Most of the baryonic matter of the Universe resides in a highly-ionized gaseous intergalactic medium¹. This gas flows along dark-matter filaments toward galaxy superclusters, clusters, and groups until it pools around the galaxies into a circumgalactic medium². Eventually, the gas settles into the interstellar medium of the galaxies, where it fuels the successive generations of star formation that ultimately produce the stars and heavy elements that make up galaxies today. The gas has been studied for decades using absorption lines produced by Hydrogen and various ions of heavy elements in the spectra of background quasi-stellar objects (QSOs). But directly imaging the extremely faint glow of this "cosmic web" of intergalactic and circumgalactic gas has remained an elusive goal of observational cosmology. Some recent progress has been made by using imaging spectrographs to record high-redshift Ly α emission, although over only very narrow fields of view³⁻⁶. Here we report direct images of intergalactic and circumgalactic gas in the distant Universe obtained using the Condor Array Telescope that we purposely built to reach extremely low-surface-brightness sensitivities over very wide fields of view⁷. We show that these images directly detect and characterize the imprint of Ly α emission from the cosmic web at an overwhelming statistical significance. By stacking portions of the images centered on tens of thousands of galaxies of known redshift, we show that they also reveal extremely faint emission from H⁰, C³⁺, and Mg⁺ and absorption from cosmic dust in the tenuous outskirts of the galaxies. Our results demonstrate that sensitive imaging observations can now detect and characterize emission (and absorption) from the cosmic web of intergalactic and circumgalactic gas (and dust).

Almost everything that is known about extremely tenuous gas in the distant Universe has been learned by studying absorption lines produced by foreground objects in the spectra of background QSOs. It became apparent soon after the discovery of the first QSO 3C 273 in 1963 8,9 that narrow absorption lines are ubiquitous in QSO spectra and that the lines are produced by cosmologically distributed gas intervening along the lines of sight 10. The origin of the gas has been surmised to include objects ranging from the extended "halos" of normal galaxies 11 through intergalactic clouds 12 through more recently the cosmic web that is predicted by hydrodynamical simulations of large-scale structure formation 13,14. Neutral Hydrogen column densities of the gas range from $\approx 10^{12}$ to $\approx 10^{17}$ cm⁻² for the "Ly α -forest" absorbers through $\approx 10^{17}$ to $\approx 10^{20}$ cm⁻² for the "Lyman-limit" absorbers through $\approx 10^{20}$ to $\approx 10^{22}$ cm⁻² for the "damped-Ly α " absorbers.

The prospect of detecting Ly α emission from the gas responsible for QSO absorption lines was first contemplated in the 1980s ¹⁵. The difficulty is that the emission is predicted to be extremely faint, with the brightness of gas fluorescing due to the cosmic ultraviolet radiation field at redshift $z \approx 3$ expected to be only $\approx 10^{-20}$ erg s⁻¹ cm⁻² arcsec⁻² in Ly α ¹⁶. This is fainter than the brightness of the night sky by a factor ≈ 1000 over even a very narrow bandpass. Recent efforts to detect this emission have used the Multi Unit Spectral Explorer (MUSE) on the Very Large Telescope (VLT) ⁵ at redshifts $z \approx 3.8$ and the Cosmic Web Imager (CWI) on the Keck telescope ⁶ at redshifts $z \approx 2.35$. These instruments are imaging spectrographs that provide substantial wavelength coverage (e.g. 48.5 nm for CWI) over very narrow fields of view (e.g. 30×20 arcsec² for CWI). Accordingly, these instruments obtain "core samples" that extend much farther in the radial direction than in the transverse direction. For example, each CWI exposure extends (for Ly α) ≈ 900 comoving Mpc in the radial direction but only $\approx 0.86 \times 0.58 = 0.50$ Mpc² in the transverse direction, for a total volume of $\approx 900 \times 0.86 \times 0.58 \approx 450$ Mpc³, with similar values applying for MUSE exposures. (We adopt a α ACDM cosmological model of matter density parameter α for Muse and Hubble constant 70 km s⁻¹ Mpc⁻¹ throughout.)

