ABSTRACT

Distant quasars (QSOs) in galaxy overdensities are considered key actors in the evolution of the early Universe. In this work, we performed an analysis of the kinematic and physical properties of the BR1202-0725 system at $z \sim 4.7$, one of the most overdense fields known in the early Universe, consisting of a QSO, a submillimeter galaxy (SMG), and three Lyman- α emitters. We used data from the JWST/NIRSpec Integral Field Unit (IFU) to analyze the rest-frame optical emission of each source in the system. Based on the continuum and Balmer line emission, we estimated a bolometric luminosity of $\log(L_{bol}/[\text{erg s}^{-1}]) = 47.2 \pm 0.4$ and a black hole mass of $\log(M_{\rm BH}/M_{\odot}) = 10.1 \pm 0.5$ for the QSO, which are consistent with previous measurements obtained with groundbased observations. The NIRSpec spectra of the SMG revealed instead unexpected [O III] and H α +[N II] profiles. The overall [O III] line profile is blue-shifted by more than 700 km s⁻¹ relative to the systemic velocity of the galaxy. Additionally, both the [O III] and $H\alpha + [N \pi]$ lines show prominent broad (~1300 km s⁻¹), blueshifted wings associated with outflowing ionized gas. The analysis of NIRSpec and X-ray observations indicates that the SMG likely hosts an accreting supermassive black hole as supported by the following results: (i) the excitation diagnostic diagram is consistent with ionization from an active galactic nucleus (AGN); (ii) the X-ray luminosity is higher than 10^{44} erg s⁻¹; and (iii) it hosts a fast outflow ($v_{out} \sim 5000$ km s⁻¹), comparable to those observed in luminous QSOs. Therefore, the QSO-SMG pair of BR1202-0725 represents one of the highest-redshift double AGN to date, with a projected separation of 24 kpc. Finally, we investigated the environment of this system and found four new galaxies, detected in both [O III] and H α emission, at the same redshift of the QSO and within a projected distance of 5 kpc from it. This overdense system includes at least ten galaxies in a field of view of only 980 kpc².

Key words. quasars: supermassive black holes – quasars: emission lines – ISM: jets and outflows – Galaxies: high-redshift – Galaxies: kinematics and dynamics

1. Introduction

Cosmological numerical simulations expect luminous active galactic nuclei (AGN) to reside in the most overdense regions of the Universe (Ni et al. 2020; Habouzit et al. 2019; Valentini et al. 2021; Weinberger et al. 2018; Costa et al. 2014; Di Matteo et al. 2012; Sijacki et al. 2009; Zana et al. 2022, 2023; Barai et al. 2018). In such fields, both the growth of supermassive black holes (BHs) and the formation of new stars are thought to be triggered by galaxy mergers and interactions.

However, whether distant quasars (QSOs) form and evolve in galaxy overdensities is still an open question (see e.g., Villforth 2023, and references therein). Rest-frame UV observations with ground-based telescopes and *Hubble* Space Telescope (HST) have led to contrasting results. Some studies have found a large number of galaxies within a few Megaparsecs of $z \sim 6$

QSOs (Bosman et al. 2020; Mignoli et al. 2020; Meyer et al. 2022; Overzier 2022; Zheng et al. 2006) while others have reported no sources or only a few galaxies in the vicinity of the OSO (e.g., Willott et al. 2005; Morselli et al. 2014; Simpson et al. 2014). Even observational programs conducted with the Atacama Large Millimeter/submillimeter Array (ALMA) have produced differing and sometimes contradictory results in the identification of companion galaxies near high-redshift quasars. Some studies have identified up to three [C II] emitters in the $\sim 30'' \times 30''$ ALMA field of view (FoV; corresponding to a physical scale of ~ $180 \times 180 \text{ kpc}^2$ at $z \sim 6$), while others have only reported the emission of the QSOs (Decarli et al. 2017, 2018; Willott et al. 2017; Neeleman et al. 2019; Venemans et al. 2019, 2020; Bischetti et al. 2024). However, Zana et al. (2022, 2023) show that the dust obscuration, angular resolution, and data sensitivity may explain the different results obtained with HST. Also the small FoV and frequency coverage of ALMA can explain the

¹ Scuola Normale Superiore, Piazza dei Cavalieri 7, I-56126 Pisa, Italy

^{*} E-mail: sandra.zamoraarenal@sns.it

scatter in the number of detected satellite galaxies among different observations.

The launch of the James Webb Space Telescope (JWST) has opened a new window on the study of galaxy overdensities at high redshift through rest-frame optical emission lines. NIRCam Wide Field Slitless Spectroscopy (WFSS) observations have revealed more than ten [O III] emitters within a few Megaparsecs from the $z \sim 6$ QSOs J0305–3150 and J0100+2802 (Wang et al. 2023; Kashino et al. 2023). Only a few of these sources had been previously detected with HST and ALMA. Additionally, NIR-Spec observations in integral field spectroscopy (IFS) mode have enabled the detailed investigations of the close environment of high-z sources, finding a high prevalence of overdensities (e.g., Jones et al. 2024a; Rodríguez Del Pino et al. 2024; Arribas et al. 2024; Lamperti et al. 2024). Many AGN and QSOs at z > 3followed-up with NIRSpec IFS show the presence of at least one companion galaxy up to 30 kpc and ± 1000 km s⁻¹ of the main target (Perna et al. 2023a; Marshall et al. 2023, 2024; Loiacono et al. 2024; Übler et al. 2023, 2024). Some of these companions show spectroscopic features associated with AGN ionization, indicating that the system may host a double or even a triple AGN. Analyzing a sample of AGN at $z \sim 3$, Perna et al. (2023b) conclude that dual AGN with projected separations below 30 kpc may be more common (by at least a factor of 2 to 3) than what is predicted by the most recent cosmological simulations (De Rosa et al. 2019; Volonteri et al. 2022). Specifically, the companion galaxies of five out of 16 AGN (i.e., ~20-30%) have optical emission line flux ratios consistent with AGN excitation. In comparison, the above theoretical models predict a dual AGN fraction < 1%.

BR1202-0725 ($z \sim 4.7$) is one of the most studied overdense fields at high redshift, acting as a laboratory for studying different galaxy types, all evolving in the same environment. The system (see Fig. 1) is composed of a submillimeter galaxy (SMG), a QSO - with a SMG-QSO projected separation of 24 kpc - and three Lyman-alpha emitters (LAE1, LAE2, and LAE3; Drake et al. 2020; Carniani et al. 2013; Carilli et al. 2013).

The QSO was observed for the first time by Irwin et al. (1991) and was the first object at z > 4 to be detected in CO emission (Ohta et al. 1996). The optically obscured SMG was also found in these observations, at ~ 4" to the northwest of the QSO (see also Omont et al. 1996; Iono et al. 2006). Both the QSO and the SMG have far infrared (FIR; ~40–500 μ m) luminosities higher than 10¹³ L_{\odot} (Omont 1996; Iono et al. 2006; Carilli et al. 2002), which suggest very strong star formation activity (SFR > 1000 M_{\odot} yr^{-1}; Carilli et al. 2013) and, which according to the commonly accepted paradigm is likely triggered and sustained by merger events.

The QSO exhibits a large Ly α halo (~55 kpc, surface brightness > 1× 10⁻¹⁷ erg s⁻¹ cm⁻² arcsec⁻²; Drake et al. 2020) with high velocity widths (FWHM_{Ly α} ~ 1000 km s⁻¹), probably coupled with the bridge of gas located between the QSO and the SMG observed in [C II] 158 μ m (Wagg et al. 2012; Carilli et al. 2013; Carniani et al. 2013). The QSO contains a mass of ~ 8 × 10¹⁰ M_{\odot} of cold molecular gas (derived from the CO(J=1–0) line luminosity; Riechers et al. 2006). The CO emission of the QSO can be separated into at least two components: the main one (FWHM_{CO}= 700 km s⁻¹), with kinematics compatible with a rotating disk, and another one separated by +0.4" in declination, having a velocity shift of 180 km s⁻¹, which is likely another fainter galaxy in the merger (Salomé et al. 2012). The QSO also shows an excess of emission in the red wing of the line profile of [C II], which suggested an outflow of atomic gas from the QSO expelling mass at a rate of $\dot{M}_{out} \sim 80 M_{\odot} \text{ yr}^{-1}$ (Carilli et al. 2013).

Article number, page 2 of 21

The SMG was detected in [C II] line emission with $L_{[C II]} = 10^{10} L_{\odot}$ and its ratio $L_{[C II]}/L_{FIR} = (8.3 \pm 1.2) \times 10^{-4}$ is in agreement with previous high-redshift studies. The analysis of the CO(5–4) observations indicates the presence of a companion galaxy at 0.6" to the west-northwest of the SMG with a relative velocity of +600 km s⁻¹ (see Fig. 4 of Salomé et al. 2012).

LAE1 ($z_{Ly\alpha} = 4.703$) is located northwest of the QSO in the direction of the [C II] bridge and LAE2 ($z_{Ly\alpha} = 4.698$) toward the southwest (see left panel of Fig 1), both at the same redshift as the QSO. These objects were spectroscopically confirmed by the detection of Ly α emission in Hu & McMahon (1996) and Williams et al. (2014), respectively. In LAE1, the [N II] 122 μ m emission (Decarli et al. 2017; Pavesi et al. 2016; Lee et al. 2019) and the absence of high-ionization emission lines in the UV spectrum obtained with the FORS2 on the VLT (N v λ 1240 Å, Si IV λ 1396 Å, C IV λ 1549 Å, and He II λ 1640 Å; Williams et al. 2014) suggest that this source is not photoionized by the QSO. Similarly, also LAE2 lacks high-ionization emission lines, and together with the [C II] 158 μ m / [N II] 122 μ m ratio for LAE2 indicates that its emission is dominated by H II regions and may be driven by star formation $(L_{[C II]}/L_{[N II]} = 2.3^{+2.7}_{-0.9})$ and the CO(2-1) observations suggest that it has a considerable reservoir of molecular gas (~ $4 \times 10^{10} M_{\odot}$, Jones et al. 2016). These observations led to the conclusion that star formation is the primary source of emission for all the LAEs in the system. An additional companion (LAE3; $z_{Ly\alpha}$ = 4.7019) discovered by Drake et al. (2020) and located 5" north of the QSO, shows an SFR(Ly α) of 5 M_{\odot} yr⁻¹ and an EW(Ly α) > 34.05 Å, consistent with star formation as the primary driver of $Ly\alpha$ emission.

