ABSTRACT

It is well-known that the cores of massive stars sustain a stellar dynamo with a complex magnetic field configuration. However, the same cannot be said for the field's strength and geometry at the convective-radiative boundary, which are crucial when performing asteroseismic inference. In this Letter, we present three-dimensional (3D) magnetohydrodynamic (MHD) simulations of a 7 M_{\odot} midmain sequence star, with particular attention given to the convective-radiative boundary in the nearcore region. Our simulations reveal that the toroidal magnetic field is significantly stronger than the poloidal field in this region, contrary to recent assumptions. Moreover, the rotational shear layer, also important for asteroseismic inference, is specifically confined within the extent of the Brunt–Väisälä frequency peak. These results, which are based on the inferred properties of HD 43317, have widespread implications for asteroseismic studies of rotation, mixing and magnetism in stars. While we expect our results to be broadly applicable across stars with similar Brunt–Väisälä frequency profiles and stellar masses, we also expect the MHD parameters (e.g. Rem) and the initial stellar rotation rate to impact the geometry of the field and differential rotation at the convective-radiative interface.

1. INTRODUCTION

Stars born with masses above about 1.2 M_{\odot} have a convective core and radiative envelope during the main sequence, with the fluid motions in the core exhibiting turbulent convection. This process sets up a magnetic dynamo in the core, the strength of which is influenced mainly by rotation rate. The study of the stellar dynamos has been extensive, both analytically [\(Pitts &](#page-6-0) [Tayler](#page-6-0) [1985;](#page-6-0) [Spruit](#page-7-0) [1999;](#page-7-0) [Zahn et al.](#page-7-1) [2007;](#page-7-1) [Augustson](#page-6-1) [et al.](#page-6-1) [2019;](#page-6-1) [Charbonneau & Sokoloff](#page-6-2) [2023\)](#page-6-2) and numerically [\(Brun et al.](#page-6-3) [2005;](#page-6-3) [Zahn et al.](#page-7-1) [2007;](#page-7-1) [Browning](#page-6-4) [2008;](#page-6-4) [Featherstone et al.](#page-6-5) [2009,](#page-6-5) [2011;](#page-6-6) [Augustson et al.](#page-6-7) [2016\)](#page-6-7).

Currently, there are a number of uncertainties in stellar structure theory to be resolved. Among these are the mechanisms responsible for setting stars' rotation and chemical mixing profiles, and interior magnetic fields. One particularly important uncertainty is the amount of convective-boundary mixing (CBM) at the interface between convective cores and radiative envelopes in mainsequence massive stars, which can provide fresh hydrogen to the nuclear-burning core and extend the mainsequence lifetime by upwards of 25% [\(Bowman](#page-6-8) [2020\)](#page-6-8). CBM and more generally interior rotation and mixing processes are controlled by largely uncalibrated prescriptions in one-dimensional (1D) stellar evolution models. Whereas, magnetic fields are often neglected entirely owing to their complexity, and yet have been inferred indirectly to impact the amount of CBM [\(Briquet et al.](#page-6-9)

[2012\)](#page-6-9). Only recently have we been able to diagnose interior magnetic fields thanks to the study of stellar pulsations — asteroseismology [\(Aerts et al.](#page-6-10) [2010\)](#page-6-10).

