Abstract

Observations of the intracluster medium (ICM) in the outskirts of galaxy clusters reveal shocks associated with gas accretion from the cosmic web. Previous work based on non-radiative cosmological hydrodynamical simulations have defined the shock radius, *r* shock, using the ICM entropy, $K \propto T/n_e^{2/3}$, where T and n_e are the ICM temperature and electron density respectively; the r_{shock} is identified with either the radius at which *K* is a maximum or at which its logarithmic slope is a minimum. We investigate the relationship between *r* shock, which is driven by gravitational hydrodynamics and shocks, and the splashback radius, *r* splash, which is driven by the gravitational dynamics of cluster stars and dark matter and is measured from their mass profile. Using 324 clusters from The Three Hundred project of cosmological galaxy formation simulations, we quantify statistically how *r* shock relates to *r* splash. Depending on our definition, we find that the median $r_{\rm shock}\simeq1.38r_{\rm sphash}(2.58R_{200})$ when K reaches its maximum and $r_{\rm shock}\simeq1.91r_{\rm sphash}(3.54R_{200})$ when its logarithmic slope is a minimum; the best-fit linear relation increases as $r_{\rm shock}\propto 0.65r_{\rm sphash}$. We find that $r_{\rm shock}/R_{200}$ and $r_{\rm sphash}/R_{200}$ anti-correlate with virial mass, M_{200} , and recent mass accretion history, and $r_{\rm shock}/r_{\rm {splash}}$ tends to be larger for clusters with higher recent accretion rates. We discuss prospects for measuring $r_{\rm shock}$ observationally and how the relationship between $r_{\rm shock}$ and $r_{\rm sphash}$ can be used to improve constraints from radio, X-ray, and thermal Sunyaev-Zeldovich surveys that target the interface between the cosmic web and clusters.

Keywords: galaxies: formation - galaxies: clusters: intracluster medium - cosmology: theory, dark matter -methods: numerical

1. Introduction

Galaxy clusters are the most massive virialised structures in the present-day Universe; in hierarchical cosmologies such as the Λ Cold Dark Matter model they assemble relatively recently, with typical formation redshifts of $z_{\text{form}} \simeq 0.5$ (e.g. Hahn et al. [2007;](#page-8-0) Li, Mo, and Gao [2008;](#page-8-1) Power, Knebe, and Knollmann [2012\)](#page-9-0). Clusters sit at the nodes of the cosmic web, accreting material from filaments, which is evident in the relative positions and orbits of infalling galaxies and groups (e.g. Tempel et al. [2015\)](#page-9-1) and in accretion shocks in the hot intracluster medium (hereafter ICM; e.g. Burns, Skillman, and O'Shea [2010;](#page-7-0) Brown and Rudnick [2011;](#page-7-1) Power et al. [2020\)](#page-9-2).

A commonly used measure of the physical state of a cluster's ICM is the entropy, *K*, which is defined as,

$$
K \equiv \frac{k_{\rm B} T}{n_{\rm e}^{2/3}}\tag{1}
$$

(cf. Cavaliere and Lapi 2013); here k_B is the Boltzmann constant, *T* is the ICM gas temperature, and n_e is the electron number density, which is related to the ICM gas density. Highresolution X-ray observations, including XMM-*Newton* (e.g. Jansen et al. [2001\)](#page-8-2), *Chandra* (e.g. Weisskopf et al. [2000\)](#page-9-3), and eROSITA (e.g. Predehl et al. [2021\)](#page-9-4) have allowed the radial

variation of cluster entropy to be studied in detail, and consequently the functional form of the entropy with respect to the radius *r*, *K*(*r*), is well-understood (e.g. Panagoulia et al. [2014;](#page-9-5) Hogan et al. [2017;](#page-8-3) McDonald et al. [2019;](#page-8-4) Zhu et al. [2021\)](#page-9-6). *K*(*r*) can be characterised by its logarithmic slope, *k*, which is defined as,

$$
k \equiv \frac{\mathrm{d}\ln K}{\mathrm{d}\ln r},\tag{2}
$$

which is itself a function of radius.