In this work, we present new JWST NIRSpec IFS observations of BR1202-0725. We analyze the kinematic and physical properties of the main objects presented above, and we also study four newly identified galaxy companions that are part of the system. The observations on which the work is based are presented in Sect. 2 together with an overview of the data reduction. Section 3 provides a detailed description of the system based on these observations and illustrates the data analysis. Sections 4 to 6 focus on the results obtained for QSO, SMG and LAEs, respectively. In the latter, we also present the four newly detected galaxy companions of the QSO in addition to the LAEs and the ones found by Salomé et al. (2012). The discussion is given in Sect. 7 and a summary of our results and final conclusions are presented in Sect. 8.

Throughout this paper, we adopt the standard cosmological parameters $H_0 = 70 \text{ km s}^{-1} \text{ Mpc}^{-1}$, $\Omega_M = 0.30$, and $\Omega_{\Lambda} = 0.70$, giving a cosmology corrected scale of 6.48 kpc arcsec⁻¹ at z = 4.7.

2. Observations and data reduction

We used JWST NIRSpec IFS (Jakobsen et al. 2022; Böker et al. 2023, 2022) observations obtained as part of the NIRSpec IFS GTO program "Galaxy Assembly with NIRSpec IFS" (GA-NIFS)¹. These data cover the QSO, the SMG, and two Ly α emitters (LAE1 and LAE2) with two different pointings (covering 3.6 × 6.5 arcsec²) that overlap by 10% because the main sources are spatially separated by a projected distance larger than 3 arcsec (see Fig. 1).

The observations were acquired on 1st July 2023. Two disperser/filter combinations were used: G235H/G170LP and

¹ Proposal ID 1220, cycle 1 (PI: Nora Luetzgendorf). GA-NIFS website: https://ga-nifs.github.io/.

Fig. 1. HST ACS F775W filter (*i*-band; left) and JWST NIRSpec IFU H α (3.74 μ m < λ < 3.75 μ m; right) image of BR1202-0725. Dust continuum emission from ALMA in Band 7 is shown as black contours. Star symbols illustrate the position of the three Lyman- α emitters. North is up, east is left. A logarithmic color scale is used.

G395H/F290LP, with a spectral resolution $R \sim 2700$ and covering the wavelength ranges 1.66 – 3.05 μ m and 2.87 – 5.14 μ m, respectively (corresponding to the rest-frame range 2910 – 9020 Å at a redshift ~ 4.7). The selected spectral configuration covers the main rest-frame optical emission lines at the redshift of the system, including the Balmer lines (H α , H β), [O III] $\lambda\lambda$ 4959,5007 Å, [N II] $\lambda\lambda$ 6548,84 Å, and [S II] $\lambda\lambda$ 6717,31 Å. Each grating was observed for 3559 s, in two different exposures to target the QSO and the SMG.

We retrieved the raw data from the MAST (Barbara A. Mikulski Archive for Space Telescopes) archive. Then, we reduced them with a customized version of the JWST pipeline (version 1.14.0), using the Calibration Reference Data System (CRDS) context jwst 1225.pmap. Some modifications to the pipeline allow us to improve the data quality and they are described in detail in Perna et al. (2023b), but here we summarize the major changes. First, we applied the "calwebb_detector1" step of the pipeline to account for detector level correction. Before calibrating the count-rate images through the "calwebb_spec2" module of the pipeline, we corrected them by subtracting the 1/f noise through a polynomial fitting. We identified and removed outliers directly in the calibrated 2-d images, by applying an algorithm similar to "lacosmic" (van Dokkum 2001). Briefly, we computed the derivative along the dispersion direction, and we rejected the 98th percentile of the distribution (see D'Eugenio et al. 2024, for details). The final data cube was created by combining the individual calibrated 2-D exposures by using the 'drizzle' weighting obtaining a cube with a spaxel size of 0.05".

In this work, we also used [C II] 158 μ m and adjacent continuum observations from ALMA in Band 7 to compare the shape of the [C II] spectrum of the SMG with those of [O III] and H α from JWST and to compare the location of the dust continuum with that of H α . We retrieved the raw visibilities of the program 2019.1.01587.S (PI: F. Lelli) from the ALMA archive and calibrated them with the Common Astronomy Software Application (CASA) by using the script included in the dataset. By using the task "tclean", we cleaned the calibrated visibilities using a "Briggs" weighting scale and a robust parameter equal to 0.5 to obtain the final data cube. The data cube has a beam size of $0.17'' \times 0.12''$, roughly matching the NIRSpec IFS resolution (~ 0.09'' - 0.15''; D'Eugenio et al. 2024).

We used HST observations to calculate the astrometric offsets between the NIRSpec IFU and the ALMA data (see Sect. 3.1). They were acquired on 24th May 2005 with the Advanced Camera for Surveys (ACS) and the F775W filter. These data are part of proposal ID 10417 (PI: X. Fan) and are organized in four exposures and a total exposure time of 9445 s. The data were downloaded from the Hubble Legacy Archive (HLA) and reduced by the Space Telescope Science Institute (STScI) using available calibration files taken for this observation and accounting for the different dithering positions.

Finally, we also employed *Chandra* archival data to investigate whether the SMG emits X-rays. BR1202-0725 was observed twice with ACIS-S, once during Cycle 3 for 10 ks (ObsID 3025, presented in Iono et al. 2006) and a second time in Cycle 9 for 30 ks (ObsID 9232, presented in Li et al. 2021). The results of the X-ray data analysis are presented in Sect. 7.2.

3. Data Analysis

3.1. Astrometry correction

Since astrometric offsets between the NIRSpec IFU data and the position of the sources on the sky have been reported in the literature (e.g., Perna et al. 2023b; Jones et al. 2024a,b), we registered the JWST observations to the HST image (ACS-F775W). We verified the astrometric accuracy of the HST image by comparing the position of the star in the oV with the coordinates reported in Gaia DR3 catalog (Gaia Collaboration et al. 2023). We used the position of the QSO to register the JWST data to HST ones and found a shift of $\Delta RA = +0.199$ arcsec and $\Delta Dec = -0.144$ arcsec.

In this work, we assumed that the ALMA astrometry is sufficiently precise for our purpose, considering that the ALMA positional accuracy varies from 5% to 20% of the beam depending on the S/N, which corresponds to an accuracy of 0.03 arcsec for a beam of $0.17'' \times 0.12''$. The high S/N ensures that the ALMA astrometry is correct within 1 NIRSpec spaxel.

3.2. BR1202-0725

The well-studied BR1202-0725 system has been observed in a wide range of molecular and atomic lines (e.g., Omont 1996; Salomé et al. 2012; Carilli et al. 2013; Benford et al. 1999; Lu et al. 2017). However, this is the first time it was observed in rest-frame optical emission lines. The left panel of Fig. 1 shows the HST ACS image in the F775W filter, covering the spectral range 6801 – 8630 Å (corresponding to the UV rest frame emission between 1193Å and 1514Å at z = 4.7) with the two JWST pointings used in this study superimposed. The JWST map at the wavelength of the H α emission line (3.74 μ m < λ < 3.75 μ m) is shown in the right panel. The ALMA dust continuum emission is shown as black contours.

The QSO is the most prominent source in H α in the FoV of the NIRSpec IFS data, appearing in the bottom-left part of the map, and it is dominated by the point spread function (PSF) emission. However, LAE1 is also very prominent, showing a spatially resolved structure that could be connected with the bridge between the QSO and the SMG observed in [CII] (Carniani et al. 2013). The SMG is located in the top-right part of the map, showing an elliptical appearance in the ionized gas. This object has been studied in other FIR and mm/submm emission lines, such as [N II] at 122 and 205 μ m (rest-frame), with ALMA and the IRAM Plateau de Bure Interferometer (PdBI) (Decarli et al. 2014; Drake et al. 2020). Despite some attempts to study the optical emission with SINFONI, that results in a non-detection of the [O II] $\lambda\lambda$ 3726, 29 Å doublet (Couto et al. 2016), and an integrated spectrum from the AKARI space telescope encompassing the H α emission of the QSO and SMG (Jun et al. 2015), this is the first time that this optically obscured, submillimeter-bright object can be spatially resolved at rest-frame optical wavelengths, thanks to the high resolution and sensitivity of JWST.

3.3. Point spread function modeling

One of the main goals of this work is identifying the presence of companion galaxies close to the QSO and studying their properties. Therefore, it is fundamental to remove the point-like emission of the QSO that outshines a large fraction of the IFS FoV.

Following the approach of Decarli et al. (2024), we generated a set of 17 images of the PSF by integrating the emission of the QSO in different wavelength bands with a width varying between 0.01 μ m and 0.13 μ m depending on either the presence of mission line or cosmic rays in the field (see Fig. A.1 in Appendix A). The selected bands exclude the brightest forbidden emission lines, such as [O III], [S II] and [N II], as well as narrow Balmer lines, because they are not associated with the spatially unresolved emission of the accretion disk, and are therefore likely to be spatially extended.