There has been a great deal of advancement in understanding the rotation and mixing profiles of stars thanks to asteroseismology [\(Aerts](#page-6-11) [2021\)](#page-6-11). The highradial order gravity modes in slowly pulsating B-type (SPB; $3 \leq M \leq 8$ M_☉) stars are particularly sensitive to the Brunt–Väisälä peak just outside the convective core, and reveal precise core masses and near-core rotation rates [\(Moravveji et al.](#page-6-12) [2015,](#page-6-12) [2016;](#page-6-13) Pápics et al. [2017;](#page-6-14) [Szewczuk et al.](#page-7-2) [2021;](#page-7-2) [Michielsen et al.](#page-6-15) [2021;](#page-6-15) [Pedersen](#page-6-16) [et al.](#page-6-16) [2021\)](#page-6-16). However, asteroseismic studies of SPB stars have generally assumed rigid interior rotation profiles, and have also not considered the impact of an interior magnetic field. The exception to this is HD 43317 which is the only confirmed magnetic SPB star to have undergone forward asteroseismic modelling (Pápics et al. [2012;](#page-6-17) [Briquet et al.](#page-6-18) [2013;](#page-6-18) [Buysschaert et al.](#page-6-19) [2017,](#page-6-19) [2018\)](#page-6-20). Recently, [Lecoanet et al.](#page-6-21) [\(2022\)](#page-6-21) used the best-fitting asteroseismic model of [Buysschaert et al.](#page-6-20) [\(2018\)](#page-6-20) and $DEDALUS$ [\(Burns et al.](#page-6-22) [2020\)](#page-6-22) to solve the linear eigenvalue problem assuming a purely dipolar interior magnetic field geometry to constrain an upper limit of the near-core field strength of HD 43317 as approximately 5×10^5 G. This result, whilst being an important step forward in the novel field of magneto-asteroseismology [\(Bowman](#page-6-23) [2023\)](#page-6-23), assumed the magnetic field geometry and a rigid radial rotation profile, which are simplifi-

cations if compared to previous numerical simulations. In this Letter, we perform 3D MHD simulations of a $7-M_{\odot}$ mid-main sequence star and reveal the magnetic field geometry and rotational profile at the core-envelope boundary in such massive stars.

2. NUMERICAL SETUP

Our 3D spherical simulations are done using RAYLEIGH [\(Featherstone & Hindman](#page-6-24) [2016;](#page-6-24) [Feather](#page-6-25)[stone et al.](#page-6-25) [2022;](#page-6-25) [Matsui et al.](#page-6-26) [2016\)](#page-6-26), an open-source pseudospectral code which solves the MHD equations in the anelastic approximation. The discretisation is done with a finite-difference scheme in the radial direction and spherical harmonics in the horizontal directions. The whole simulation domain is resolved with 2400 radial (r) grid points, 256 grid points in the polar (θ) direction and 512 grids in the azimuthal (ϕ) direction, equivalent to a spherical harmonic $\ell_{\text{max}} = 170$. The code implements parallel frameworks using Message Passing Interface (MPI) and Open Multi-Processing (OpenMP) to achieve efficient scaling to more than 10000 cores. The simulation solves the MHD equations:

$$
\overline{\rho}(r) \left[\frac{\partial \mathbf{v}}{\partial t} + \mathbf{v} \cdot \nabla \mathbf{v} + 2\Omega_0 \hat{\mathbf{z}} \times \mathbf{v} \right] =
$$

$$
\frac{\overline{\rho}(r)}{\overline{c_P}(r)} \overline{g}(r) S \hat{r} + \overline{\rho}(r) \nabla \left(\frac{P}{\overline{\rho}(r)} \right)
$$

$$
+ \frac{1}{\overline{\rho}} (\nabla \times \mathbf{B}) \times \mathbf{B} + \nabla \cdot \mathbf{D} \tag{1}
$$

$$
(r)\overline{T}(r)\left[\frac{\partial S}{\partial t} + \mathbf{v} \cdot \nabla S + v_r \frac{d\overline{S}}{dr}\right] =
$$

$$
\nabla \cdot \left[\overline{\rho}(r)\overline{T}(r)\overline{\kappa}(r) \nabla S\right] + Q(r)
$$

 $\overline{\rho}$

$$
+\Phi(r,\theta,\phi)+\frac{\overline{\eta}(r)}{4\pi}\left[\boldsymbol{\nabla}\times\boldsymbol{B}\right]^{2},\qquad(2)
$$

$$
\frac{\partial \boldsymbol{B}}{\partial t} = \boldsymbol{\nabla} \times [\boldsymbol{v} \times \boldsymbol{B} - \overline{\eta}(r) \boldsymbol{\nabla} \times \boldsymbol{B}], \qquad (3)
$$

$$
\mathcal{D}_{ij} = 2\overline{\rho}(r)\,\overline{\nu}(r)\left[e_{ij} - \frac{1}{3}\left(\mathbf{\nabla}\cdot\mathbf{v}\right)\delta_{ij}\right],\qquad(4)
$$

$$
\Phi(r,\theta,\phi) = 2\overline{\rho}(r)\overline{\nu}(r) \left[e_{ij}e_{ij} - \frac{1}{3} (\nabla \cdot \mathbf{v})^2 \right], \qquad (5)
$$

$$
\nabla \cdot [\overline{\rho}(r) \, \boldsymbol{v}] = \, 0, \qquad (6)
$$

 $\nabla \cdot \boldsymbol{B} = 0.$ (7)