Observationally we find that *K* is consistent with being a power-law near R_{500} such that $k \approx 1.1$ (see, e.g. Babyk et al. [2018;](#page-7-3) Ghirardini et al. [2019\)](#page-8-5); here *R*_{500,crit} is the radius at which the enclosed matter density is 500 times the critical density, $\rho_{\text{crit}} = 3H^2/8\pi G$. This power-law behaviour is recovered in hydrodynamical cosmological simulations (e.g. Voit, Kay, and Bryan [2005\)](#page-9-7), independent of hydrodynamics solver and galaxy formation model (e.g. Sembolini et al. [2016\)](#page-9-8). At larger radius, simulations predict that *K*(*r*) reaches a maximum at $\simeq 1.6$ $R_{200, \text{mean}}$, where $R_{200, \text{mean}}$ encloses a mean matter density that is 200 times the cosmological mean matter density, $\rho_{\text{mean}} = \Omega_{\text{m}} \rho_{\text{crit}}$, where Ω_{m} is the matter density parameter (cf. Lau et al. [2015\)](#page-8-6). We note that this predicted radius is larger than that inferred from observational data (cf. S. A. Walker

et al. [2012\)](#page-9-9), which indicate that the entropy profile reaches its maximum closer to $R_{200,\text{crit}} \equiv R_{200}$, the radius enclosing a mean matter density of $200\rho_{\text{crit}}$. Regardless, the presence of a turnover in the entropy profile is interpreted as arising from infalling gas from the cosmic web generating an accretion shock at the 'shock radius', *r* shock, which is consistent with empirical measurements of the interface between cluster outskirts and filaments in the cosmic web (e.g. Kawaharada et al. [2010\)](#page-8-7). For this reason we can regard *r* shock as a characteristic measure of the boundary between a cluster's accreted gas reservoir and gas in the process of accreting from the cosmic web.

The splashback radius, *r* splash, provides an analogous characteristic measure of the boundary between collisionless material - dark matter and galaxies - that is orbiting within a cluster's potential and material that is infalling for the first time (e.g. More, Diemer, and Kravtsov [2015;](#page-8-8) Mansfield, Kravtsov, and Diemer [2017;](#page-8-9) Diemer et al. [2017;](#page-8-10) Deason et al. [2021\)](#page-8-11). By convention, *r* splash is defined as the radius at which the logarithmic slope of the spherically averaged density profile reaches its minimum value. Observational estimates of *r* splash using, for example, the luminosity density profile, galaxy number densities, and weak lensing measurements (e.g. Chang et al. [2018;](#page-7-4) Bianconi et al. [2021;](#page-7-5) Gonzalez et al. [2021\)](#page-8-12) indicate good consistency between simulation predictions and observationally inferred values, although observational estimates will be sensitive to a cluster's dynamical state and the structure of the cosmic web in which it is embedded (e.g. Lebeau et al. [2024\)](#page-8-13).

The question arises naturally as to the relationship between *r* shock and *r* splash. Both are characteristic of the growth of clusters by the accretion of material from their surroundings. Analytical models have assumed that *r* shock and *r* splash are coincident (e.g. Patej and Loeb [2015,](#page-9-10) who assume that the shock in the hot gas profile is coincident with a break in the dark matter profile). However, *r* shock arises because of the collisional nature of accreting gas whereas *r* splash is a result of the complex dynamics of collisionless components in an evolving gravitational potential, and so it's likely that instances in which $r_{\rm shock}$ and $r_{\rm splash}$ are coincident and infrequent at cluster mass scales.

The goal of this paper is to quantify the relationship between $r_{\rm shock}$ and $r_{\rm sphash}$ and its predicted variation with mass and recent accretion history using a statistical sample of massive galaxy clusters from The Three Hundred collaboration's simulation suite (cf. Cui et al. [2018;](#page-8-14) Cui et al. [2022\)](#page-8-15). This is a mass complete sample of clusters drawn from a 1 h^{-1} Gpc box, which have a diversity of assembly histories and larger-scale environments.

In the following sections, we describe briefly The Three Hundred project and our approach to calculating *r* shock and *r* splash (§ [2\)](#page-1-0). We present the measured relationship between $r_{\rm shock}$ and $r_{\rm sphash}$ and their variation with cluster mass and accretion rate $(\S$ [3\)](#page-2-0), and we discuss our results in the context of previous work $(\S 4)$ $(\S 4)$. Finally, we summarise our main findings in \S [5.](#page-6-0)

2. The Simulated Dataset

We use the 324 clusters from the latest GIZMO-Simba runs hereafter GIZMO-Simba-7k (Cui et al., In Preparation) - of The Three Hundred collaboration's suite of zoom simulations of galaxy clusters (cf. Cui et al. [2018\)](#page-8-14). These are a higher resolution extension - with re-calibrated galaxy formation prescriptions - of the GIZMO-Simba runs - hereafter GIZMO-Simba-3k - presented in Cui et al. [\(2022\)](#page-8-15). GIZMO-Simba-3k modelled galaxy formation processes (radiative cooling, star formation and feedback, black hole formation and growth, multiple modes of black hole feedback) using a variant of the SIMBA galaxy formation model presented in Davé et al. [\(2019\)](#page-8-16), calibrated for cluster scales as detailed in Cui et al. [\(2022\)](#page-8-15), and run with GIZMO (Hopkins [2015\)](#page-8-17). GIZMO-Simba-7k uses an updated version of the SIMBA model – SIMBA-C (Hough et al. [2023\)](#page-8-18), which adopts the advanced chemical enrichment model of Kobayashi, Karakas, and Lugaro [\(2020\)](#page-8-19). SIMBA-C also includes several other modifications, including a jet velocity that depends on the host dark matter halo's mass via the approximate escape velocity and a lower black hole seeding mass ($M_* \gtrsim 6 \times 10^6 M_{\odot}$ compared to $M_* \gtrsim 5 \times 10^9 M_{\odot}$ in SIMBA). We refer interested readers to Hough et al. [\(2023\)](#page-8-18) for more details. We note that the calibration of GIZMO-Simba-7k considered both the stellar and gas properties of the cluster, unlike GIZMO-Simba-3k, which was calibrated against only stellar properties; this produce improved ICM properties in GIZMO-Simba-7k.