We interpolated these PSF images at each wavelength of the data cube, and we obtained a data cube with the normalized image of the PSF at each wavelength. Then, we scaled the flux of each one using an aperture of 0.25" centered on the peak of the QSO (see Decarli et al. 2024). Finally, we subtracted the PSF models from the JWST data and Fig. 2 shows the emission of the QSO at the wavelength of the H β emission line (2.75 μ m < λ < 2.77 μ m, observed frame) before and after subtraction of our modeled PSF. We notice that our procedure

Fig. 2. Original (left) and PSF-subtracted (right) maps of the QSO at the wavelength corresponding to the H β emission line.

slightly over-subtracts the QSO emission at the center, hence the flux measurements in this region are not reliable. Therefore, we masked a region of radius of 0.2" from the centroid of the QSO in the PSF-subtracted data cube and limited our analysis to the emission at larger distances from the bright source.

3.4. Aperture correction

The aperture correction is necessary to determine the total emission flux of the targets since the PSF of the instrument depends on the wavelength. Following Loiacono et al. (2024), we determined the flux losses from 1.7 μ m to 5.2 μ m for four different apertures by using the PSF models generated in Sect. 3.3. Figure B.1 reports the fraction of flux recovered from the four apertures with respect to an aperture with a radius of 1 arcsec, which is large enough to recover all the emission of point-like sources. All spectra and fluxes reported hereafter are corrected for the flux losses depending on the selected aperture and wavelength. We present the procedure and the results in Appendix B.

4. QSO

Figure 3 illustrates the spectrum of the QSO extracted from an aperture of R = 0.5 arcsec and located at the peak of the emission (RA = 181.34634 deg, Dec = -7.70906 deg). We have calculated the errors on the integrated spectrum from the error extension of the data cube in the same spaxels of the selected region propagating them in quadrature (see Appendix C). The spectrum clearly reveals broad emission lines of H α and H β , and Fe II emission lines arising from the broad line region (BLR).

We initially modeled the featureless continuum emission of the QSO. A simple power-law function is usually adopted to reproduce the multi-blackbody emission of the accretion disk (e.g., Loiacono et al. 2024), but given the extended wavelength range covered by the NIRSpec data, we adopted two power-law functions as follows:

$$f(\lambda) = \begin{cases} A\left(\frac{\lambda}{\lambda_0}\right)^{\alpha_1} & \lambda < \lambda_0 \\ A\left(\frac{\lambda}{\lambda_0}\right)^{\alpha_2} & \lambda \ge \lambda_0 \end{cases}$$
(1)

where A is the normalization, λ_0 the break wavelength and α_1 and α_2 the power-law indexes. This profile has been widely used to reproduce the continuum emission of local QSOs (Vanden Berk et al. 2001) which change slope at the rest-frame wavelength of ~5000 Å due to the contribution of the host galaxy.

We fitted the line-free spectral regions of the spectrum with the function in Eq. 1. Figure 3 shows the QSO spectrum together

Table 1. Fitted continuum parameters for the QSO.

Parameter	Value
A	$(1.22 \pm 0.05) \times 10^{-17} \text{erg s}^{-1} \text{ cm}^{-2} \text{ Å}^{-1}$
α_1	-2.130 ± 0.009
α_2	-1.931 ± 0.005
$\lambda_0^{\rm obs}$	$2.91 \pm 0.06 \mu \text{m}$
$\lambda_0^{\text{rest, }a}$	5107 ± 108 Å

^{*a*} Relative to z = 4.6943 (Carniani et al. 2013).

with the continuum model, while the fitted parameters are shown in Table 1. Considering a redshift of z = 4.6943 (Carniani et al. 2013), we found a rest-frame value for the break wavelength of 5107 ± 108 Å, comparable to others found in the literature for QSOs at a similar redshift (e.g., Loiacono et al. 2024).

Typical type 1 QSO spectra such as the one reported show the presence of a forest of Fe II emission bumps. The analysis of the Fe II multiplets is not among the aims of this paper. However, it is important to obtain a continuum- and Fe II-free spectrum in order to fit the optical emission lines to derive QSO properties such as the BH mass. In particular, appropriately modeling the prominent Fe II multiplets in the rest-frame wavelength region between 4700 and 5400 Å is critical, since they are blended with H β and [O III] $\lambda\lambda$ 4959,5007 Å emission lines.

We tried to reproduce the Fe II emission with the following three different templates: Tsuzuki et al. (2006, T+06), Véron-Cetty et al. (2004, VC+04), and Boroson & Green (1992, BG+92). The results are shown in Fig. 4. None of them was able to accurately reproduce all the Fe II emission features in the spectrum. However, we discarded the results obtained with Tsuzuki et al. (2006) and Boroson & Green (1992) templates because they overpredict the flux emission at the wavelength range of the [O III] (see Park et al. 2022). We have thus assumed as fiducial model the results obtained with the Véron-Cetty et al. (2004) Fe II template.

Finally, we fitted the brightest nebular lines present in the integrated continuum-subtracted spectrum, H β , [O III] $\lambda\lambda$ 4959,5007 Å, [N II] $\lambda\lambda$ 6548,84 Å, H α , and [S II] $\lambda\lambda$ 6717,31 Å, using a combination of Gaussian profiles convolved with the line spread function of the instrument. We have used two Gaussian components: (i) a *Narrow* component with $\sigma < 600 \text{ km s}^{-1}$, and (ii) a broad one (dubbed *Outflow*) with 400 km s⁻¹ < σ < 2000 km s⁻¹. For the Balmer recombination lines, H α and H β , we added an additional Gaussian component with a velocity dispersion spanning a range 1000 km s⁻¹ < σ < 5000 km s⁻¹ to reproduce the emission from the BLR. We tied the kinematics of each Gaussian component for each emitting species (centroid and line width). The two emission lines of the [O III] and [N II]doublets originate from the same upper level, then we fixed the intensity ratios between each line of these doublets to their theoretical values: $I([N II] \lambda 6584)/I([N II] \lambda 6548) = 2.94$ and I([O III] $\lambda 5007)/I([O III] \lambda 4959) = 3$ (Osterbrock & Ferland 2006). We also fixed the H α /H β ratio of the Narrow and Outflow components to take values $2.3 < H\alpha/H\beta < 10$. We included the Véron-Cetty et al. (2004) Fe II template in the fitting, by allowing its amplitude and velocity dispersion to vary.

In Table 2, we report the emission line velocities and velocity dispersions for each component and the emission-line intensities of the nebular lines after the aperture correction (see Sect. 3.4). Figure 5 shows the fitted profiles for each component. We can see that the multicomponent fitting accurately reproduces the spectrum at the wavelengths of the emission lines, with a

Table 2. Emission line properties of the QSO as constrained from our best fit of the spectrum (Fig. 5). The top table reports the velocity shift and velocity dispersion of the emission lines, while their fluxes are reported in the bottom table.

^{*a*} Relative to z = 4.6943 (Carniani et al. 2013).

^{*b*} In units of 10^{-17} erg s⁻¹ cm⁻².

 c These measurements should be taken with caution due to the degeneracies in the fitting.

narrow and a broad component with velocity dispersions of 660 \pm 30 km s⁻¹ and 1360 \pm 80 km s⁻¹, respectively. The BLR is blueshifted by -410 km s⁻¹ relative to *z* = 4.6943 (Carniani et al. 2013) and has σ = 4160 \pm 60 km s⁻¹.

We stress that the *Narrow* and *Outflow* components in the fitting are strongly affected by degeneracies, and the Fe II multiplets present in the spectrum also influence the values obtained for the [O III] emission line. Therefore, these results should be interpreted with caution. For the **BLR** component, the velocity dispersion and amplitude vary depending on the fitting priors. Specifically, the velocity dispersion ranges from 3400 km s⁻¹ to 4600 km s⁻¹ (mean value of 3900 km s⁻¹ with a standard deviation of 400 km s⁻¹), which translates into an H α emission line flux range of 470 – 660 ×10⁻¹⁷ erg s⁻¹ cm⁻². However, as shown in Sect. 7.3, the different BH masses obtained from the above range of values are well within the uncertainty on the calibration used to estimate them, therefore they are consistent among each other.

5. SMG

Figure 6 shows the integrated spectrum of the submillimeter galaxy located ~24 kpc north-west of the QSO (see Fig. 1). The spectrum was extracted from an aperture of R = 0.3 arcsec centered on the position RA = 181.34575 deg and Dec = -7.70825 deg. In contrast to the QSO, the continuum emission from the SMG is detected with low signal-to-noise and its intensity does not depend strongly on the wavelength.

The G395H data clearly reveal blended H α and [N II] emission and the [S II] doublet. He I λ 5875 Å and [O I] λ 6300 Å are also visible in the spectrum, with lower signal-to-noise ratios (S/N = 2.6). At lower wavelengths, the [O III] λ 5007 Å is detected with a signal-to-noise ratio higher than 21, while the H β line is not detected due to the high dust attenuation of the galaxy.

We note that the peak of [O III] is blueshifted with respect to the other optical lines observed in the NIRSpec data. By adopting the systemic redshift of z = 4.6891 determined from [C II] and CO far-infrared emission lines (see Carniani et al. 2013 and Salomé et al. 2012, respectively), we find that the peak of H α +[N II] is consistent with the systemic redshift of the galaxy

Fig. 3. JWST/NIRSpec rest-frame optical spectrum of the QSO in the two gratings/filters G235H/F170LP and G395H/F290LP (green and purple lines, respectively), extracted from an aperture of $R = 0.5^{"}$. The brightest nebular lines are marked and the Fe II multiplet bands are highlighted in gray. The green dashed line shows the broken power-law continuum model fitted to reproduce the featureless continuum emission. The gray line in the bottom panel shows the residuals of the fitting.