The radial velocity, v_r , together with the latitudinal velocity, v_{θ} , and the azimuthal velocity, v_{ϕ} , form the velocity vector, v . The radial, polar and azimuthal magnetic fields, represented by B_r , B_θ and B_ϕ respectively, form the magnetic field vector, \boldsymbol{B} . S and P are the perturbation entropy and pressure, respectively. The quantities with an overline are the radially dependent reference state values density, $\bar{\rho}$, specific pressure heat capacity, $\overline{c_P}$, gravity, \overline{g} , temperature, \overline{T} , entropy, \overline{S} , thermal diffusivity, $\bar{\kappa}$, magnetic diffusivity, $\bar{\eta}$, and viscosity, $\bar{\nu}$.

The reference input state data are taken from the 1D stellar evolution code Modules for Stellar Astrophysics (MESA; [Paxton et al.](#page-6-27) [2011,](#page-6-27) [2013;](#page-6-28) [Paxton et al.](#page-6-29) [2015;](#page-6-29) [Paxton et al.](#page-6-30) [2018,](#page-6-30) [2019;](#page-6-31) r23.05.01) for an input model of a 7 M_{\odot} star in the middle of the main sequence. The middle of the main-sequence here is defined to be when the central hydrogen mass fraction of the evolving star is $X_c = 0.35$. For the MESA simulations, we set the stellar metallicity, Z, to be equal to the solar value of $Z = 0.02$, the mixing-length parameter to be 1.8 and the convective overshoot profile is set to exponential (cf. [Buysschaert et al.](#page-6-20) [2018\)](#page-6-20). Lastly, the stellar rotation rate, Ω_0 , was initially set to a solid body rotation rate of 1.8×10^{-5} rad s⁻¹ (i.e. 4.04 d/11.5% critical breakup velocity), which is slower than that of HD 43317.

Figure [1](#page-2-0) shows the smoothed Brunt–Väisälä frequency, thermal diffusivity profiles and density of the reference state model. To obtain these, we perform a cubic spline interpolation to the output of the MESA models and used the Hann function as a window to smooth all abrupt variations in the profiles. Furthermore, we clip the profiles between 1% and 90% of the total stellar radius (R_{star}) to avoid numerical instabilities due to the large density stratification near the stellar surface. The middle panel displays the square of Brunt–Väisälä or the buoyancy frequency, an output from MESA used to calculate $d\overline{S}/dr$ (see Eq. (2)) in the radiation zone. The inclusion of the Brunt–Väisälä spike at the convectiveradiative interface, left over from the receding convective core, has also not been investigated in previous studies. These are crucial differences that allow these simulations to better inform asteroseismology, which is extremely sensitive to this region [\(Bowman](#page-6-8) [2020\)](#page-6-8).

The bottom panel of Fig. [1,](#page-2-0) shows the different values of the diffusivities and viscosity used in our MHD simulations. In the convection zone, we have used a much higher thermal diffusivity, at 7×10^{12} cm² s⁻¹, shown by the green line, than the stellar thermal diffusivity generated by MESA, shown by the red line. This is also true for the viscosity, at also 7×10^{12} cm² s⁻¹, and the magnetic diffusivity, at 2.5×10^{12} cm² s⁻¹, which was done to ensure numerical stability. At the convective-radiative boundary, we decrease the diffusivities since they are meant to mimic "turbulent" diffusivities and would be physically smaller in the radiative region. We reduce $\overline{\kappa}$ to match the realistic thermal diffusivity profiles towards the top of the domain. The viscosity and magnetic diffusivity profiles are then decreased to match the thermal diffusivity profiles up to approximately 0.592 R_{star} , where both the viscosity and magnetic diffusivity profiles are set to a constant value of 1×10^{11} cm² s^{-[1](#page-2-1)} towards the top of the domain. Table 1 provides a summary of the parameter space of our model.