These clusters form a mass complete sample at *z*=0 in the MultiDark Planck 2 simulation (Klypin et al. [2016\)](#page-8-20), a 1*h* –1 Gpc box on a side. They have virial masses in the range $6.4\times 10^{14} h^{-1} M_{\odot} \lesssim M_{200} \lesssim 2.6\times 10^{15} h^{-1} M_{\odot},$ where M_{200} is the mass corresponding to an overdensity criterion of 200 times the critical density at that epoch. The zoom region extends 15 $h^{-1}\mathrm{Mpc}$ from the centre of the cluster at *z*=0, corresponding to several virial radii; dark matter and gas cell masses in this region are $m_{\rm dm} \simeq 10^8 h^{-1} M_{\odot}$ and $m_{\rm gas} \simeq 2 \times 10^8 M_{\odot}$ $10^7 h^{-1} M_{\odot}$ respectively. The adopted cosmological parameters are $(\Omega_{\rm m}, \Omega_{\rm B}, \Omega_{\Lambda}, h, \sigma_8)$ = (0.307, 0.048, 0.693, 0.678, 0.823).

For each cluster, we use group catalogues constructed with the AHF halo finder (cf. Knollmann and Knebe [2009\)](#page-8-21), which includes information about the stellar and gas content of the main halo and its substructures. We compute radial profiles for the mass density and gas entropy using 100 equally spaced logarithmic bins between minimum and maximum cluster-centric radii of $0.5R_{200}$ and $5R_{200}$; here the centre is the densityweighted centre of the adaptive mesh refinement grid in AHF. The presence of substructure in the outskirts of the halo can bias estimates of the logarithmic slope, which influences the value of *r* splash. To avoid this, we evaluate the density and mass-weighted temperature in 48 angular segments within each radial bin and take the median value within the bin as our estimate of the density and temperature at that radius. With this information we can estimate the entropy in a given radial bin following Equation [1.](#page-0-0) Note th[a](#page-1-1)t for each gas element^a

in the cluster we have an associated internal energy per unit mass, $u = 3k_B T/(2\mu m_p)$, from which we can estimate the temperature, and a local density, $ρ = μ_e m_p n_e$; here μ and $μ_e$ are the mean molecular weights of the gas and the electrons, respectively, and m_p is the proton mass. The profiles and their logarithmic slopes are smoothed by a Gaussian filter to allow for reliable identification of maxima and minima.

Note that there are two different definitions for shock radius in the literature - one defined by the radius at which the entropy profile reaches its maximum or "peak" (cf. Lau et al. [2015\)](#page-8-6), which we indicate by *r* shock,p, and one defined by the radius at which the logarithmic slope of the entropy profile is a minimum (cf. Shi [2016\)](#page-9-11), which we indicate by $r_{\text{shock,m}}$. We provide predictions for both *r* shock,p and *r* shock,m.