Fig. 4. QSO rest-frame optical continuum-subtracted spectrum (gray line) in the spectral region 4700 – 5400 Å. The emission lines H β and [O III] $\lambda\lambda$ 4959,5007 Å (marked with vertical lines) are blended with the Fe II emission, which can be clearly seen at ~3 μ m. The following fitted Fe II templates are shown: Véron-Cetty et al. (2004, VC+04, red line), Boroson & Green (1992, BG+92, blue line) and Tsuzuki et al. (2006, T+06, yellow line). The lines in the bottom panel shows the different residuals of the fitting.

while the peak of the [O III] line is shifted by -1000 km s^{-1} (Fig. 7). Both the profiles of the [O III] doublet and $H\alpha + [N II]$ are very broad and show an asymmetric shape with a prominent emission at shorter wavelengths that suggest the presence of galactic outflows (e.g., Cresci et al. 2015; Carniani et al. 2015; Harrison et al. 2015; 2016; Balmaverde et al. 2016; Brusa et al. 2016; Perna et al. 2017; Leung et al. 2019; Vayner et al. 2021, 2024; Venturi et al. 2023; Speranza et al. 2024).

We fitted the brightest nebular lines of the SMG by using a combination of Gaussian profiles. Due to the complexity of the blended H α and [NII] profiles (see Fig. 6), we

started by fitting only the [O III] doublet emission to determine the kinematics of the blueshifted broad wings. We used a combination of two Gaussian components: (i) a narrow component with $\sigma < 400 \text{ km s}^{-1}$, and (ii) a broad component with 400 km s⁻¹ < σ < 1500 km s⁻¹. We dubbed the narrow and broad components as *Narrow 2* and *Outflow*. We adopted the label *Narrow 2* because this component is not at the systemic redshift of the galaxy defined from [C II] and CO. We used a second-order polynomial to model the continuum in this spectrum, although the results show that it is almost constant with a value of 1.6×10^{-20} erg s⁻¹ cm⁻² Å⁻¹.

The upper panel of Fig. 8 shows the best-fit model for the [O III] doublet. The *Outflow* component has a velocity dispersion of 1300 ± 500 km s⁻¹ and is blueshifted by -2450 ± 40 km s⁻¹ relative to the systemic velocity of the galaxy. The profile of this line is similar to the broad blueshifted wings observed in luminous QSOs, associated with fast outflowing gas.

The *Narrow 2* instead has a velocity dispersion consistent with what is expected from a rotating massive galaxy ($\sigma = 300 \pm 100 \text{ km s}^{-1}$), but is blue-shifted by $-760 \pm 90 \text{ km s}^{-1}$ relative to the systemic redshift determined from [C II]. This remarkable velocity shift suggests that this emission is associated with outflowing gas. A similar shift has been observed in AGN called "blue outliers", in which the peak of the [O III] is blueshifted by more than -250 km s^{-1} with respect to the peak of H α and H β lines (Zamanov et al. 2002). In the local and $z \sim 1$ Universe, these features are observed in highly accreting AGN, and the velocity shift is thought to be due to strong nuclear outflows (Zamanov et al. 2002; Marziani et al. 2003; Lanzuisi et al. 2015; Marziani et al. 2016; Cracco et al. 2016; Perna et al. 2021, 2023b). In conclusion, as similar profiles have been observed in other AGN, we believe that the entire [O III] emission line of the SMG (*Narrow 2+Outflow*) is tracing a ionized outflow.

We stress that the extraction aperture of the spectrum (radius = 0.3'') encloses all the outflow emission. It does not encompass the whole galaxy emission, which is more extended than the aperture, but this does not affect our analysis, which focuses

Fig. 5. Continuum-subtracted JWST NIRSpec spectrum of the QSO. The best-fit model is shown with a black solid line, while the results of the individual components are reported with different colors: the blue dashed line shows the *Narrow* + *Outflow* components, and the purple dotted line corresponds to the *BLR* component. The fitted Véron-Cetty et al. (2004) Fe II template (VC+04) is shown with the orange dash-dotted line.

Fig. 6. JWST NIRSpec rest-frame optical spectrum of the SMG in the two gratings/filters G235H/F170LP and G395H/F290LP (blue and red lines, respectively), extracted from an aperture of $R = 0.3^{"}$. The principal nebular lines are marked with vertical dashed lines and the errors of the spectrum are shown in light gray.

Fig. 7. Comparison of the SMG line profiles of the $[O \ m]$, $H\alpha + [N \ n]$, and $[C \ n]$ emission lines in velocity space. All line profiles are normalized to their peak value. The vertical black dotted line indicates the zero velocity at the systemic redshift of z = 4.6891 for $[O \ m] \lambda 5007$, $H\alpha$, and $[C \ n]$ emission lines.

on the properties of the broad component rather than on those of the extended galaxy emission.

As discussed above, the blended $H\alpha + [N II]$ profile is complex, and the results strongly depend on the number of components used to reproduce the shape of the emission lines. There-

fore, we considered the two following possible scenarios: (1) the broad asymmetric profile of the complex line is due to the presence of galactic outflows; (2) the SMG hosts a type 1 AGN and the very broad component is associated with the emission of the broad line region. We discuss these alternative scenarios in the following. The combination of both is also possible; therefore, we will discuss the two extreme scenarios in the following sections.

5.1. Scenario 1: High-velocity outflow hosted by the SMG

The two components (*Outflow* and *Narrow 2*) adopted to model the [O III] line profile, significantly blueshifted relative to the systemic velocity, are not sufficient to reproduce the profile of the H α , [N II], and [S II]. Therefore, for the five emission lines of these three species we added an additional Gaussian component with $\sigma < 500 \text{ km s}^{-1}$ dubbed *Narrow 1*. We also fixed the kinematics (centroid and line width) of the *Narrow 2* and *Outflow* components to the best-fit results from the [O III] fitting process.

The middle panel of Fig. 8 illustrates the best-fit model (Reduced chi-squared, $\chi = 13.89$) and Table 3 reports the best-fit values for the free parameters. The H α +[N II] complex is wellreproduced with this fitting and the *Narrow 1* centroid is within 110 km s⁻¹ of the systemic redshift of the galaxy. As the line

Fig. 8. Fitting results for the SMG spectrum, showing the *Narrow 1*, *Narrow 2*, *BLR*, and *Outflow* components (dotted purple, dashed red, dashed yellow, and dash-dotted blue lines, respectively). The errors considered in the fitting procedure are displayed in gray and the residuals of the fits are shown at the bottom of each panel. Top panel: Fit of the $[O \text{ III}] \lambda\lambda 4959,5007$ Å emission lines. The vertical dotted lines mark the position of [O III] at the systemic redshift determined from [C II]. Middle and bottom panels: Fits of the $H\alpha$, $[N \text{ II}] \lambda\lambda 6548,6584$ Å, and $[S \text{ II}] \lambda\lambda 6717,6731$ Å emission lines for the first (outflow) and second (BLR) scenarios described in Sect. 5. The black vertical lines indicate the position of the emission lines for the *Narrow 2* component found in [O III].

spread function of the instrument is about FWHM ~ 100 km s⁻¹, we can conclude that *Narrow 1* arises from the gas at rest in the galaxy. This component is also consistent with the kinematics of the He I λ 5875 Å and [O I] λ 6300 Å nebular emission lines, and also with that of [C II] and CO lines. The kinematics of this component is consistent with being gas in the host, but the velocity

Remarkably, no H α *Outflow* component is found in this fitting, with only [N II] doublet lines being non zero. However, there could be some degeneracies in the fitting due to the complexity and broadening of the blended H α +[N II] profile. The best-fit model indicates that [N II]-to-H α flux ratio of the *Outflow* component is higher than 7 (log([N II] λ 6584 Å/H α) > 0.85), an extreme line ratio that suggests that the blueshifted H α component is blended with the [N II] due to the degeneracy.

We determined the upper limit on the reddening calculating the standard deviation of the spectrum at the position of the H β emission line, obtaining a value of 0.85×10^{-20} erg s⁻¹cm⁻² (1 σ). By assuming that the Balmer lines has the same line width as the other nebular lines, we found that the Balmer ratios for the narrow components are H $\alpha_{Narrow 1}/H\beta_{Narrow 1} > 9.2$ and H $\alpha_{Narrow 2}/H\beta_{Narrow 2} > 7.1$. The extinction A_V can be calculated by adopting the Galactic extinction law of Miller & Mathews (1972), with a specific attenuation of $R_V = 2.97$ and the theoretical ratio H $\alpha/H\beta = 2.863$ from Osterbrock & Ferland (2006, for $n_e = 100$ cm⁻³, $T_e = 10^4$ K, case B recombination). We thus obtained $A_{V, Narrow 1} > 3.5$ mag and $A_{V, Narrow 2} > 2.7$ mag.

5.2. Scenario 2: The SMG as a Type 1 AGN

We present now the other more "extreme" scenario in which the broad blue-shifted H α component might be associated with the emission of a BLR. To test the case that the broad component in H α +[N II] is due to emission from the BLR, we replaced the *Outflow* component in fitting this line complex with another Gaussian profile dubbed *BLR*, only associated to the H α line, allowing its velocity dispersion to vary between 1000 and 5000 km s⁻¹, as typical of BLRs in active galactic nuclei. The results of the spectral fitting are listed in Table 3. We stress that, even if the broad component in H α +[N II] is due to a BLR and not an outflow, this does not change the fact that the very broad component observed in [O III] (see Sect. 5) can only be explained by the presence of a fast outflow.