We used the Condor Array Telescope to obtain very deep direct images of Condor field 416, which encompasses and extends most of the Cosmic Evolution Survey (COSMOS) field ¹⁷. through luminance broad-band and custom narrow-band filters. The luminance filters are sensitive to wavelengths ≈ 400 to 700 nm. The narrow-band filters are tuned to a central wavelength (in the Condor f/5 beam) of 422.5 nm with a bandpass of only 1 nm (see Extended Data Fig. 1). The central wavelength corresponds to a redshift z=2.4754 for Ly α , which was chosen based on results of ref. 6 (see below) and is proximate to the Hyperion protocluster at redshift $z \approx 2.45^{18}$. The bandpass corresponds to a velocity interval of $\Delta v \approx 710$ km s⁻¹ and a redshift interval of $\Delta z \approx 0.0059$ for Ly α . The exposure time through the luminance filters totals 26.3 h and through the narrow-band filters totals 171.8 h, where both values are equivalent exposure times for the full array. The images were processed using the Condor data pipeline^{7,19} (see Methods). The final processed narrow-band image reaches a 1σ uncertainty of 3×10^{-19} erg s⁻¹ cm⁻² arcsec⁻² per $0.85 \times 0.85 \text{ arcsec}^{-2}$ pixel, which corresponds to a 3σ uncertainty of 8×10^{-20} erg s⁻¹ cm⁻² arcsec⁻² per 10×10 arcsec² region. This is essentially identical to the sensitivity of the CWI image of the COSMOS field by ref. 6, which reaches a 3σ depth for a 0.8-nm-wide line (i.e. comparable to the Condor 1 nm bandpass) of 8×10^{-20} erg s⁻¹ cm⁻² arcsec⁻² per 10×10 arcsec² region. The corresponding values for the final processed luminance image are a 1σ uncertainty of 4.8×10^{-32} erg s⁻¹ cm⁻² Hz⁻¹ arcsec⁻² (or 29.7 mag arcsec⁻²) per pixel and a 3σ uncertainty of 1.4×10^{-32} erg s⁻¹ cm⁻² Hz⁻¹ arcsec⁻² (or 31.0 mag arcsec⁻²) per 10×10 arcsec⁻² region.

The Condor field of view is $\approx 2.3 \times 1.5 \text{ deg}^2$, and each Condor narrow-band exposure extends (for Ly α) ≈ 18 comoving Mpc in the radial direction and $\approx 240 \times 160 \approx 38,000 \text{ Mpc}^2$ in the transverse direction, which exceeds the CWI value by a factor $\approx 76,000$. The total volume probed by each Condor exposure is $\approx 18 \times 240 \times 160 \approx 690,000 \text{ Mpc}^3$, which exceeds the CWI value by a

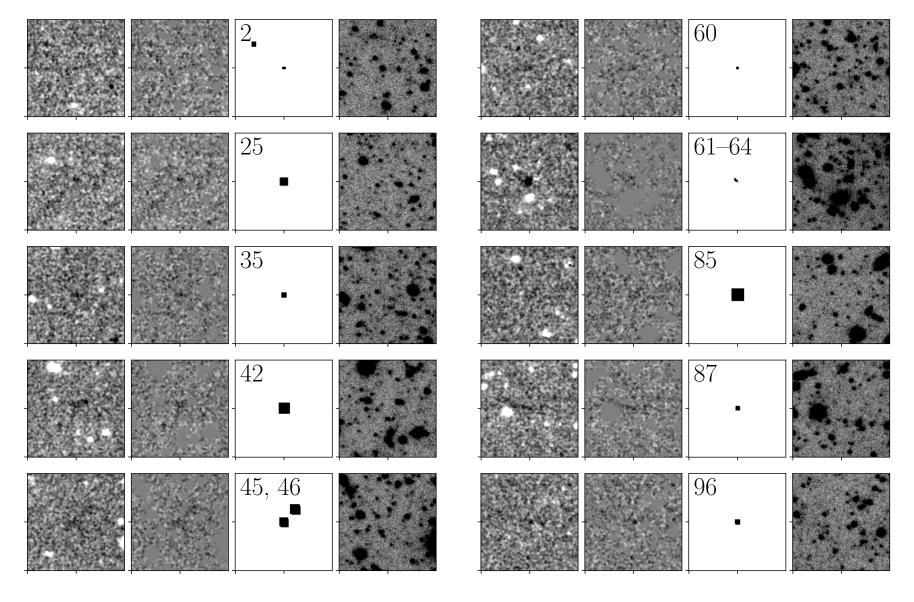

Fig. 1: Examples of detected features of (1) high statistical significance and (2) large rest-frame equivalent width (for Ly α). Each panel shows small portions of (left to right) difference image, masked difference image, detection map, and luminance image. Images extend $2.8 \times 2.8 \text{ armin}^2$, which at redshift z = 2.4754 corresponds to 1.4 proper Mpc or 4.9 Mpc comoving Mpc on a side. Brightest single pixels in portions of masked difference image are of surface brightness $\approx 10^{-18} \text{ erg s}^{-1} \text{ cm}^{-2} \text{ arcsec}^{-2}$.

factor ≈ 1500 . The ability of Condor to probe enormous transverse areas and volumes one redshift slice at a time gives it capabilities that are complementary to those of MUSE and CWI.

The luminance image shows evidence of modest Galactic cirrus toward the SE edge of the image, around J2000 coordinates 10:07, +02:15, which does not appear to overlap the COSMOS field proper. To at least a first approximation, any line emission at 422.5 nm is insignificant in comparison to continuum over the very large bandpass of the luminance filter, so the luminance image roughly traces continuum, whereas the narrow-band image traces line emission plus continuum. We subtracted the luminance image from the narrow-band image to form a "difference" image that in most regions traces more or less only line emission, thus accounting for any extremely faint cirrus that may be present across the field. (The difference image does not necessarily trace only line emission in regions near bright stars and galaxies, for which continuum color effects can be significant.) The narrow-band, luminance, and difference images are shown in Extended Data Fig. 2, 3, and 4, respectively.

