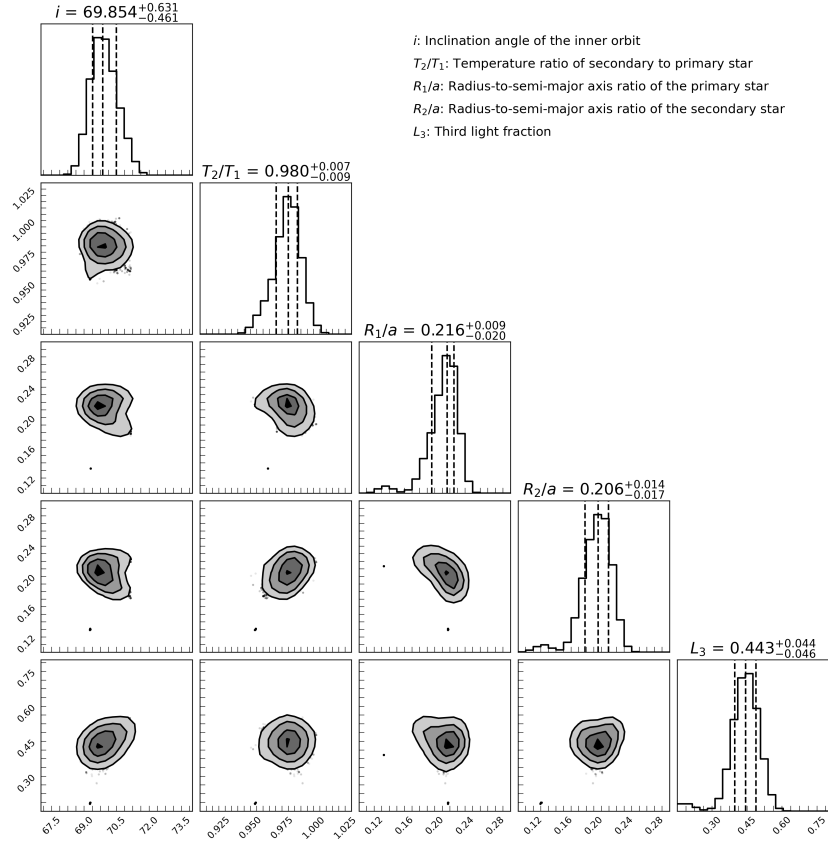

Figure 8. The MCMC corner plot for the triple star system *Gaia* DR3 249662295687401216. The fitted model includes the binary parameters (inclination i , temperature ratio T_2/T_1 , R_1/a , R_2/a) and the third light fraction L_3 .

Figure 9. MCMC corner plot for the triple-star system *Gaia* DR3 249662295687401216. The fitted model parameters are: for the inner binary: $q_1 = 0.919 \pm 0.006$, $K_1 = 138.798^{+0.727}_{-0.749}$, $\sqrt{e_1} \cos \omega_1 = 0$, $\sqrt{e_1} \sin \omega_1 = 0.0014 \pm 0.001$; Outer binary: $\sqrt{e_2} \cos \omega_2 = -0.008^{+0.015}_{-0.008}$, $\sqrt{e_2} \sin \omega_2 = 0.144^{+0.085}_{-0.068}$, $q_2 = 0.427^{+0.077}_{-0.068}$, $K_3 = 21.275^{+1.752}_{-1.484}$; and the system velocity $\gamma = 7.74^{+1.038}_{-0.988}$ km/s.