The best-fit model ($\chi = 13.80$) illustrated in the bottom panel of Fig. 8 shows that an individual BLR Gaussian profile in H α with velocity dispersion of 1370 km s⁻¹ (Table 3) is sufficient to reproduce the prominent wings in the spectrum of $H\alpha$ +[N II]. However, we note that the component is blueshifted by – 1600 km s⁻¹ with respect to the systemic velocity of the galaxy. Velocity shifts of BLR lines of thousands of km s⁻¹ have been already observed in other AGN from the Sloan Digital Sky Survey (e.g., Shields et al. 2009; Steinhardt et al. 2012; Eracleous et al. 2012; Li et al. 2022; Zhang 2024) and several explanations have been proposed to explain the spectral displacement of the BLR Balmer lines (see Ju et al. 2013; Komossa & Merritt 2008; Gaskell 2010): a) dense gas clouds forming the BLR are moving on elliptical Keplerian orbits; b) a recoiling supermassive black hole; c) binary black holes. Multi-epoch spectra are necessary to investigate the origin of the blueshifted BLR among the aforementioned explanations, therefore we refrain from further speculations.

Table 3. Emission line properties of the SMG as constrained from our best fit of the spectrum in Fig. 8 (extracted from an aperture radius of 0.3''). Emission line intensities are in units of 10^{-20} erg s⁻¹ cm⁻².

Fig. 9. JWST NIRSpec rest-frame optical spectra of LAE1 and LAE2 in the two gratings/filters used (G235H/F170LP and G395H/F290LP, blue and red lines, respectively), extracted from apertures of R = 0.6" and 0.3", respectively. The errors in the spectra are shown in light gray and the kinematic components used to model the emission lines in LAE1 are marked with different curve styles and colors (the two main narrow components are shown with a dashed black and a dotted purple line, respectively, while the broad component is marked shown with a dashed gray line). The spikes that appear in the H β emission line of LAE1 are instrumental artifacts, therefore the measurements of this emission line in LAE1 are not completely reliable.

6. LAEs and companions

As BR1202-0725 is one of the most overdense fields known in the early Universe, we exploited the NIRSpec IFS data to study the properties of its environment. The two Lyman- α emitters, LAE1 and LAE2, are detected with a high level of significance in both spectral configurations of the NIRSpec data in the integrated spectra extracted from apertures of R = 0.6 arcsec and 0.3 arcsec for the two sources, respectively (see Fig. 9).

The optical lines of LAE1 reveal a double-horned profile that might suggest the presence of a rotating disk. However, the analysis of the channel maps rather indicates a scenario of two independent galaxies that partially overlap along the line of sight. Taking into account the relative positions and velocities of these two galaxies, they could be an on-going merging system (Fig. D.1). The two sources, hereafter dubbed LAE1a and LAE1b, are separated by a projected distance of about ~2.8 kpc, which is larger than the typical galaxy size at similar redshift and mass (e.g., 1.5–2 kpc; Ormerod et al. 2024). The relative velocity between LAE1a and LAE1b is \approx 590 km s⁻¹ and their emission lines have similar velocity dispersions of 160 km s⁻¹ and 167 km s⁻¹, respectively. Modeling the spectral shape of the line requires an additional broad component ($\sigma = 570 \pm 20$ km s⁻¹), which may originate from tidal interactions or outflows.

The other known companion galaxy in the system, LAE2, is detected only in H α and [S II], whose redshift is consistent, within the errors, with those determined from Ly α and [C II]. The H α emission map features a south-north elongation, but unfortunately, the sensitivity of current observations is not sufficient for a spatially resolved kinematic analysis of the H α emission of the galaxy.

In addition to LAE1 and LAE2, we robustly identified four other companion galaxies (C1, C2, C3, C4) within 1" of the QSO by performing a blind line search in the PSF-subtracted data cube. The two panels of Fig. 10 show the emission maps obtained by integrating the PSF-subtracted data-cube over two

Fig. 10. JWST NIRSpec PSF-subtracted maps integrated over the two wavelength ranges reported in each panel, both encompassing [O III] λ 5007 Å emission in the same FoV. The QSO position is marked with a plus symbol. The companions found near the QSO are highlighted with red circles, which represent the apertures used to extract their integrated spectra (reported in Fig. 11).

wavelength ranges including [O III] λ 5007 Å line emission at different spectral shifts, $2.86 - 2.865 \,\mu\text{m}$ and $2.85 - 2.86 \,\mu\text{m}$, respectively. The two wavelength ranges correspond to the spans of velocity $1080 - 1600 \text{ km s}^{-1}$ and $30 - 1080 \text{ km s}^{-1}$ with respect to the [O III] wavelength redshifted to z = 4.6943. One of the companions (C1) is very bright in [OIII] and is located at around 3.25 kpc to the east of the QSO with an apparent elongation to the north-west, while the two other bright sources (C2 and C3) are within a radius of \sim 2.3 kpc from the QSO. The last one (C4) is located to the south-west of the QSO. All the sources are detected in both $[O_{III}]$ and $H\alpha$ and have redshifts within 1200 km s⁻¹ from the systemic velocity of the QSO. We extracted the integrated spectra of the new companion galaxies, C1, C2, C3, and C4, from the apertures shown in Fig. 10 (with radii of 0.2, 0.1, 0.15, and 0.1 arcsec for C1, C2, C3, and C4, respectively) and we report them in Fig. 11. A single Gaussian component per line was sufficient to fit the emission lines. The emission line observed fluxes and the main emission line ratios of these newly found sources are reported in the upper part of Table 5, together with those of the LAEs. We stress that the errors on the Guassian parameters might be larger due to the uncertainties introduced by the PSF subtraction. LAE3 falls outside the FoV of the NIRSpec IFS observations (Fig. 1, left), therefore we cannot constrain its emission-line properties.

In conclusion, the BR1202-0725 system includes at least ten galaxies, namely the QSO, the SMG, and the companions LAE1a, LAE1b, LAE2, LAE3, C1, C2, C3, and C4, in a projected area of 980 \mbox{kpc}^2 and within a relative velocity range of ~ 1200 km s⁻¹. A similarly large number of companions has also been recently found in SPT0311-58 at $z \sim 6.9$ thanks to NIRSpec IFU observations (Arribas et al. 2024). Interestingly, this system shares several similar structural and kinematic properties with BR1202-0725. In particular, it is also formed by two main (dusty) galaxies and about ten nearby companions with relative radial velocities, and projected distances similar to what we found in BR1202-0725. Table 4 shows the coordinates, redshifts, velocity shifts and projected distances of all the galaxies found in this field. All the spectra of the companions show $H\alpha$, $H\beta$, $[O_{III}] \lambda\lambda 4959,5007$ Å, and $[O_{II}] \lambda\lambda 3727,29$ Å emission lines, except for LAE2 in which only H α and [S II] are detected, while LAE1 and C1 also show [Ne III] λ 3869 Å (see Figs. 9 and 11). The emission line fluxes and commonly used line ratios are reported in Table 5. The blind line search analysis also revealed the presence of four other candidate emitting sources in the NIR-Spec FoV (see Fig. E.1), but the significance of the detection is too low to confirm the origin of the signals and to determine their redshifts. The spectra and coordinates of these candidate sources are reported in Fig. E.2 and Table E, respectively (see Appendix **E**).

7. Discussion

7.1. Ionization nature of the sources in BR1202-0725

To investigate the mechanism of ionization of the various sources in the BR1202-0725 system, we made use of the so-called BPT diagnostic diagram (Baldwin et al. 1981), which exploits the [O III] λ 5007 Å / H β and [N II] λ 6584 Å / H α line ratios to distinguish between star-forming regions and those dominated by AGN radiation, shocks, or non-thermal activity. We report the BPT diagram for the galaxies analyzed in this study in Fig. 12.

For the component associated with the gas at rest in the SMG (SMG Narrow 1, vertical orange line), there is no detection of the $[O ext{ III}] \lambda 5007 \text{ Å}$ or H β emission lines (see Fig. 8), but both best-fit results of Scenario 1 and Scenario 2 return a log($[N ext{ II}]/H\alpha$) ratio of 0.32 (Table 3), not consistent with star formation processes. The two other components of the SMG (*SMG Narrow 2* and *SMG Outflow* in Scenario 1) have extreme $[O ext{ III}]/H\beta$ and $[N ext{ II}]/H\alpha$, fully consistent with the gas being AGN photoionized, rather than SF-ionized. Then, the location of the SMG in the BPT together with both scenarios proposed to reproduce the observed integrated spectrum (a BLR or just an outflow with velocity shift of ~ -2500 km s^{-1}), indicate that the SMG hosts an accreting supermassive black hole. This supports a dual AGN scenario in this complex system at $z \sim 4.7$.

The LAE1a and LAE1b and the companion C1 exhibit $[N II]/H\alpha$ ratios consistent with star formation processes if they were in the local Universe. However, at high *z* the traditional low-*z* BPT becomes insensitive to the mechanism of ionization in this part of the diagram, where both low-metallicity star-forming galaxies and AGN accumulate (see e.g., Feltre et al. 2016; Übler et al. 2023; Maiolino et al. 2023; Hirschmann et al. 2023; Cameron et al. 2023; Scholtz et al. 2023). Therefore, the

^{*a*} These measurements should be taken with caution due to the presence of spikes at the wavelengths of H β in the spectrum of LAE1 (see Fig. 9); for this reason, we have not used the ratios involving this line to estimate the metallicity of LAE1a and LAE1b. ^{*b*} Assuming a solar photospheric value of 12+log(O/H)_o = 8.69 (Asplund et al. 2009).

Fig. 12. The $[O \ m]/H\beta$ vs $[N \ n]/H\alpha$ BPT diagnostic diagram for all objects analyzed. The demarcation between H π and AGN-ionized regions (Kauffmann et al. 2003; Kewley et al. 2001, dash-dotted and dashed black lines, respectively) are reported. The vertical lines indicate the $[N \ n]/H\alpha$ ratio for the two sources in which we have not values of $[O \ m]$ and H β emission lines, with the errors showed with shaded bands (the errors are not visible for the *SMG Narrow 1* component).

nature of LAE1a, LAE1b, and C1 is uncertain. For the LAE2 there is no detection of either $[O III] \lambda 5007$ Å or H β emission lines, then it might be ionized by either AGN or star formation processes. The nature of the C3 companion is also uncertain because it lies close to the demarcation line between AGN- and star formation-dominated ionization in the BPT diagram. Finally, C2 and C4 are the companions which are mostly consistent with being ionized by the QSO photons.