3. Results

We begin with a visual impression of the most massive cluster in our sample, showing the relative positions of *r* splash, *r* shock,p, and $r_{\text{shock,m}}$. This cluster has a *z*=0 virial mass of M_{200} =2.82 \times $10^{15}h^{-1}M_{\odot}$ and virial radius of *R*_{200,crit} = 2.298*h*⁻¹Mpc. Although it is not currently undergoing a significant merger, it has accreted 75% of its mass since *z*=0.5, which indicates that it has a high recent accretion rate. In Figure [1,](#page-2-1) we show projections of the distribution of dark matter (top panel), gas (middle panel), and stars (lower panel) around the most massive cluster in our sample at *z*=0 within a comoving cube of size 20 h^{-1} Mpc. In each of the panels, the heavy solid, red solid, and heavy dashed circles indicate the virial radii, $R_{200} = 2.30h^{-1}$ Mpc and $R_{200, \text{mean}} = 3.81h^{-1}$ Mpc, and splashback radius, *r* splash = 1.61*R*²⁰⁰ for dark matter; if not specified, R_{200} indicates $R_{200,\text{crit}}$ throughout this paper. The heavy dotted and dot-dashed circle in the middle panel (projected gas distribution) indicate the two definitions of shock radius, $r_{\rm shock,p}$ = 2.17 $R_{\rm 200}$ and $r_{\rm shock,m}$ = 2.95 $R_{\rm 200}$, respectively. For completeness, we also estimate $r_{\rm{splash}}$ = 1.93 R_{200} for the gas profile and *r* splash = 1.71*R*²⁰⁰ for stellar profile. It's interesting to note that, for this particular cluster, the splashback radius of the gas is within ∼10% of the shock radius defined relative to the peak of the entropy profile; the splashback radii of the dark matter and stars are within 5% of each other, as we might expect given their collisionless nature; and the splashback radius of the dark matter is ∼ 20% smaller than that of the gas. For reference, the radial (dark matter, stellar, gas) density and gas entropy profiles used to estimate *r* splash and *r* shock are shown in Figure [2.](#page-3-0)

This trend - for R_{200} < $r_{\rm{splash}}$ < $r_{\rm{shock,p}}$ < $r_{\rm{shock,m}}$ - is characteristic of the typical cluster in this sample. We demonstrate this in Figure [3](#page-3-1) in which we show the median dark matter density profiles (blue curves and shaded regions; top) and gas entropy profiles (red curves and shaded regions; bottom) and their corresponding logarithmic slopes for all 324 clusters; the shaded bands indicate the range of variation between the 10th and 90th percentiles within each radial bin.

Heavy solid, red solid, dashed, dotted and dot-dashed circles indicate *R*200,crit, *R*200,mean, *r*splash, *r*shock,p, and *r*shock,m respectively.

Figure 1. Projected dark matter, gas, and stellar densities (top to bottom) at z =0 in the most massive cluster in our sample within a cubic region 20 h^{-1} Mpc, centred on the density-weighted centred of AHF's adaptive mesh refinement grid. The dark matter halo's mass and radius are M_{200} = 2.82 \times $10^{15}h^{-1}M_{\odot}$ and $R_{200,crit}$ = 2.298 h^{-1} Mpc, and it has accreted 75% of its present day mass since *z*=0.5.

Figure 2. Density (top) and gas entropy (bottom) radial profiles, along with their logarithmic slopes (lower panels) for the cluster shown in Figure [1.](#page-2-1) Dashed vertical lines in the top panel correspond to $r_{\rm{splash}}$ = $1.61R_{200}$ (blue) for dark matter, *r* splash = 1.93*R*²⁰⁰ (purple) for gas, *r* splash = 1.71*R*²⁰⁰ (gray) for stars, respectively. Dotted, and dot-dashed vertical lines in the bottom panel correspond to $r_{\text{shock,p}} = 2.17R_{200}$ and $r_{\text{shock,m}} = 2.95R_{200}$ respectively.

The dashed, dotted, and dot-dashed lines indicate the locations of *r* splash, *r* shock,p, and *r* shock,m of the median cluster. We find that $r_{\text{splash}} = 1.87^{+0.39}_{-0.41}R_{200}$, $r_{\text{shock,p}} = 2.58^{+0.45}_{-0.43}R_{200}$ and $r_{\text{shock,m}} = 3.58^{+0.57}_{-0.62}R_{200}$. We also include the splashback radii for gas - $r_{\text{splash}}/R_{200} = 1.72^{+0.55}_{-0.45}$ - and stars - $r_{\text{splash}}/R_{200}$ = $2.07^{+0.42}_{-0.39}$ $2.07^{+0.42}_{-0.39}$ $2.07^{+0.42}_{-0.39}$ - in Figure 3 (purple and grey curves and shaded regions, top). This means that the stellar mass density profile traces that of the underlying dark matter, and indeed we see a stronger splashback feature in the stars. In contrast, the gas mass density profile is smoother and shows no obvious feature, and formally reaches a minimum slope at a smaller radius compared to the stars although this is not a strong feature.

For this typical cluster, we note that the relative coincidence of *r* splash for the gas and *r* shock,p evident in Figure [2](#page-3-0) is absent. This is not so surprising because we expect strong cluster-to-cluster variations in density and temperature in the

 $10²$

Dark Matter

p(r)/pcnt

with their logarithmic slopes for all The Three Hundred collaboration's suite of simulated clusters. The curves and shaded regions correspond to the median and the range between the 10^{th} to 90^{th} percentiles from the distribution of cluster profiles. The dashed line in the top panel represents the location of *r*splash. The dotted and dot-dashed lines in the bottom panel indicate the location of $r_{\text{shock,p}}$ and $r_{\text{shock,m}}$, respectively. Curves are colour coded as in Figure [2.](#page-3-0)

outskirts of clusters (e.g. Power et al. [2020\)](#page-9-2), which will dampen any splashback features in the median gas density profile. We defer a more detailed study of the relationship between gas splashback and shock radii to a subsequent paper. Note that from here and for the remainder of the paper, when we refer to *r* splash we use the value defined for the dark matter.