Low-surface-brightness Ly α emission of redshift $z \approx 2.4754$ from the cosmic web could in principle be seen only in regions between continuum sources and would be characterized by large rest-frame equivalent width limits (say $\gtrsim 5$ nm), i.e. would appear much brighter in the narrow-band image than in the luminance image. Such emission is seen throughout the entire field of view. Detection of this faint emission may be optimized by processing the images with a matched filter ²⁰, which requires knowledge of the sizes and shapes of the emitting features. Lacking such knowledge, we searched for faint emission by binning the images on scales ranging up to 50×50 pix², seeking to identify features of (1) high statistical significance and (2) large rest-frame equivalent width (see Methods). This analysis, which is most sensitive to compact and concentrated (rather than irregular or filamentary) sources, identified 112 features of statistically-significant, strong line emission that can be reasonably interpreted only as Ly α of redshift $z \approx 2.4754$. The resulting catalog of features is presented in Extended Data Table 1, and images of the features are presented in Extended Data Figure 5. The narrow-band image is also sensitive to [O II] 372.7 nm emission of redshift $z \approx 0.1336$, and indeed such emission is seen, but of much lower rest-frame equivalent width.

Examples of several of the detected features are illustrated in Fig. 1, which shows small portions of the difference image, the "masked" difference image (which was formed by masking pixels of the difference image corresponding to pixels detected in the luminance image above a 1σ threshold), the detection map, and the luminance image. Features shown in Fig. 1 include a compact source (35); compact sources that appear to be embedded in filamentary structures that stretch up to and beyond 1 Mpc in extent (2, 25, 60, 87, and 96); diffuse, extended sources (42, 45, 46, and 85); and emission in the vicinity of a known active galactic nucleus (AGN) ACS–GC 20118705 ²¹ (61 through 64, and see below). The brightest single pixels in the portions of the masked difference image (i.e. that are free of continuum) shown in Fig. 1 are of surface brightness $\approx 10^{-18}$ erg s⁻¹ cm⁻² arcsec⁻².

The distribution of pixel intensities of the difference image in regions between continuum sources is sensitive to the surface-brightness intensity distribution 22 of Ly α emission at redshift $z \approx 2.4754$ from the cosmic web, irrespective of whether emission is or is not "detected" in any given pixel. This is illustrated in Fig. 2, which shows distributions of pixel intensities of the masked difference image (see Methods). The top panel of Fig. 2 shows the observed distribution together with a χ^2 fit to a normal distribution. The observed distribution appears to be very well described by a normal distribution except for an apparent systematic excess of pixels of positive intensity $\gtrsim 7 \times 10^{-19}$ erg s⁻¹ cm⁻² arcsec⁻². That the pixel-to-pixel measurement uncertainties would be characterized by a normal distribution is not unexpected given that the narrow-band image is formed by combining 6185 dithered individual exposures. The fit yields $\chi^2 = 562.9$ for 129 degrees of freedom, which indicates a statistically unacceptable fit, with a p value of essentially zero. We

interpret the departures of the observed distribution from a normal distribution as due to Ly α emission from the cosmic web.

Motivated by the intensity distribution of the rest-frame ultraviolet continuum of high-redshift galaxies ²² and the H⁰ column density distribution of QSO absorption lines ²³, we choose to describe the Ly α surface brightness distribution h(x) as a function of Ly α surface-brightness intensity x by a truncated power law with exponential cutoff

$$h(x) = A\delta(x) + \frac{B}{x_0}H(x - x_{\min})\left(\frac{x}{x_0}\right)^{-\alpha} \exp\left(-\frac{x}{x_0}\right),\tag{1}$$

where $\delta(x)$ is the Dirac delta function and H(x) is the Heaviside step function. Here the delta function term and the faint-end truncation at intensity x_{\min} serve to regularize the distribution (see Methods), x_0 is a characteristic intensity, α is a power-law index, and the ratio B/A is related to the fraction of the sky covered by emission. The observed distribution g(x) is the convolution of h(x) with the pixel-to-pixel measurement uncertainty distribution, which we take to be a normal distribution $N(x; \sigma, \bar{x})$ of standard deviation σ and mean \bar{x} , i.e.

$$g(x; \alpha, x_0, B/A, \sigma, \bar{x}) = \int_0^\infty h(x'; \alpha, x_0, B/A) N(x - x'; \sigma, \bar{x}) dx'$$

$$= AN(x; \sigma, \bar{x}) + \frac{B}{x_0} \int_{x_{\min}}^\infty \left(\frac{x'}{x_0}\right)^{-\alpha} \exp\left(-\frac{x'}{x_0}\right) N(x - x'; \sigma, \bar{x}) dx'.$$
(2)

(A non-zero value of \bar{x} can account for small errors in background determination.) The bottom panel of Fig. 2 shows the observed distribution together with a χ^2 fit to the model of equation (2). The fit yields $\chi^2 = 139.2$ for 126 degrees of freedom, which indicates a statistically acceptable fit, with a p value of 0.20. Thus the fit to the model of equation (2) is statistically superior to the fit to a normal distribution, reducing χ^2 by $\Delta\chi^2 = 423.7$ with the introduction of only three additional parameters; this is extremely unlikely by chance, with a p value of essentially zero. We take the difference between the top and bottom panels of Fig. 2 and in particular the difference between the goodness of fit of the respective fits as demonstrating that the difference image in regions between continuum sources detects the imprint of Ly α emission from the cosmic web at redshift $z \approx 2.4754$ at an overwhelming statistical significance.