We calculated the ionization parameter (*U*) for the companion galaxies in the system using the [O II] $\lambda\lambda$ 3727,29 Å / [O III] λ 5007 Å ratio (Díaz & Pérez-Montero 2000). We obtained values ranging from -3.16 to -2.56 in the logarithmic scale (see Table 5).

Assuming that the ionization of the companions is due to star formation and not AGN photons (though this cannot

be unambiguously assessed based on the BPT diagram; see Fig. 12), we estimated their metallicities by using the following strong-line diagnostics: R2 = $[O \amalg \lambda 3727, 29 \text{\AA}/\text{H}\beta, \text{R3} = [O \amalg \lambda 5007 \text{\AA}/\text{H}\beta, O3O2 = [O \amalg \lambda 5007 \text{\AA}/[O \amalg \lambda 3727, 29 \text{\AA}, \hat{\text{R}} = 0.47 \text{ R2} + 0.88 \text{ R3}, \text{ N2} = [N \amalg \lambda 6584 \text{\AA}/\text{H}\alpha, O3N2 = ([O \amalg \lambda 5007 \text{\AA}/\text{H}\beta)/([N \amalg \lambda 6584 \text{\AA}/\text{H}\alpha))$. We adopted the recently introduced diagnostic ratio $\hat{\text{R}}$ (Laseter et al. 2024) in place of the traditional R23 = $([O \amalg \lambda \lambda 3727, 29 \text{\AA} + [O \amalg \lambda \lambda 4958, 5007 \text{\AA})/\text{H}\beta$, since the former is more suited for high-*z* galaxies. For C1, the only source for which we found a non-zero extinction from $\text{H}\alpha/\text{hb}$ ($A_V = 0.16 \pm 0.08$), we corrected the line fluxes for extinction, assuming a Calzetti et al. (2000) reddening curve with $R_V = 4.05$. To obtain the gas metallicity from the above ratios, we adopted the best-fit polynomial calibrations from Curti et al. (2017, 2020), slightly revisited in

Curti et al. (2023, 2024) to better probe the low-O/H regime at high z. Assuming a solar photospheric value $12+\log(O/H)_{\odot} = 8.69$ (Asplund et al. 2009), most of the sources have values consistent with $Z/Z_{\odot} \sim 0.5$, while LAE1a and C1 have lower values, of ~ 0.3 solar, and only C3 has a higher value with $Z/Z_{\odot} = 0.8$ (see Table 5).

Still under the assumption that gas excitation driving line emission is due to star formation and not to the QSO, we find that each of the companions has a SFR higher than ~ 1 M_{\odot} yr⁻¹ (using the H α -to-SFR relation from Kennicutt & Evans 2012).

We stress again, however, that these estimates should be taken with great caution, given that a contribution to the gas ionization from the bright QSO may affect the line emission fluxes and their ratios. This is especially the case of C2 and C4, whose line ratios are more clearly in the AGN region of the BPT (Fig. 12).

7.2. X-ray detection of the SMG

To further probe the AGN nature of the SMG, we investigated its X-ray properties with archival data by *Chandra*, the only Xray facility that can spatially resolve the QSO and the SMG of the system. The X-ray emission of the QSO is detected in both observations, while only Iono et al. (2006) addressed the X-ray emission of the SMG, presenting a tentative detection (below the 3σ level).

We reduced both archival observations (see Sect. 2) with the chandra_repro tool of CIAO v.4.16 (Fruscione et al. 2006) and merged the two datasets with the merge_obs script of CIAO, to maximize the chances of detecting the X-ray emission from the SMG. A soft-band (0.5-2 keV) image (smoothed with a 2-pixel Gaussian kernel) from the resulting data is shown in Fig. 13. With a standard circular extraction region of 1" radius, we measured 3 counts at the position of the SMG in the soft band (0.5-2)keV observed-frame) and no counts in the hard band (2-7 keV observed-frame), which is not surprising given the drop of Chandra's effective area above 2 keV. With a background level of 0.08 counts, we measured 2.9±1.7 net counts in the soft band associated with the SMG, corresponding to the $\simeq 2.8-11.4$ keV restframe energy range. As a comparison, we detected 33.9±5.8 net counts in the same energy band in a circular aperture of 1" radius centered on the QSO. We follow the approach of Vito et al. (2019) to test the significance of the measured X-ray emission at the position of the SMG (i.e., 3 total counts in the soft band). First, we estimated the probability of this being a spurious detection, that is, due to background fluctuations, applying Eq. A21 of Weisskopf et al. (2007). We found a false-detection probability of $P = 8.9 \times 10^{-5}$, making this a detection at $\gtrsim 4\sigma$. To doublecheck this result, we measured the probability of detecting 3 total counts in the soft band by chance by performing aperture photometry in regions of 1" radius randomly distributed in the field over 10⁶ positions. Considering the full merged field, only 24 regions out of the 10⁶ considered present more than 3 total counts with a false-detection probability of $P = 7.4 \times 10^{-5}$. This result could be due to the variation of exposure time from the central region, where the two observations overlap, to the outskirts of each separate field, combined to a larger Chandra PSF moving off-axis. We thus repeated the exercise restricting the sampled area to the part of the field that was exposed in both observations, finding a false-detection probability of $P = 1.5 \times 10^{-4}$ and thus a significance of the X-ray emission at the position of the SMG that is slightly less than 4σ .

Given this tentative 4σ detection, we measured the X-ray flux of the SMG in the soft band and estimated its intrinsic X-

Fig. 13. Soft-band (0.5-2 keV) Chandra image of BR1202-0725 $(10'' \times 10'' \text{ box})$. Data were smoothed with a Gaussian kernel of 2-pixel radius. Circular regions mark the positions of the QSO (blue) and of the SMG (magenta).

ray luminosity. Assuming a photon index $\Gamma = 1.9$ (in agreement with typical values at these redshifts; e.g., Vignali et al. 2005; Just et al. 2007) and converting the measured count rate with the PIMMS tool v.4.12d², we found a soft-band observed flux of $f_{0.5-2 \text{ keV}} \simeq 7.8 \times 10^{-16} \text{ erg s}^{-1} \text{ cm}^{-2}$. Assuming the same photon index, we converted this flux to intrinsic 2-10 keV luminosity in the two extreme cases of no absorption ($N_{\rm H} < 10^{20} \,{\rm cm}^{-2}$) and Compton-thick ($N_{\rm H} = 10^{24} \,{\rm cm}^{-2}$) column densities, which return $L_{2-10 \,{\rm keV}} = 2.1 - 17 \times 10^{44} \,{\rm erg \, s}^{-1}$, respectively. The estimated X-ray luminosity is higher than 2×10^{44} erg s⁻¹ at any absorption level and, as such, cannot be explained by SF processes only: previous works estimate a SFR in the range 1000-5000 M_{\odot} yr⁻¹ (see Carniani et al. 2013), which corresponds to an X-ray luminosity of 3×10^{43} erg s⁻¹ in the 0.5–8 keV restframe band, based on the relation of Mineo et al. (2014). This is less than half the 0.5–8 keV lower limit we get from the estimated X-ray luminosity ($L_{0.5-8 \text{ keV}} \simeq 3 \times 10^{44} \text{ erg s}^{-1}$, assuming no absorption). This tentative X-ray detection thus supports the scenario of the SMG harboring an AGN.

7.3. Black hole properties

We determined the properties of the black hole of the QSO and the SMG from the best-fit results of the spectral fitting. We report them in Table 6. For the SMG, we used the results from Scenario 2, where we assumed that the broad component of the $H\alpha$ emission line is associated with the BLR.

Initially, we estimated the impact of dust attenuation on the observed flux of the optical lines by measuring the Balmer decrement. We measured a $(H\alpha/H\beta)_{BLR}$ ratio of 2.36 (± 0.14) for the BLR component of the QSO. The theoretical ratio in low-density gas is 2.87 assuming Case-B recombination and an electron temperature of $T_e \sim 10^4$ K (Osterbrock & Ferland 2006), while it spans a range between 3 and 10 in the dense BLR gas where the optical line depths and collisional effects are different from those in H II regions (Dong et al. 2008; Baron et al. 2016). The ratio

² https://cxc.harvard.edu/toolkit/pimms.jsp.

measured in the QSO therefore suggests that a dust extinction correction is not necessary.

We used the H α luminosity to determine the bolometric luminosity of the AGN hosted in the SMG by using the relation from Stern & Laor (2012). This gives a log($L_{bol,H\alpha}/[erg s^{-1}]$) = 47.2 ± 0.4 for the QSO, which is consistent with the bolometric luminosity calculated from the monochromatic continuum in UV at λ 1350 Å, of 47.32 ± 0.02 (Jun et al. 2015) and 47.929 ± 0.029 (Yu et al. 2021). We also determined the bolometric luminosity from the monochromatic luminosity at the rest-frame wavelength of 5100 Å (λL_{5100}) following Netzer (2019):

$$\begin{cases} \log(L_{\text{bol},5100}) = \log(\lambda L_{5100}) + \log(k_{\text{bol}}) \\ \log(k_{\text{bol}}) = 10 - 0.2 \times \log(\lambda L_{5100}) \end{cases}$$
(2)

We infer $\log(L_{bol,5100}/[\text{erg s}^{-1}]) = 47.52 \pm 0.02$, in agreement with the other measurements.