3. MAGNETIC FIELD EVOLUTION

Parameters	Values (in cgs units)	
R_{domain}/cm	3.04×10^{11}	
R_{CZ}/cm	4.04×10^{10}	
$\tau_{\rm rot}/\rm days$	4.04	
$\tau_{\rm sim}/\rm{days}$	275	
$c_s/cm s^{-1}$	2.0×10^6 (minimum)	
	CZ	RZ
$v_{\rm rms}/\text{cm s}^{-1}$	82300 cm s^{-1}	1130 cm s^{-1}
Re	823	
Re _m	1320	
Ro	0.718	
$\tau_{\kappa}/\mathrm{days}$	3090	$14400/1.18 \times 10^9$
τ_n /days	7410	$7.82\times10^7/1.18\times10^9$
$\tau_{\rm CZ}/{\rm days}$	6.62	

Table 1. Stellar model parameters. The radius of the simulation domain and the convection zone are represented by R_{domain} and R_{CZ}, respectively. $\tau_{\rm rot}$ and $\tau_{\rm sim}$ are the rotational period and total simulation time, whilst c_s is minimum sound speed in the whole domain. Under the convection zone (CZ) and radiation zone (RZ) headers, $v_{\rm rms}$ is the root-mean-square velocity. The Reynold's and magnetic Reynold's numbers are represented by Re and Rem, while the Rossby number by Ro. The thermal diffusion timescale is $\tau_{\kappa} = L^2/\kappa$ and the magnetic diffusion timescale is $\tau_{\eta} = L^2/\eta$, where L is either the size of the convection zone or the radiation zone. τ_{CZ} is the convective timescale and is calculated as R_{CZ}/v_{rms} .

We begin by solving only the hydrodynamical equations to allow the onset of stellar convection until steadystate velocities are reached. Once the simulation reaches this stage, we introduce a weak dipolar magnetic field of strength ~ 1 G and solve the full MHD equations. The interaction between the convective motions and the magnetic field leads to large increases in the magnetic energy in the convective core as the dynamo is established. In the radiative zone the large scale dipole field decays on a magnetic diffusion timescale, which is much larger than our total simulation time (see τ_{sim} and τ_n in Table [1\)](#page-2-1).

Figure [2](#page-3-0) shows the magnetic streamlines when the magnetic field is in steady-state, where we observe a complex magnetic field structure in the core, surrounded by a dipolar field in the radiation zone. The magnetic field inside the core is sustained by a magnetic dynamo, generated by the convective motions. Starting from the convective-radiative boundary, where the Brunt–Väisälä frequency is zero (see Fig. [1\)](#page-2-0), the magnetic field strength decreases with radius until it matches the imposed large-scale dipolar magnetic field. However, close to the boundary, Fig. [2](#page-3-0) shows that the magnetic field is dominated by streamlines in the azimuthal di-

Figure 1. Reference state density, $\bar{\rho}$ (top panel), Brunt– Väisälä frequency squared (middle panel) and various diffusivity profiles (bottom panel) as functions of stellar radius in units of total stellar radius, R_{star}. The solid, grey vertical lines show the extent of the Brunt–Väisälä frequency peak and the inset shows a zoom-in of this peak. The viscosity profile coincides exactly with the thermal diffusivity profile up to 0.6 $R_{\rm star}$.

rection, representative of a strong toroidal field in that region.