The Ly α surface brightness intensity distribution h(x) is a fundamental statistical description of the cosmic web that must be matched by any successful cosmological simulation of large-scale structure formation. Further, the first moment of the distribution is the Ly α luminosity density. Adopting the best-fit parameter values of the model of equation (2) given in the caption to Fig. 2, the comoving Ly α luminosity density of the cosmic web at redshift $z \approx 2.4754$ is $2.9 \pm^2 \times 10^{40}$ erg s⁻¹ Mpc⁻³. We emphasize that this value includes contributions from all sources of Ly α emission in the difference image in regions between continuum sources, including Ly α -emitting galaxies, the circumgalactic medium, and the intergalactic medium.

The central wavelength of the narrow-band filter was chosen to correspond to the redshift z=2.4754 of a 1×1 arcmin² region of apparent particularly high density of Ly α emission in the CWI image presented in the middle, right-most panel of Fig. 4b of ref. 6. Portions of the smoothed difference, difference, and luminance images containing this region are presented in Fig. 3, with the boundary of the CWI image indicated. Both the Condor and CWI images show obvious Ly α emission of redshift $z\approx 2.4754$ from the AGN ACS–GC 20118705²¹ (near the SW corner of the bounded region), but otherwise there is little correspondence between the images. The Condor image shows features not seen in the CWI image, and vice versa. In particular, the Condor image shows two apparent filaments or tails in the vicinity of ACS–GC 20118705 that are not seen in the

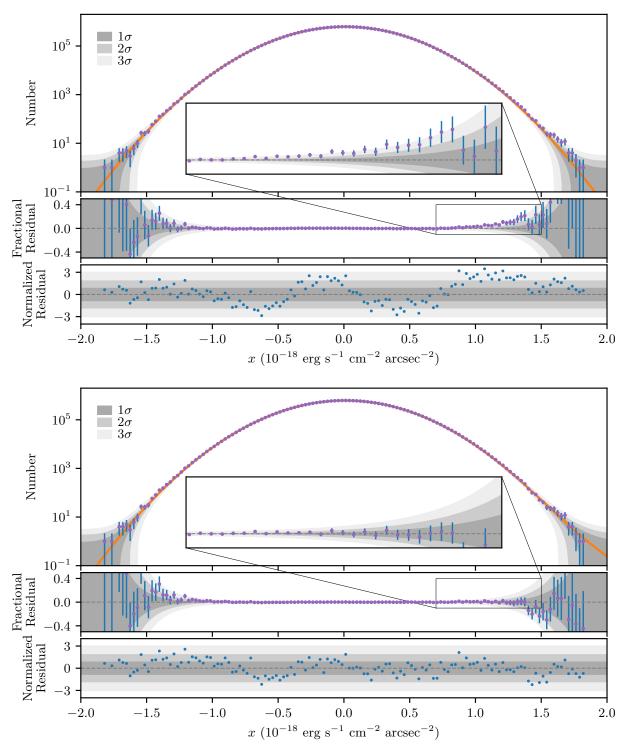

Fig. 2: Distributions of pixel intensities of masked difference image, i.e. of pixels of difference image between continuum sources. Top panel shows observed distribution fitted by normal distribution of best-fit parameter values $\sigma=3.3878\pm0.0021\times10^{-19}$ erg s⁻¹ cm⁻² arcsec⁻² and $\bar{x}=1.166\pm0.014\times10^{-20}$ erg s⁻¹ cm⁻² arcsec⁻². Bottom panel shows observed distribution fitted by model of equation (2) adopting $x_{\rm min}=10^{-21}$ erg s⁻¹ cm⁻² arcsec⁻² (although fit is insensitive to choice of $x_{\rm min}$) of best-fit parameter values $\sigma=3.3727\pm0.0021\times10^{-19}$ erg s⁻¹ cm⁻² arcsec⁻², $\bar{x}=5.65\pm0.14\times10^{-21}$ erg s⁻¹ cm⁻² arcsec⁻², $\alpha=0.66\pm0.50,\ x_0=1.286\pm0.035\times10^{-19}$ erg s⁻¹ cm⁻² arcsec⁻², and $B/A=0.32\pm0.20$. In each case, top plot shows observed and fitted distributions, middle plots show fractional residuals, and bottom plot show normalized residuals (in units of standard deviation σ), and inset shows zoom of portion of middle plot. Grey regions show 1-, 2-, and 3- σ confidence intervals.