The properties of the H α emission line can also be used to estimate the BH mass ($M_{\rm BH}$) assuming the gas in the BLR is virialized. In the local Universe, Reines et al. (2013) infer

$$\log\left(\frac{M_{\rm BH}}{M_{\odot}}\right) \approx 6.57 + 0.47 \cdot \log\left(\frac{L_{\rm H\alpha}}{10^{42} \, {\rm erg \, s^{-1}}}\right) + 2.06 \cdot \log\left(\frac{FWHM_{\rm H\alpha}}{10^3 \, {\rm km \, s^{-1}}}\right),\tag{3}$$

where $L_{\text{H}\alpha}$ and $FWHM_{\text{H}\alpha}$ are the line luminosity and width, respectively, of the H α emission line associated to the BLR (see also Greene & Ho 2005). The calibration has an intrinsic scatter of 0.5 dex (Reines et al. 2013). We thus measured a BH mass of the QSO of $\log(M_{\text{BH}}/M_{\odot}) = 10.1 \pm 0.5$, which is consistent within 2σ with the estimates derived from Mg II ($\log(M_{\text{BH}}/M_{\odot}) = 9.1 \pm 0.3$; Carniani et al. 2013) and C IV corrected from outflows effect ($\log(M_{\text{BH}}/M_{\odot}) = 9.65 \pm 0.01$; Yu et al. 2021). It is important to emphasize that degeneracies in the fitting of the QSO spectrum (see Sec. 4) do not affect the estimated black hole mass, since all the values obtained from the different fittings are consistent with each other within the uncertainties, which are dominated by the error on the calibration.

The excitation diagnostic diagrams and the tentative X-ray detection indicate that the SMG hosts an AGN at its center. We thus estimated its black hole mass and bolometric luminosity from the best-fit results of the BLR H α component inferred in Scenario 2. We measured a lower limit on the Balmer decrement of $(H\alpha/H\beta)_{BLR} > 6$, which is within the range of values measured in low-redshift Seyferts and QSOs (Dong et al. 2008; Baron et al. 2016). However, the rest-frame UV emission is heavily obscured due to the high dust content in the interstellar medium, so the measured H α luminosity (Table 6) is a lower limit. Therefore, the quantities derived for the BH of the SMG are lower limits as well. We thus inferred log($L_{bol,H\alpha}/[erg s^{-1}]$) > 44.9 and log(M_{BH}/M_{\odot}) > 8.0.

If the mass of the black hole of the SMG is confirmed by future observations, BR1202-0725 would be one of the most distant systems with two BHs with similar masses ($M_{BH} \ge 10^8 M_{\odot}$) within a projected distance of 24 kpc (see also Matsuoka et al. 2024; Übler et al. 2024). Simulations of $z \sim 6$ luminous QSOs predict that highly accreting supermassive BHs live in overdense fields hosting galaxies with similar stellar and BH masses (Barai et al. 2018; Valentini et al. 2020; Zana et al. 2022; Di Mascia et al. 2021). For example, Di Mascia et al. (2021) show a simulated system similar to the BR1202-0725 one where a bright UV QSO lies at the center of the field and another luminous AGN is hosted in dusty galaxies that are obscured in the UV due to the interstellar medium dust. In these simulations, the most massive BHs of the system grow by accretion of the surrounding gas or by mergers with other BHs. Therefore, BR1202-0725 may represent the typical system where bright QSOs form and evolve, but luminous companion AGN can be obscured by the dust of their host galaxy.

Table 6. BH properties of the QSO and SMG. The properties of the BLR of the SMG are derived from the H α *BLR* component from Scenario 2.

	QSO	SMG
$\log(L_{\mathrm{H}\alpha}/[\mathrm{erg \ s}^{-1}])$	45.07 ± 0.02	> 42.8
$\log(\lambda L_{5100} / [erg s^{-1}])$	46.903 ± 0.007	-
$\log(L_{bol,5100}/[erg s^{-1}])$	47.52 ± 0.02	-
$\log(L_{bol,H\alpha}/[erg s^{-1}])$	47.2 ± 0.4	> 44.9
$\log(M_{\rm BH,Hlpha}/M_{\odot})$	10.1 ± 0.5	> 8.0
$\log(L_{\rm edd}/[{\rm erg \ s^{-1}}])$	48.2 ± 0.5	> 46.1
$\lambda_{ m edd}$	0.1	0.1

7.4. Outflow properties in the SMG

The spectra of the SMG show evidence for broad blueshifted component likely associated with galactic outflows (Figs. 6, and 8). We determined the properties of the outflowing gas from the *Outflow* broad component of the [O III] line because the spectral fitting of the oxygen line is less affected by degeneracies than the H α +[N II] complex. We assumed a uniformly filled conical outflow for which the mass outflow rate of the ionized gas is defined as $\dot{M}_{\rm ion} = M_{\rm ion}v_{\rm out}/R_{\rm out}$, where $M_{\rm ion}$ is the outflow mass, $v_{\rm out}$ the outflow velocity, and $R_{\rm out}$ the size of the outflow.

Following Cresci et al. (2015) and Carniani et al. (2015), we determined the mass of the ionized outflowing gas from the flux of the Outflow broad component of the optical lines fixing the electron density to 500 cm⁻³ and solar gas-phase metallicity to be consistent with other outflow measurements in AGN at lower redshift (Carniani et al. 2015; Fiore et al. 2017). We estimated the outflow velocity as $v_{out} = |\Delta v_{Outflow}| + 2\sigma_{Outflow}$, where $\Delta v_{Outflow}$ is the velocity shift of the centroid of the Outflow component relative to the systemic redshift of the galaxy and $\sigma_{Outflow}$ its velocity dispersion (see Table 3). We found that the SMG is expelling more than $5 \times 10^6 M_{\odot}$ of ionized gas at a velocity ~ 5000 km s⁻¹ (see Table 7). Such high velocity is very high even for an extreme starburst galaxy (Heckman & Borthakur 2016; Perrotta et al. 2021), which indicates that this outflow is driven by an AGN (e.g., Carniani et al. 2015; Fiore et al. 2017; Förster Schreiber et al. 2019; Cresci et al. 2023). Similar velocities are observed only in AGN with bolometric luminosities higher than 10⁴⁷ erg s⁻¹ (Carniani et al. 2015; Zakamska et al. 2016; Fiore et al. 2017; Perrotta et al. 2019; Perna et al. 2023a). This further supports that the SMG hosts an accreting supermassive BH.

We estimates the mass outflow rate assuming a size of 1 kpc for the outflow (corresponding to the spatial resolution of NIR-Spec, being the outflows unresolved; D'Eugenio et al. 2024), resulting in a mass outflow rate of ~ 25 M_{\odot} yr⁻¹. The measured mass outflow rate is more than one order of magnitude lower than the SFRs inferred from the far-infrared continuum luminosity (2600 M_{\odot} yr⁻¹; Carniani et al. 2013). Then, the mass loading factor (\dot{M}_{ion} /SFR) of the wind assuming the SFR from far-infrared is ~ 1%. This low mass loading factor suggests that

the star formation process is currently dominating gas consumption.

However, in this work, we are only probing the ionized gas phase, and contributions from molecular and neutral phases is missing (see Rupke & Veilleux 2013; Herrera-Camus et al. 2019; Roberts-Borsani et al. 2020; Fluetsch et al. 2021; Belli et al. 2024; Baron et al. 2022; Cresci et al. 2023; Perna et al. 2019). We also emphasize that the measured ionized mass outflow rate value might represent a lower limit, as it is not corrected for dust attenuation, meaning the intrinsic [O III] luminosity associated with the outflow may be higher than observed.

Table 7. Outflow properties of the SMG. Outflow mass and velocity for both galaxies are inferred from the [O III] broad component and assuming $n_e = 500 \text{ cm}^{-3}$, solar metallicity, and outflow extension of 1 kpc.

$\log(M_{\rm out}/M_{\odot})$	6.67 ± 0.11
$v_{\rm out} [\rm km s^{-1}]$	5000 ± 1000
$\log(\dot{M}_{\rm out}/[M_{\odot} {\rm yr}^{-1}])$	1.4 ± 0.2
$\log(\dot{E}_{out}/[erg s^{-1}])$	44.5 ± 0.3
$\log(\dot{P}_{out}/[g \text{ cm s}^{-2}])$	33.8 ± 0.2

8. Conclusions

In this study, we have presented new JWST NIRSpec IFS observations of BR1202-0725, one of the most extensively studied overdense fields at $z \sim 4.7$. The high resolution and sensitivity of these observations enabled us to investigate for the first time the ionized properties of this system in the rest-frame optical wavelength range. We analyzed the kinematic and physical properties of the main sources in the system, the QSO and the SMG, from their integrated spectra, and we searched for galaxy companions that are part of this system. The main results of this work are the following:

- The two companion galaxies identified from previous ground-based observations, LAE1 and LAE2, are detected in the strongest optical emission lines ($[O III]+H\beta$ and/or $H\alpha+[N II]$). LAE1 is detected with a high level of significance in both NIRSpec filters, while LAE2 is detected only in H α and [N II]. The optical lines of LAE1 exhibit two spectrally and spatially isolated components (LAE1a and LAE1b), which suggest a merger scenario between two galaxies at a projected distance of ~ 2.8 kpc. The line ratios measured in LAE1 indicate that the gas excitation is driven by OB stars.
- We robustly identify four new additional companion galaxies within 1 arcsec (i.e., ~ 6.5 kpc) of the QSO. They are detected in both [O III] and H α emission, and their redshifts are consistent with the systemic velocity of the QSO within 1050 km s⁻¹.
- − The spectrum of the QSO clearly reveals broad ($\sigma \sim 4300$ km s⁻¹) emission lines of Hα and Hβ and Fe II emission multiplets, both arising from the BLR, an accretion-disk continuum, and nebular emission lines. The broad Hα line emission implies a bolometric luminosity of log($L_{bol,H\alpha}$ /[erg s⁻¹]) = 47.2 ± 0.4, consistent with those calculated from the monochromatic continuum at 1350 Å and 5100 Å. For the QSO, we measure a black hole mass of log($M_{\rm BH}/M_{\odot}$) = 10.1 ± 0.5, compatible within 2 σ with those estimated from Mg II and C IV.
- The [O III] profile of the SMG is surprisingly blueshifted by more than -700 km s⁻¹ at its peak relative to the systemic

redshift of the galaxy (determined from [C II]) and includes two distinct components. The broadest component has a velocity and a velocity dispersion of -2450 ± 40 km s⁻¹ and 1300 ± 500 km s⁻¹, respectively, and it is likely associated with a fast galactic outflow. The other [O III] component has a velocity dispersion more consistent with the one measured from [C II] and CO for the cold gas, but is shifted by -760 ± 90 km s⁻¹. Similar spectroscopic features have also been observed in some local and intermediate-redshift QSOs dubbed "blue outliers". These QSOs show [O III] emission lines blueshifted by more than 250 km s⁻¹ at peak with respect to the systemic redshift of the galaxy. These profiles have been associated with spatially compact outflows in the narrow line region of AGN.