4. NEAR-CORE MAGNETIC FIELD GEOMETRY

The main aim of this work is to determine the magnetic field geometry at the core-envelope boundary of a mid-main sequence massive star, so we start with a time snapshot of the magnetic field configuration at different shells (radii) after the system has evolved (see Fig. [3\)](#page-4-0). This time was chosen to be within the steady-state evolution of both the averaged kinetic and magnetic energies inside the convection zone, which were reached

Figure 2. Magnetic field geometry from our simulations. The gold-blue magnetic field lines show a predominantly dipolar field geometry within the radiative envelope, whereas the dark blue-red-green magnetic field lines show a more complex magnetic field structure inside the convective core.

within 30 days for the kinetic energy and 50 days for the magnetic energy. At this point, the average magnetic field is around 100 kG in the convection zone and lower in the shear layer, dropping to the imposed 10 G at the top of the shear layer. Note that this is within the upper limit constraint of 500 kG placed on HD 43317. We show the ratio of the toroidal to poloidal components of the magnetic field, mainly to demonstrate the changes to the field geometry, using Mollweide projection plots in this figure. The first row shows that there is more energy in the poloidal components of the magnetic field compared to the energy in the toroidal component deeper inside the convection core. As the radius approaches 0.12 R_{star}, which is the location where $N = 0$, we observe more energy in the toroidal magnetic field. Moving past this boundary into the Brunt–Väisälä frequency peak, we observe a larger surface area of the shell, having a ratio of toroidal to poloidal energies that exceeds unity. At $r = 0.127 R_{star}$, the ratio of toroidal to poloidal field peaks with $B_T / B_P > 10$ almost over the whole shell. This is true up to $r = 0.149 R_{star}$ and at radii larger than this, the poloidal field starts to dominate again, as the ratio of energies starts to fall below unity over the whole shell.

The randomly-spread poloidal and toroidal energies inside the convection core generally follow the pattern of convective fluid motions. However, around the convective-radiative boundary, a strong shear layer forms within the Brunt–Väisälä frequency peak, perpendicular to the stellar rotational axis (see Figure 5). The rotation profile is columnar, exhibiting a strong radial differential rotation at the interface, with prograde flow at lower latitudes and retrograde motion at higher latitudes. The radial shear drags magnetic field lines in the azimuthal direction, causing the toroidal magnetic field to become stronger within the shear layer (Pitts $\&$ [Tayler](#page-6-0) [1985;](#page-6-0) [Zahn et al.](#page-7-1) [2007\)](#page-7-1). The latitudinal differential rotation causes the toroidal field to change sign at mid-latitudes. Figure [4](#page-5-0) shows the Mollweide projections at different times as different rows, and for different radii as different columns. In the first column, where the shells are located just below the convective-radiative boundary, there are no large differences in the magnetic field energy distribution between the toroidal and poloidal components. As we move into the shear layer within the Brunt–Väisälä peak, the toroidal field energy begins to dominate over time at all latitudes. Further inside the Brunt–Väisälä frequency peak, regions that are initially dominated by the poloidal field can be seen to become to more dominated by the toroidal field, away from the equatorial plane.

In Fig. [5,](#page-5-1) we show the shell-averaged radial profiles of the ratio of toroidal to poloidal magnetic energies (solid lines), alongside the azimuthal velocity squared, relative to the rotating frame (dashed lines) at different times. Within the convection zone, the ratios range from 10-100, but vary dramatically as seen in Fig. [4.](#page-5-0) Moving into the convective-radiative interface, demarcated by the Brunt–Väisälä frequency peak, the toroidal field dominates throughout. The toroidal field is generally 100 times stronger than the poloidal field and maps regions of strong azimuthal shear, as expected. Outside this region, within the bulk of the radiation zone, the (seed) poloidal field dominates.

Within the shear layer, we also find that, at steadystate evolution, the ratio of the magnetic energy to the kinetic energy ranges between 0.15 and 0.4. These ratios are fairly low, and hence the magnetic field strength is not large enough to reduce the hydrodynamically-driven differential rotation in the region. However, at larger rotation rates, where a larger field might be induced, the near-core differential rotation could be reduced by magnetic tension.

5. CONCLUSIONS

We present 3D spherical MHD simulations of the internal fluid and magnetic field evolution of a mid-main sequence 7 M_☉ star at 11.5% the critical breakup velocity. The simulations were run with RAYLEIGH using reference state data from the 1D stellar evolution code MESA. The simulation domain covers between 1% to 90% of the total stellar radius, and the initial magnetic seed was set as a weak dipole field.