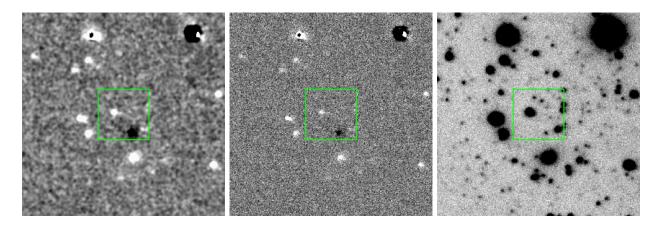

Fig. 3: Portions of (left to right) smoothed difference, difference, and luminance images containing 1×1 arcmin² region (shown by green box) of apparent particularly high density of Ly α emission in CWI observations. Region within green box may be directly compared with middle, right-most panel of Fig. 4b of ref. 6. Images extend 4×4 arcmin² centered at J2000 coordinates 10:00:22, +02:24:18, which at redshift z=2.4754 corresponds to 2.0 proper Mpc or 7.0 comoving Mpc on a side. Smoothed difference image is smoothed by Gaussian of standard deviation 1.5 pix. North is up, and east is to left.

CWI image, one at roughly 2 o'clock and one at roughly 10 o'clock; the Condor image also shows various spatially-unresolved sources not seen in the CWI image, and vice versa. (Indeed, sources 61 through 64 of Extended Data Table 1 and Extended Data Fig. 5 are detected in the vicinity of the AGN.) We cannot explain this difference, although we note that the Condor difference image is a difference between two direct images whereas the CWI image is a highly-processed product that involves iterative adaptive smoothing of spectroscopic observations.

Nearly two million galaxy redshifts have been measured in the COSMOS field (by spectroscopic or photometric techniques), which provides an opportunity to "stack" cutouts of images of many galaxies of similar redshift in order to form a "composite" image of the galaxies that is far more sensitive than any single image alone. We formed stacked median cutouts of the luminance image of galaxies over a range of redshift and brightness (see Methods). An example of the result for galaxies of redshift near the primary target redshift z=2.4754 is presented in Fig. 4, for galaxies in four brightness ranges. For each brightness range, Fig. 4 shows the composite image and the radial profile measured from the center of the image. In each case, the composite image exhibits (1) a bright core, which is produced by starlight emitted by the galaxies, and (2) a dark "halo" surrounding the core that extends ≈ 250 proper kpc in radius. The composite images of all but the brightest galaxies further exhibit (3) an extended dark halo that extends at least ≈ 1.7 proper Mpc or ≈ 6.0 comoving Mpc. The composite images are approximately azimuthally symmetric, as is expected if the galaxies are randomly distributed with no preferred orientation.

The dark halos and extended dark halos appear to be universal and are present in composite images of galaxies of redshift spanning z=0 through beyond 3 and a range of brightnesses, although there is a tendency for the halos of the brightest galaxies at a given redshift to be less pronounced. We found that the effect persists across different stacking algorithms (including median and sigma clipping), is apparent in stacks that we formed from the luminance and narrow-band images, and is even apparent in stacks that we formed from Subaru broad-band images of the COSMOS field 24 . We conclude that the effect is *not* the result of an instrumental or processing artifact.

We interpret the dark halos surrounding the bright cores as due to obscuration of background galaxies by the dusty circumgalactic medium of the galaxies. This sets a characteristic scale of ≈ 250 proper kpc radius for the circumgalactic medium in dust at redshift $z \approx 2.48$, which is in line with other measures of extended dust around galaxies ^{25,26}. We consider the composite images

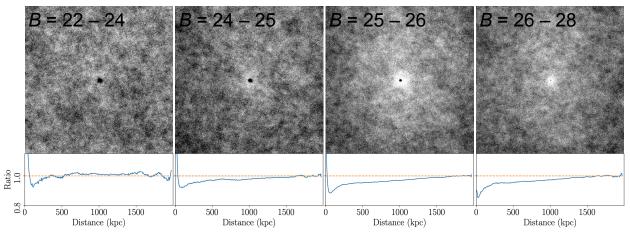

Fig. 4: Stacked median cutouts of luminance image (top panels) and radial profiles (bottom panels) of galaxies of redshift within $\Delta z = 0.5$ of z = 2.5 and of (left to right) *B*-band magnitude 22 to 24 (554 galaxies), 24 to 25 (4355 galaxies), 25 to 26 (8828 galaxies), and 26 to 28 (4877 galaxies). Radial profiles are normalized to unity at right-hand edges. Images extend 5.7×5.7 arcmin², which corresponds to 2.8 proper Mpc or 9.7 comoving Mpc on a side. Images are reversed, with emission dark.

of Fig. 4 (and similar images formed at other redshifts and brightnesses) to be vivid and graphic direct images of the circumgalactic medium of galaxies in dust. We speculate that perhaps the effect is less apparent in brighter galaxies because brighter galaxies are preferentially early-type galaxies whereas fainter galaxies are preferentially late-type galaxies, and a dusty circumgalactic medium may be less prevalent around early-type galaxies.

The extended dark halos surrounding the bright cores are far too large to be associated with individual galaxies and indeed extend to scales comparable to the galaxy correlation length of ≈ 7 comoving Mpc²⁷. We interpret the extended dark halos as due to obscuration of background galaxies by dusty material spread on intergalactic scales, i.e. overlapping dusty halos of correlated galaxies or dust distributed in intergalactic space or both. Future analyses will more completely characterize properties of cosmic dust in the circumgalactic and perhaps intergalactic medium.