The clusters in our sample have diverse assembly histories and larger-scale environments, and so we expect cluster-tocluster variations in *r* splash and *r* shock. We quantify this in Figure [4](#page-4-0) in which we show how *r* shock,p (upper panels) and *r* shock,m (lower panels) vary with *r* splash for each cluster, in units of *R*₂₀₀; on the left we investigate trends with virial mass, *M*200, while on the right we look at trends with the fractional

Figure 4. The relationship between the shock radius *r*shock and splashback radius *r*splash for each of the 324 clusters in our sample. Upper panels correspond to *r*shock,p identified with the maximum of *K*, while the lower panels correspond to *r*shock,m identified with the minimum of its logarithmic slope. The points are colour coded by the virial mass *M*²⁰⁰ (left panels) and the fractional increase in *M*²⁰⁰ since *z* = 0.5, ∆*M*/*M* (right panels). The red and blue stars indicate the median values *r*shock and *r*splash, while the light and heavy dashed lines correspond to the one-to-one relationships and the best-fit linear relationships. The shaded band in the left-hand panels indicates the 1- σ variation estimated by bootstrapping.

increase in M_{200} since $z = 0.5$,

$$
\frac{\Delta M}{M} = \frac{M_{200}(z=0) - M_{200}(z=0.5)}{M_{200}(z=0)}.
$$
 (3)

Compared to Γ , the accretion rate conventionally used in the literature (cf. the equation 1 of Zhang et al. [2021\)](#page-9-12)^{[b](#page-4-1)}, Equation [3](#page-4-2) corresponds to $\Gamma \log(1 + z) \simeq 0.41\Gamma$ for *z*=0.5.

Figure [4](#page-4-0) reveals that $r_{\rm shock,p}$ is larger than $r_{\rm sphash}$ for all but a handful of clusters, while *r* shock,m is consistently larger than

b. The conventional accretion rate is,

$$
\Gamma = \frac{d \log M}{d \log a} \equiv \frac{\Delta M/M}{\Delta \log(a)}\tag{4}
$$

where *a* = 1/(1+*z*) is the expansion factor. We assume that $\Delta \log(a) \equiv -\log(a)$ when considering a change in mass with respect to *z*=0, *a*=1.

r splash for all cases. The stars indicate the median values of r_{shock} and r_{splash} for the sample are $r_{\text{shock,p}}/r_{\text{splash}} = 1.38_{-0.21}^{+0.27}$ and $r_{\text{shock,m}}/r_{\text{splash}} = 1.91^{+0.31}_{-0.42}$, while the best-fit linear relationships between *r* shock and *r* splash - which we show in the left hand panels - are

$$
r_{\text{shock,p}} = 0.64(\pm 0.06) r_{\text{splash}} + 1.39(\pm 0.11),\tag{5}
$$

and

$$
r_{\text{shock,m}} = 0.65(\pm 0.07) r_{\text{splash}} + 2.38(\pm 0.14),\tag{6}
$$

where r_{splash} , $r_{\text{shock,p}}$ and $r_{\text{shock,m}}$ are in units of $h^{-1}\text{Mpc}$. We estimate $1 - \sigma$ uncertainties via bootstrapping; these are listed in parentheses and by the shaded bands around the best-fit lines in Figure [4.](#page-4-0) The Spearman rank correlation coefficients are *rs*=0.469 and 0.564 (with vanishingly small *p*-values) for

$$
\frac{r_{\text{shock,p}}}{R_{200}} = -0.82 \log_{10} M_{200} + 15.02(\pm 0.08),\tag{7}
$$

$$
\frac{r_{\text{shock,m}}}{R_{200}} = -1.05 \log_{10} M_{200} + 19.23(\pm 0.09),
$$
 (8)

and

$$
\frac{r_{\text{splash}}}{R_{200}} = -0.56 \log_{10} M_{200} + 10.23(\pm 0.07),\tag{9}
$$

where, as before, M_{200} is in units of $h^{-1}M_{\odot}$. 1- σ uncertainties, estimated via bootstrapping, are in parentheses, and are shown as shaded bands in the Figure. We find Spearman rank correlation coefficients of $r_s = -0.20$ for $r_{\text{shock,p}}$, $r_s = -0.18$ for $r_{\rm shock,m}$ and r_s = –0.14 for $r_{\rm splash},$ with respect to $M_{200},$ which indicates that there is a weak anti-correlation with virial mass.