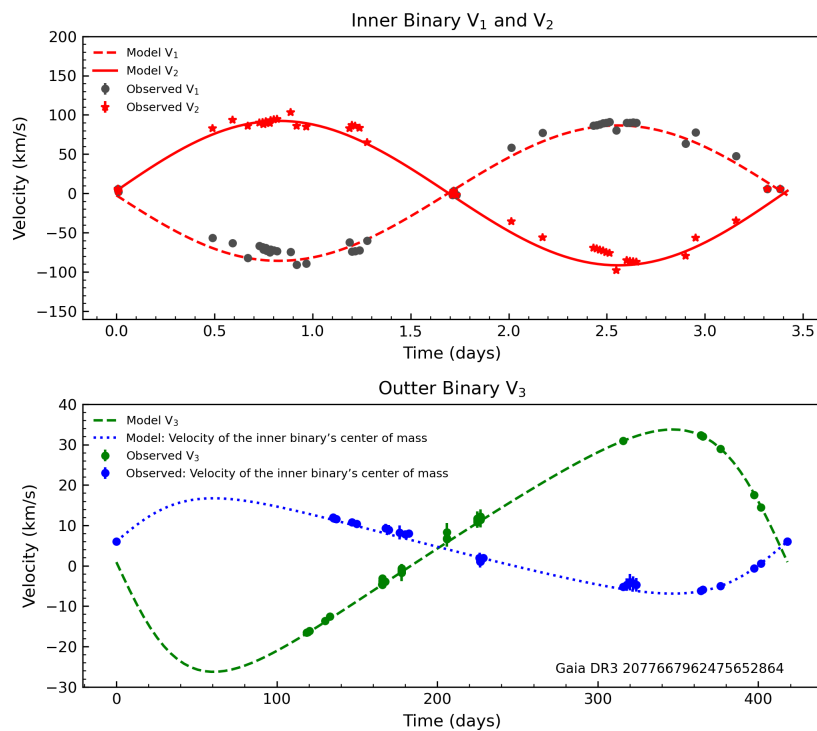

Figure 10. RV fitting for the triple star system *Gaia* DR3 2077667962475652864. The black points and red stars represent the observed data after phase folding, and the red line indicates the fitted RV curve. The blue points show the velocity of the inner binary's center of mass, while the green dashed line represents the fitted curve for the inner binary's center of mass velocity. The green points indicate the velocity of the tertiary star, and the green dashed line illustrates the fitted curve for the tertiary star's velocity. V_1 and V_2 denote the RVs of the primary and secondary stars in the inner binary, respectively, and V_3 represents the RV curve of the tertiary star.

Figure 11. MCMC corner plot for the triple-star system *Gaia* DR3 2077667962475652864. The fitted model parameters are: for the inner binary, $q_1 = 0.937 \pm 0.003$, $K_1 = 91.971^{+0.160}_{-0.153}$, $\sqrt{e_1} \cos \omega_1 = 0$, $\sqrt{e_1} \sin \omega_1 = 0.009 \pm 0.001$; for the outer binary, $\sqrt{e_2} \cos \omega_2 = 0.028^{+0.001}_{-0.0}$, $\sqrt{e_2} \sin \omega_2 = -0.293 \pm 0.001$, $q_2 = 0.393 \pm 0.003$, $K_3 = 30.001^{+0.049}_{-0.047}$; and the systemic velocity $\gamma = 4.582^{+0.023}_{-0.025}$ km/s.

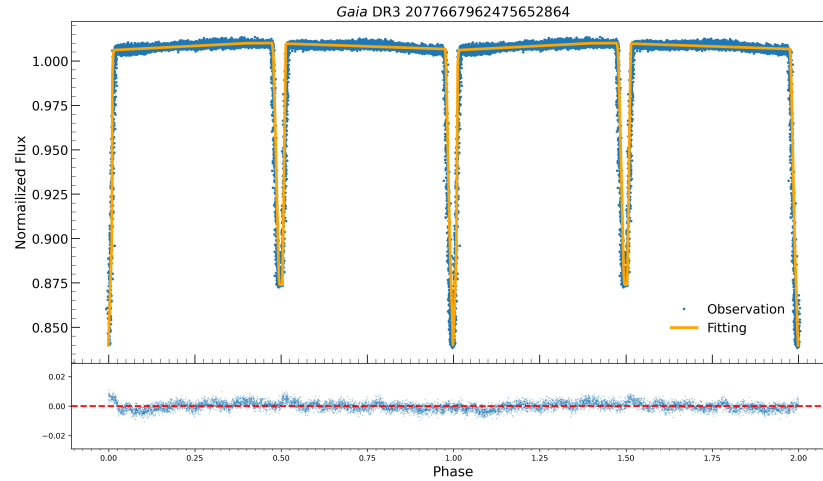

Figure 12. Light curve of the triple *Gaia* DR3 2077667962475652864. The blue dots indicate phase-folded observations, and the solid yellow line indicates the results of the fit. The horizontal axis indicates the phase, and the fitting residuals are shown at the bottom of the plot.

Figure 13. The MCMC corner plot for the triple system j03, representing the results of inner orbital fitting. The fitted parameters are: $q_1 = 0.600^{+0.008}_{-0.009}$, $K_1 = 96.693^{+0.615}_{-0.610}$, $\sqrt{e_1} \cos \omega_1 = 0.001$, $\sqrt{e_1} \sin \omega_1 = -0.032^{+0.005}_{-0.006}$ and the systemic velocity $\gamma = 14.538^{+0.322}_{-0.311}$ km/s.