A similar stacking technique can be applied to the narrow-band image to search for faint fluorescence emission from ions distributed in the extended gaseous envelopes of galaxies that are inferred on the basis of statistical comparison of QSO absorption lines and galaxies along the lines of sight in H⁰ (ref. 28), C³⁺ (ref. 29), and Mg⁺ (ref. 30). Here the stacked median cutouts of the narrowband image involve a complex blend of emission (including continuum emission from foreground and background galaxies and continuum and line emission from the target galaxies) and absorption (including line absorption by gas and continuum absorption by dust of the target galaxies). To address this complexity, we formed "on-band" and "off-band" stacked median cutouts of the narrowband image of galaxies of various redshifts (see Methods). Redshifts of the galaxies included into the on-band images shift a resonance transition into the filter bandpass, and redshifts of the galaxies included into the off-band images do not shift any resonance transition into the filter bandpass. Subtracting the off-band image from the on-band image then removes continuum emission and absorption, leaving only the line emission and absorption of the resonance transition. In practice, we bracketed each on-band image with a pair of off-band images, one formed from slightly lower redshifts and one formed from slightly higher redshifts, and we subtracted the mean off-band image (thereby accounting for the possibility of gradients in the continuum emission and absorption with wavelength). We used a weighted median stacking method to allow for galaxy redshift uncertainties, with weights determined by taking the uncertainties to be normally distributed with a standard deviation of 0.1.

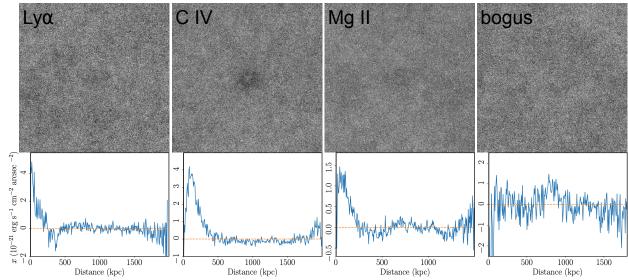

Fig. 5: Composite on-band minus off-band images (top panels) and radial profiles (bottom panels) for resonance transitions of (left to right) Ly α from galaxies of redshift $z \approx 2.48$ (6935 on-band galaxies), C IV 154.9 nm from galaxies of redshift z = 1.73 (24, 100 on-band galaxies), and Mg II 279.6 nm from galaxies of redshift $z \approx 0.51$ (55, 270 on-band galaxies) and for a "bogus" redshift z = 3.08 that does not correspond to any resonance transition (3499 on-band galaxies). Analysis incoporates roughly one to three times as many off-band galaxies, depending on transition. Images extend 5.7×5.7 arcmin², which corresponds to 2.1 to 2.9 proper Mpc or 3.2 to 10.8 comoving Mpc on a side, depending on redshift. Images are reversed, with emission dark.

Results for the resonance transitions of Ly α from galaxies of redshift $z\approx 2.48$, C IV 154.9 nm from galaxies of redshift z=1.73, and Mg II 279.6 nm from galaxies of redshift $z\approx0.51$ and for a "bogus" redshift z = 3.08 that does not correspond to any resonance transition are presented in Fig. 5. For each transition at each redshift, Fig. 5 shows the composite on-band minus off-band image and the radial profile measured from the center of the image. In each real case, the composite image shows extremely faint but significant emission. The composite image of Ly α emission indicates a peak median intensity of $\approx 4 \times 10^{-21} \text{ erg s}^{-1} \text{ cm}^{-2} \text{ arcsec}^{-2}$ and an extent of ≈ 250 proper kpc, the composite image of C IV emission indicates a peak median intensity of $\approx 4 \times 10^{-21}$ erg s⁻¹ ${\rm cm}^{-2}~{\rm arcsec}^{-2}$ and an extent of $\approx 400~{\rm kpc}$, and the composite image of Mg II emission indicates a peak median intensity of $\approx 1 \times 10^{-21} \text{ erg s}^{-1} \text{ cm}^{-2} \text{ arcsec}^{-2}$ and an extent of $\approx 250 \text{ kpc}$. In the bogus case, the composite image does not show significant emission. The extent of the Ly α emission of redshift $z \approx 2.48$ indicated by the composite image of the first panel of Fig. 5 is in remarkable agreement with the extent ≈ 230 kpc of the Ly α absorption at redshifts $z \lesssim 1$ inferred by comparing QSO absorption lines and galaxies²⁸. And, strikingly, the radial profile of the C IV image of Fig. 5 exhibits a clear ring-like structure, which is consistent with the long-held notion that the extended envelopes of C IV-absorbing gas surround the extended envelopes of Ly α -absorbing gas²⁹. We consider the composite images of Fig. 5 to be vivid and graphic direct images of the circumgalactic medium of galaxies in gas.