The bottom panel shows shows how *r* splash and *r* shock vary with $\Delta M/M$, in units of R_{200} . We find,

$$
\frac{r_{\text{shock,p}}}{R_{200}} = -1.05(\pm 0.11)\,\Delta M/M + 3.13(\pm 0.06),\tag{10}
$$

$$
\frac{r_{\text{shock,m}}}{R_{200}} = -1.34(\pm 0.12) \,\Delta M/M + 4.27(\pm 0.07),\tag{11}
$$

and

$$
\frac{r_{\text{splash}}}{R_{200}} = -0.98(\pm 0.10) \,\Delta M/M + 2.36(\pm 0.05). \tag{12}
$$

As above, 1-σ uncertainties are in parentheses and are shown as shaded bands in the Figure. The Spearman rank correlation coefficients are $r_s = -0.48$ for $r_{\text{shock,p}}$, $r_s = -0.51$ for $r_{\text{shock,m}}$ and r_s = –0.57 for r_{splash} , which indicate a moderate anticorrelation with our measure of the recent accretion rate.

These trends, along with the best-fit linear relationships (Equations [5](#page-4-3) and [6\)](#page-4-4), indicate that there is a moderate positive correlation between *r* shock and *r* splash, driven by a cluster's recent mass accretion rate. This is consistent with the findings of Aung, Nagai, and Lau [\(2021\)](#page-7-6). These findings are largely insensitive to mass resolution and galaxy formation model, provided care is taken to recover ICM properties that are consistent with observations. We discuss this in more detail in [Appendix 1.](#page-9-13)

4. Discussion

There has been significant progress over the last decade in our understanding of the physical processes that shape the outskirts of galaxy clusters, using both cosmological simulations and a variety of observational data. Radio synchrotron emission and polarisation (e.g. Locatelli et al. [2021;](#page-8-22) Ha, Ryu, and Kang [2023;](#page-8-23) Vernstrom et al. [2023;](#page-9-14) Böss et al. [2023\)](#page-7-7), gas entropy (Lau et al. [2015;](#page-8-6) Aung, Nagai, and Lau [2021\)](#page-7-6) and X-ray emission (e.g. Simionescu et al. [2021\)](#page-9-15), and the thermal Sunyaev–Zeldovich (tSZ) effect (Baxter et al. [2021;](#page-7-8) Anbajagane et al. [2022;](#page-7-9) Anbajagane et al. [2024\)](#page-7-10) all offer the means to probe the shocked gas associated with accretion from the cosmic web. That there is a relationship between this accretion shock and the cluster boundary defined by the splashback radius has been

Figure 5. The relationship between the shock and splashback radii, *r*shock, p, $r_{\text{shock. m}}$, and r_{solash} as a function of virial mass, M_{200} (upper panel) and recent mass accretion history (lower panel) for each of the 324 clusters in our sample. The shaded bands indicate the $1-\sigma$ variations for each set of points estimated by bootstrapping.

Equations [5](#page-4-3) and [6,](#page-4-4) respectively; this indicates that there is a moderate positive correlation between the shock radii and the splashback radius.

Figure [4](#page-4-0) shows how *r* splash and *r* shock relate to one another for a given cluster and trends between this relationship and the cluster's virial mass, *M*200, and its recent fractional change in *M*200, ∆ *M*/*M*. In Figure [5](#page-5-1) we quantify the trends between $r_{\rm{splash}}$ and $r_{\rm{shock}}$ with M_{200} and $\Delta\,$ *MM* directly. The top panel shows how *r* splash and *r* shock vary with *M*200, in units of *R*200, for all 324 clusters in our sample. The data can be

explored observationally (Anbajagane et al. [2022;](#page-7-9) Anbajagane et al. [2024\)](#page-7-10) and in non-radiative cosmological hydrodynamical simulations (S. Walker et al. [2019;](#page-9-16) Aung, Nagai, and Lau [2021\)](#page-7-6).

Our study leverages the latest iteration of The Three Hundred collaboration's suite of cosmological galaxy formation simulations of galaxy clusters, which model a broad range of physical processes - radiative cooling, star formation and supernovae, black hole growth, outflows, and jets - and provide a more realistic treatment of cluster formation than is possible in non-radiative simulations. Nevertheless, we find that a relationship between shock and splashback radii that is consistent with that found in non-radiative simulations, such as those of Aung, Nagai, and Lau [\(2021\)](#page-7-6), who found $r_{\rm shock,m}/r_{\rm splash}\simeq 1.89$ based on a sample of 65 clusters, compared to our median value of \simeq 1.91. Our results also show that both shock and splashback radii correlates with the cluster accretion rate, which is consistent with previous studies. Baxter et al. [\(2021\)](#page-7-8) found clusters with high mass fraction of the cluster in substructure, as a proxy for a high accretion rate, tend to have smaller shock and splashback radii, as we show in Figure [5.](#page-5-1)