We find that the geometry of the magnetic field evolves and changes from its original dipolar configuration to a more complex configuration inside the convection zone, due to the action of the stellar dynamo,

Figure 3. Mollweide plots showing the ratio of the toroidal magnetic field energy to poloidal field energy, BT^2/BP^2 as functions of latitudes and longitudes over a sphere. The plots in the top row show the ratios inside the convection zone. At 0.12 R_{star} , the Brunt–Väisälä frequency is approximately 0 Hz. The remaining plots show the ratios inside the Brunt–Väisälä frequency peak from its maximum value at 0.127 R_{star} to just outside the peak at 0.176 R_{star} (see Fig. [1\)](#page-2-0).

whilst remaining unaffected in the radiation zone. At the convective-radiative interface, the ratio of toroidal to poloidal field increases with time, which is driven by the shear between the regions. We also observe a latitudinal dependence consistent with the same shear flow that coincides exactly with the peak in the Brunt– Väisälä frequency profile. These results apply to specific stellar and MHD parameters (e.g. Re^m and initial rotation rates). A faster initial rotation or a larger Reynolds number could both lead to a stronger magnetic field, which could reduce differential rotation across the BVF peak. Therefore, a broader parameter study is required to ascertain the variety of behaviour possible.

The Brunt–Väisälä frequency peak just outside the convective core is precisely the region that asteroseismology of pulsation modes in SPB stars is most sensitive to [\(Bowman](#page-6-8) [2020\)](#page-6-8). Not many main-sequence stars born with a convective core have been investigated for the amount of differential radial rotation within the Brunt– Väisälä frequency peak (e.g. [Aerts et al.](#page-6-32) [2003;](#page-6-32) [Van](#page-7-3) [Reeth et al.](#page-7-3) [2018;](#page-7-3) [Burssens et al.](#page-6-33) [2023\)](#page-6-33), but such work generally requires the extent and shape of the shear layer to be assumed. Recently, [Burssens et al.](#page-6-33) [\(2023\)](#page-6-33) was the first to test the impact of this assumption on the resultant differential rotation profiles for the mid-main sequence $12M_{\odot}$ star HD 192575. They demonstrated the significant impact on the inferred core-to-envelope rotation ratio when assuming the shear layer to be either the width of the Brunt–Väisälä frequency or the (much) smaller CBM region. The former was shown to provide the statistically better fit, which is supported by 2D structure models by [Mombarg et al.](#page-6-34) [\(2023\)](#page-6-34) and our 3D MHD simulations presented in this work.

To date, only a single asteroseismic study has probed the properties of an interior magnetic field deep inside an SPB star. Assuming a purely dipolar field geometry and a rigid rotation profile for the mid-main sequence SPB star HD 43317 [\(Buysschaert et al.](#page-6-20) [2018\)](#page-6-20), an upper limit of the near-core magnetic field was constrained to be 5×10^5 G [\(Lecoanet et al.](#page-6-21) [2022\)](#page-6-21). Furthermore, there are currently no forward modelling results that directly include magnetic fields. Parameter studies of massive stars that include the impact of a magnetic field include [Prat et al.](#page-6-35) [\(2019,](#page-6-35) [2020\)](#page-7-4) and [Van Beeck et al.](#page-7-5) [\(2020\)](#page-7-5), which show significant differences in pulsation mode frequencies when using a perturbative approach

 10^{1} $r = 0.116$ Rstar $r = 0.134 R_{star}$ $r = 0.152$ Rstar $t = 128.83 d$ $\frac{BL^{2}}{BL^{2}}$ 01 $t = 213.00 d$ $t = 260.28 d$ 10^{-1}

with a mixed poloidal and toroidal magnetic field topology. In our work, we provide numerical evidence that the magnetic field topology for such stars in the near-core

region is predominantly toroidal. Moreover, we demonstrate that the location of the shear layer and the predominantly toroidal magnetic field geometry is within the Brunt–Väisälä frequency peak for a representative mid-main sequence massive star. These results are important for future forward-asteroseismic modelling studies that aim to constrain interior rotation rates, mixing profiles, and interior magnetic fields for stars born with convective cores.