Our results clearly demonstrate that Condor, equipped with broad- and narrow-band filters and dedicated to obtaining very long exposures, can detect and characterize the cosmic web in Ly α and can detect and study the circumgalactic medium in gas and dust. Some, but not all, of our results rely on the huge number of galaxy redshifts that have been measured in the COSMOS field, and these results will be difficult to replicate or build upon in other fields. But the COSMOS field itself remains ripe for exploration, and future observations and analyses of this and other fields will probe deeper into the cosmic web and will establish properties of intergalactic and circumgalactic gas and dust as functions of galaxy environment and cosmic epoch.

Methods

Observations and Data Processing

Condor is an "array telescope" that consists of six apochromatic refracting telescopes of objective diameter 180 mm, each equipped with a large-format (9576 × 6388 pix²), very-low-read-noise ($\approx 1.2~{\rm e^-}$), very-rapid-read-time ($< 1~{\rm s}$) CMOS camera⁷. Over the period stretching from January through June 2024, we used Condor to obtain very deep direct images of Condor field 416 through luminance broad-band and custom narrow-band filters. The total exposure time of 26.3 h through the luminance filters and 171.8 h through the narrow-band filters corresponds to a reach ³¹ of the luminance observations of $1.4 \times 10^4~{\rm m}^2~{\rm s}$ and of the narrow-band observations of $9.5 \times 10^4~{\rm m}^2~{\rm s}$. All individual exposures were obtained with an exposure time of 600 s, and the telescope was dithered by a random offset of $\approx 15~{\rm arcmin}$ between each individual exposure.

We worked together with Chroma Technology Corp. to design and fabricate the custom narrow-band filters tuned to a central wavelength in the Condor f/5 beam of 422.5 nm with a bandpass of only 1 nm and a peak throughput of $\approx 85\%$. The filter response function (measured by Chroma) together with an indication of the predicted central wavelength in the Condor f/5 beam (calculated by Chroma) is shown in Extended Data Fig. 1.

We processed the observations using the Condor data pipeline ^{7,19}. The data pipeline performs bias subtraction; field flattening and background subtraction; astrometric calibration; identification and masking of cosmic ray events, satellite trails, and pixels that exhibit significant random telegraph noise; photometric calibration; drizzling onto a common coordinate grid; and coaddition of the individual exposures. The narrow-band, luminance, and difference images are shown in Extended Data Fig. 2, 3, and 4 respectively.

Detection of Faint Emission

To detect low-surface-brightness Ly α emission of redshift $z \approx 2.4754$ in regions between continuum sources, we binned the narrow-band and luminance images on scales ranging from 1×1 pix² through 50×50 pix², in steps of 1 pix. At each step, we identified binned pixels of (1) high statistical significance (> 5σ) in the narrow-band image and (2) large rest-frame equivalent width ($W_{\text{rest}} > 5$ nm for $Ly\alpha$) in the combination of narrow-band and luminance images, cumulating the identified pixels at every step. The sensitivities of the narrow-band, luminance, and difference images are roughly constant over the central portions of the images but decrease toward the edges, due to vignetting and dithering. For simplicity, we applied the analysis only over the central portions of the image, specifically over pixel indices ranging in the horizontal direction from 2300 to 9400 and in the vertical direction from 1700 to 7000, where the indices are zero indexed at the lower-left corner of the image. The result is a "detection map" of 112 features of statistically-significant, strong line emission that can be reasonably interpreted only as Ly α of redshift $z \approx 2.4754$. The resulting catalog of features is presented in Extended Data Table 1, which for each feature lists ID number, J2000 Right Ascension and Declination, energy flux f, uncertainty in energy flux σ_f , radius r (estimated simply from the number of pixels occupied by the feature in the detection map), and average surface brightness $\langle x \rangle$. (Note that the energy flux of each feature includes only whatever portion of the feature is contained within the detection map.)

Ly α Surface Brightness Distribution

Motivated by the intensity distribution of the rest-frame ultraviolet continuum of high-redshift galaxies²² and the H⁰ column density distribution of QSO absorption lines²³, we seek to describe the Ly α surface brightness distribution h(x) as a function of surface brightness intensity x by a

simple functional form based on a power law $h(x) \propto x^{-\alpha}$. But a power law alone cannot suffice, because for such a distribution, the zeroth moment diverges for $\alpha > 1$ at the lower limit and the first moment diverges for $\alpha < 2$ at the upper limit. The divergence of the first moment can be handled by truncating h(x) at sufficiently large x, say by introducing an exponential cutoff $\exp(-x/x_0)$, where x_0 is a characteristic intensity. The divergence of the zeroth moment can in principle be handled by in some way truncating h(x) at sufficiently small x. The difficulty is that the normalization of the zeroth moment is very sensitive to the details of this truncation, which are hard to measure because small values of x are buried in the noise.

To address this difficulty, we truncate h(x) below some value x_{\min} , which is chosen in such a way that it is of order or smaller than the pixel-to-pixel measurement uncertainty. We then conceptually consider the intensities of points on the sky with $x < x_{\min}$ to be equivalent to x = 0. As long as the power-law functional form approximately holds to values of x as small as (or smaller than) x_{\min} , then the results are insensitive to the value of x_{\min} . Note that this procedure does not presume that the distribution is actually truncated at x_{\min} , but rather only that any value $x < x_{\min}$ is roughly equivalent to x = 0, given the measurement uncertainty.