We note that our results on the relationship between *r* splash and halo mass are broadly consistent with previous work. O'Neil et al. [\(2021\)](#page-9-17) found that *r* splash decreases with mass for halo masses in the range $10^{13} - 10^{15} M_{\odot}$ in the Illustris TNG simulations, while Towler et al. [\(2024\)](#page-9-18) found that *r* splash has a weak negative mass dependence for halos more massive than $10^{14}M_{\odot}$ in the FLAMINGO simulations. Towler et al. [\(2024\)](#page-9-18) also reported a correlation between *r* splash and accretion rate, in agreement with our results. O'Neil et al. [\(2021\)](#page-9-17) found that *r* splash computed from the gas profile is ∼ 10 – 20% lower than computed using the dark matter profile, while *r* splash computed from the galaxy number density profile (essentially the stellar mass density profile) is similar to that of the dark matter profiles; this is consistent with our results.

Observational limits on the location of accretion shocks in galaxy clusters' outskirts have been recovered by stacking Compton-*y* maps (Baxter et al. [2021;](#page-7-8) Anbajagane et al. [2022;](#page-7-9) Anbajagane et al. [2024\)](#page-7-10). These studies detect an integrated tSZ signal; this is proportional to the line-of-sight integral of the electron pressure, which is related to, but not equal nor proportional to, the gas entropy. Anbajagane et al. [\(2022\)](#page-7-9) locate the accretion shock via a minimum in the logarithmic derivative of the tSZ signal and estimate *r* shock,m/*r* splash > 2.16 ± 0.59. This is slightly higher than the results suggested by cosmological simulations, but this is not a one-to-one comparison. Future X-ray experiments capable of mapping the outskirts of clusters should allow for a more direct comparison with estimates of the shock radius based on gas entropy (e.g. Simionescu et al. [2021\)](#page-9-15).

5. Conclusions

Using 324 simulated galaxy clusters from The Three Hundred collaboration, we have investigated the relationship between the shock radius, *r* shock, which characterises the boundary between a cluster's gaseous outskirts and accreting gas from the

cosmic web, and the splashback radius, *r* splash, which characterises the boundary between collisionless material orbiting within the cluster and matter that is infalling for the first time. Depending on our definition, we find the shock radius is larger than splashback radius for most, if not all, clusters. If we stack our clusters and estimate *r* splash and *r* shock from the median radial profiles for dark matter density and gas entropy respectively, we find that the median cluster has $r_{\rm shock,p} \simeq$ 1.38*r* splash(2.58*R*200), estimated from where *K* reaches its maximum, and $r_{\text{shock,m}} \simeq 1.91 r_{\text{splash}}(3.54 R_{200})$, estimated from when its logarithmic slope is a minimum. If we evaluate *r* splash and r_{shock} for each cluster individually, we find that the best-fit linear relation increases as $r_{\rm shock}\propto 0.65 r_{\rm splash}$, independent of definition, and we observe that *r* shock/*r* splash tends to be larger in clusters that have experienced higher recent mass accretion rates, which is driven primarily by strength of the dependence of *r* splash on the accretion rate rather than any dependence of *r* shock. We find that *r* shock/*R*²⁰⁰ and *r* splash/*R*²⁰⁰ anti-correlate with virial mass, M_{200} , and recent mass accretion history.

These results are consistent with the results of recent studies (e.g. Aung, Nagai, and Lau [2021\)](#page-7-6) but draw on a larger statistical, mass complete, sample of simulated, run using a state-of-the-art galaxy formation model, and calibrated to reproduce the observed galaxy cluster population, building on the work of Cui et al. [\(2022\)](#page-8-15). While this consistency is to be expected - as previous work has shown (e.g. Power et al. [2020\)](#page-9-2), the key properties of galaxy cluster outskirts are shaped by the physics of gravitational dynamics and strong hydrodynamic shocks - it is important to verify it. These results also confirm that analytical models that assume the coincidence of *r* shock and *r* splash (e.g. Patej and Loeb [2015\)](#page-9-10) need to be modified, and need to account for mass accretion history and larger scale environment.