- Based on the analysis of the broad [O III] component, we find that the outflow in the SMG is expelling ~ $5 \times 10^6 M_{\odot}$ of ionized gas at a velocity ~ 5000 km s⁻¹. Similar velocities have only been observed in AGN with high bolometric luminosity ($L_{bol} > 10^{46}$ erg s⁻¹). Despite the high velocity, the mass loading factor (ratio between the mass outflow rate and the host galaxy star formation rate) is of the order of 1 percent, suggesting that the star formation processes are currently dominating gas consumption, rather than the material ejection due to the outflow.
- The integrated spectrum of the SMG also reveals a complex Hα+[N II] profile with a prominent blueshifted wing that requires different components to be reproduced. On the one hand, a narrow component at the systemic redshift of the galaxy is needed, and its velocity dispersion ($\sigma \sim 470$ km s⁻¹) is consistent within the errors with that measured from the far-infrared lines. On the other hand, the broad blueshifted and asymmetric wing in the Hα+[N II] profile does not yield a simple interpretation. It can be explained by either the high-velocity outflow also observed in [O III] emission or a BLR component in Hα. In this last scenario, the broad Hα implies log($L_{\text{bol},\text{H}\alpha}/[\text{erg s}^{-1}]$) > 44.9 and log(M_{BH}/M_{\odot}) > 8.0.
- Independently on the interpretation of the broad and asymmetric wing of the H α +[N II] emission line complex, all components have high [O III]/H β (> 10) and/or [N II]/H α (> 1), which robustly indicate AGN excitation. The presence of an accreting black hole at the center of the SMG is also supported by the analysis of *Chandra* X-ray observations, which yield an X-ray luminosity > 10⁴⁴ erg s⁻¹ at the location of the SMG, and the extreme outflow velocities comparable to those observed only in luminous quasars.

We conclude that the BR1202-0725 QSO+SMG system hosts two supermassive black holes within a projected separation of 24 kpc and represents one of the most distant dual AGN systems in the Universe. Current JWST observations also reveal that the system is composed by at least ten sources (the QSO, the SMG, four LAEs, and four galaxy companions). This makes BR1202-0725 one of the most overdense fields known in the early Universe. The number of galaxies found within a few tens of kiloparsecs from the QSO of BR1202-0725 is the order of magnitude higher than the average number of companions detected around high-redshift guasars in a similar field of view.

Acknowledgements. We thank F. Vito for the useful discussion regarding the X-ray data analysis. GV, SC and SZ acknowledge support from the European Union (ERC, WINGS, 101040227). EB and GC acknowledge support of the INAF Large Grant 2022 "The metal circle: a new sharp view of the baryon cycle up to Cosmic Dawn with the latest generation IFU facilities". SA, MP, and BRdP acknowledge grant PID2021-127718NB-100 funded by the Spanish Ministry of Science and Innovation/State Agency of Research (MICIN/AEI/

10.13039/501100011033). AJB acknowledges funding from the "FirstGalaxies" Advanced Grant from the European Research Council (ERC) under the European Union's Horizon 2020 research and innovation program (Grant agreement No. 789056). FDE and GCJ acknowledge support by the Science and Technology Facilities Council (STFC), by the ERC through Advanced Grant 695671 "QUENCH", and by the UKRI Frontier Research grant RISEandFALL. IL acknowledges support from grant PRIN-MUR 2020ACSP5K_002 financed by European Union - Next Generation EU. RM acknowledges support by the Science and Technology Facilities Council (STFC), from the ERC Advanced Grant 695671 "QUENCH", and funding from a research professorship from the Royal Society. HÜ acknowledges support through the ERC Starting Grant 101164796 "APEX".

Appendix A: PSF modeling

Fig. A.1. QSO spectrum (top panel, G235H/F170LP and G395H/F290LP gratings/filters in red and blue, respectively) with examples of the empirical PSF models adopted in our analysis (bottom panels). The wavelength ranges used to compute the PSF are highlighted in gray.

Fig. A.2. Example of two PSF-subtracted spectra in the two different gratings for two different sources (G235H/F170LP for C1 and G395H/F290LP for C2, upper and lower panels, respectively). The modeled PSFs in the same aperture of the integrated spectra (see Sect. 3.3) and the PSF-subtracted spectra are shown with dashed black and solid gray lines, respectively.

Appendix B: Aperture correction results

The aperture correction can be calculated using point source observations from the same instrument and configuration (grating/filter) of our observation. In Sect. 3.3, we used the QSO emission itself to model the PSF from our data. Then, we used this modeling to calculate the wavelength-dependent correction adopting four different apertures of radius 0.2, 0.3, 0.4, and 0.5 arcsec centered on the QSO.

Figure B.1 and Table B.1 show the fraction of the flux at different observed wavelengths normalized to the value obtained in the aperture of 1 arcsec radius, which includes almost the entire emission of the PSF. This fraction decreases when the wavelength increases due to the larger PSF. For an aperture of radius = 0.5 arcsec, the flux lost at the H β and H α wavelengths at redshift *z* = 4.7 is around 6 % and 8 %, respectively, this value being larger for smaller apertures.

We verified that these results obtained from the continuum also work for the BLR broad Balmer lines. We thus extracted the integrated spectrum of the QSO in two different apertures: R = 0.5'' and 1.0'' and modeled the broad H α with a Gaussian with a velocity dispersion spanning a range 1000 km s⁻¹ > σ > 5000 km s⁻¹, and we also quantified the flux lost in the spectral domain. We found that the integrated flux of the BLR component in both apertures is very similar, with a ratio $F_{\text{BLR}}(R = 0.5'') / F_{\text{BLR}}(R = 1'') = 0.95$ (we are losing less than a 5% of the BLR flux in the smallest one). This value is similar to the aperture corrected flux reported in Table B.1 with a value F_{fraction} ($\lambda = 3.74$, R = 0.5'') = 0.92. Then, the values calculated in Table B.1 can be used to correct the integrated spectrum.

Fig. B.1. Fraction of the total flux included in four different apertures ($R = 0.2^{"}, 0.3^{"}, 0.4^{"}$ and 0.5") as a function of the observed wavelengths, normalized to the value obtained in the aperture of $R = 1^{"}$.

Table B.1. Fraction of total flux included in four different apertures at
different observed wavelengths normalized to the value obtained in the
aperture of $R = 1''$.

Appendix C: NIRSpec errors

The errors on the integrated spectrum of a source can be calculated (i) from the error extension present in the data cube in the same spaxels of the selected region propagating them in quadrature; or (ii) considering the spatial noise of our data calculating the root mean square (RMS) at each wavelength in apertures without source emission.

We calculated the errors using these two methods in three different random apertures (RA₁ = 181.3455 deg, Dec₁ = -7.7087; RA₂ = 181.3460 deg, Dec₂ = -7.7079; RA₃ = 181.3458 deg, Dec₃ = -7.7092). For the G235H grating, the mean error obtained for each method is 0.0065 and 0.0067 × 10⁻²⁰ erg s⁻¹ cm⁻² Å⁻¹, respectively. The mean errors in the G395H grating are larger due to the low S/N of the data, 0.025 and 0.022 × 10^{-20} erg s⁻¹ cm⁻² Å⁻¹ with method (i) and (ii), respectively. The results of both methods are totally compatible between them according to the mean dispersion of the results in different apertures, then we used the first method to determine the errors in the integrated spectra of the sources within the system.

Appendix D: LAEs and companions

Fig. D.1. Channel maps of H α emission from LAE1. Contours begin at 3σ and are in steps of 5σ . Each channel map covers a FoV of $1'' \times 1''$ and spans 0.002 μ m, which corresponds to 160 km s⁻¹. The green ellipses indicate the location and extension of the two merging galaxies: LAE1a and LAE1b. The emission around these sources is not aligned in the same direction, which discards a rotation scenario.

Appendix E: Additional candidate galaxies

Fig. E.1. JWST NIRSpec PSF-subtracted map integrated over the wavelength range 3.635 μ m < λ < 3.846 μ m, encompassing H α +[N II] emission lines. The QSO position is marked with a plus symbol. The candidate galaxies found around the QSO are highlighted with stars.

 Table E.1. Coordinates of the additional candidate companion galaxies in BR1202-0725.

Name	RA $[deg]^a$	Dec $[deg]^a$
C5	181.34649464	-7.70866054
C6	181.34648063	-7.70872999
C7	181.34615827	-7.70895221
C8	181.34632646	-7.70866054

Fig. E.2. JWST NIRSpec rest-frame optical spectra (integrated in circular apertures with R = 0.1 arcsec) of the candidate galaxies found around the QSO in the two gratings/filters used (G235H/F170LP and G395H/F290LP; blue and red lines, respectively). The errors in the spectra are shown in light gray. Vertical dashed lines mark the position of the main emission lines in the spectrum at the systemic redshift of the QSO.