Our work has potentially interesting consequences for observational studies of the outskirts of clusters, and efforts to measure empirically the accretion shock. Measurements of *r* splash and phase space caustics using cluster galaxies (e.g. Deason et al. [2021\)](#page-8-11) could offer the means to constrain the recent mass accretion history. This could help to predict the projected radial scale at which we might expect to detect the accretion shock, based on the relationship we have measured in our sample of clusters, which would help to guide measurements of non-thermal emission with radio telescopes (e.g. Vernstrom et al. [2023\)](#page-9-14), X-ray emission (e.g. Ichikawa et al. [2013;](#page-8-24) Simionescu et al. [2021;](#page-9-15) McCall et al. [2024\)](#page-8-25) and the thermal Sunyaev–Zeldovich (tSZ) effect (Anbajagane et al. [2024\)](#page-7-10), especially when stacking is required to boost sensitivity. Future work will focus on using mock observables to verify the most reliable methods to recover accurate combined measurements of *r* splash and *r* shock.

Appendix 1. Sensitivity to Mass Resolution and Galaxy Formation Model

We have checked the sensitivity of our results to mass resolution, by comparing measurements for the GIZMO-Simba-7k shown here and the GIZMO-Simba-3k runs, and galaxy formation model, by comparing both sets of the GIZMO-Simba runs to the GadgetX runs (cf. Cui et al. [2018\)](#page-8-14). We see similar qualitative trends regardless of mass resolution or galaxy formation model.

The relation between *r* shock,p to *r* splash predicted by GIZMO-Simba-7k, GIZMO-Simba-3k, and GadgetX in the form of Equation [5](#page-4-3) is given by the pairs of coefficients (0.64,1.39), (0.54, 1.45), and (0.58, 1.64) respectively. And the relation between *r* shock,m to *r* splash predicted by GIZMO-Simba-7k, GIZMO-Simba-3k, and GadgetX in the form of Equation [6](#page-4-4) is given by the pairs of coefficients (0.65,2.38), (0.41, 2.88), and (0.47, 3.19) respectively. Similarly, figure [6](#page-10-1) shows the relationship between shock and splashback radii as a function of M_{200} and $\Delta M/M$, for the relations encoded in

- *r* shock,p/*R*²⁰⁰ versus *M*²⁰⁰ (Equation [7\)](#page-5-2): (-0.82,15.02), (- 0.81,14.59), and (-0.70,13.17)
- *r* shock,m/*R*²⁰⁰ versus *M*²⁰⁰ (Equation [8\)](#page-5-3): (-1.05,19.22), (- 1.31,23.26), and (-0.85,16.73)
- *r* splash/*R*²⁰⁰ versus *M*²⁰⁰ (Equation [9\)](#page-5-4): (-0.56,10.23), (-0.45, 8.59), and (-0.53,9.78)
- *r* shock,p/*R*²⁰⁰ versus ∆ *M*/*M* (Equation [10\)](#page-5-5): (-1.05,3.13), (-1.01, 2.99), and (-1.10,3.29)
- *r* shock,m/*R*²⁰⁰ versus ∆ *M*/*M* (Equation [11\)](#page-5-6): (-1.05,3.13), (-1.01, 4.18), and (-1.02,4.59)
- *r* splash/*R*²⁰⁰ versus ∆ *M*/*M* (Equation [12\)](#page-5-7): (-0.98,2.36), (- 0.94, 2.37), and (-1.01,2.40)

The trends between *r* splash/*R*200, *r* shock,m/*R*200, *r* shock,p/*R*²⁰⁰ and ∆ *M*/*M* are similar across the different resolutions and galaxy formation models. There are differences in the strength

Figure 6. The relationship between the shock and splashback radii, $r_{\text{shock, m}}$, $r_{\text{shock, p}}$ and r_{splash} as a function of virial mass, M_{200} and recent mass accretion history ∆*M*/*M* in the GIZMO-Simba-3k (left two panels) and GadgetX (right two panels) runs for each of the 324 clusters in our sample. The shaded bands indicate the 1 - σ variations for each set of points estimated by bootstrapping.

of the anti-correlation between the *R*²⁰⁰ normalised values of *r* splash, *r* shock,m, *r* shock,p, and *M*²⁰⁰ between runs; there is better quantitative agreement between *r* shock,p/*R*²⁰⁰ and *M*²⁰⁰ between the GIZMO-Simba-7k run and the GIZMO-Simba-3k run than between the GIZMO-Simba-7k run and the GadgetX. This partly reflects the philosophy underpinning the GadgetX runs, which were calibrated to recover the properties of ICM of observed clusters and partly the improvement in calibration of the GIZMO-Simba-7k runs compared to the GIZMO-Simba-3k runs, which have produced ICM properties more consistent

with observations. This explains the stronger scaling of *r* shock,p with *M*²⁰⁰ and the larger spread in values at a given *M*²⁰⁰ compared to the two other models.

We conclude that, provided care is taken to calibrate runs to recover ICM properties that are consistent with observed clusters, the relations between $r_{\rm shock}, r_{\rm splash}$, M_{200} , and Δ M/M are consistent across mass resolution and galaxy formation model.