Accordingly, we adopt the functional form of the Ly α surface brightness distribution h(x) as a function of Ly α surface brightness intensity x of equation (1). Here the first term accounts for all $x < x_{\min}$ and the second term accounts for all $x > x_{\min}$ and the ratio A/B is related to the fraction of the sky covered by emission of $x > x_{\min}$. This procedure serves to "regularize" a simple functional form that is otherwise practically difficult to work with.

We experimented with fitting the observed distribution using a maximum-likelihood method applied to individual pixels and a χ^2 method applied to bins of pixels. We found that both methods yielded essentially identical results. For the final analysis, we adopted the χ^2 method, both because it is computationally far less burdensome than the maximum-likelihood method and because it provides a simple goodness-of-fit test.

Due to the drizzling process used to coadd the individual exposures, pixels of the narrow-band, luminance, and difference images are correlated with their neighbors. For the masked difference image, we measured that, as a result of this correlation, the pixel-to-pixel standard deviation is reduced by a factor ≈ 0.88 with respect to the value determined from the propagated uncertainty image. This means that the pixels that fall within some χ^2 bin are not statistically independent, which increases the statistical variance of the bin. We accounted for this effect using the measured value of the factor. As above, we applied the analysis only over the central portions of the image, i.e. over pixel indices ranging in the horizontal direction from 2300 to 9400 and in the vertical direction from 1700 to 7000.

We estimated parameter uncertainties using a bootstrap resampling technique. Examples of the results are illustrated in Extended Data Fig. 5, which shows the distributions of parameter values obtained in 1000 resamplings for the parameters \bar{x} , α , and x_0 of the model of equation (2). (Similar distributions were obtained for the other parameters.) The distributions of these parameter values are clearly bimodal, with the values given in the caption of Fig. 2 drawn from the rightmost peak in all cases. We took the parameter uncertainties to be the approximate widths of the right-most peaks, although we cannot exclude an alternate solution in the other peaks. We estimated the uncertainty of the luminosity density using a similar bootstrap resampling technique. Higher-sensitivity observations will be needed to unambiguously measure parameter values.

Image Stacking

Interpreting a "stack" of cutouts of images of many galaxies of similar redshift involves accounting for a complex blend of the effects of continuum and line intensity and gas and dust optical depth

radial profiles of the target galaxies and of intensities of background and foreground galaxies. Here we explore the interpretation of stacks of broad- and narrow-band galaxy images.

First, consider stacking of broad-band images. We write the mean intensity I(R, z) of an ensemble of stacked broad-band galaxy images as a function of radius R and redshift z as

$$I(R, z) = G_C(R) + I_B(z) \exp\left[-\tau_D(R)\right] + I_F(z), \tag{3}$$

where $G_C(R)$ is the target galaxy continuum intensity radial profile (contributed by starlight, including the possibility of a faint, extended stellar halo), $I_B(z)$ and $I_F(z)$ are, respectively, the mean background and foreground intensities (contributed by randomly distributed background and foreground galaxies), and $\tau_D(R)$ is the target galaxy dust optical depth radial profile. In the optically-thin regime appropriate for the outskirts of galaxies,

$$I(R,z) \approx G_C(R) + I_B(z) \left[1 - \tau_D(R) \right] + I_F(z) = G_C(R) + I_0(z) - I_B(z)\tau_D(R), \tag{4}$$

where

$$I_0(z) = I_B(z) + I_F(z).$$
 (5)

In the limit $R \to 0$, $G(R) \gg I_0(z)$, and

$$I(R,z) \approx G(R).$$
 (6)

In the limit $R \to \infty$, $G(R) \to 0$ and $\tau_D(R) \to 0$, and

$$I(R,z) \approx I_B(z).$$
 (7)

Equation (4) may be rewritten as

$$\frac{I(R,z)}{I_0(z)} \approx 1 - \frac{I_B(z)}{I_0(z)} \tau_D(R) + \frac{G_C(R)}{I_0(z)}.$$
 (8)

The radial profiles of Fig. 4 show $I(R,z)/I_0(z)$ and so may be interpreted directly in the context of equation (8). The radial profiles of Fig. 4 indicate that $I(R,z)/I_0(z) < 1$ at $R \gtrsim 30$ kpc, from which we conclude that

$$I_R(z)\tau_D(R) > G_C(R) \tag{9}$$

at $z \approx 2.48$ and $R \gtrsim 30$ kpc. If it is assumed that $I_B(z)\tau_D(R) \gg G(R)$, then equation (8) provides a way to determine $\tau_D(R)$, if $I_B(z)$ and $I_F(z)$ are known (through measurement or modeling). But in general, even if $I_B(z)$ and $I_F(z)$ are known, then equation (8) indicates that it will be difficult to untangle $G_C(R)$ (of faint, extended stellar halos) from $\tau_D(R)$.

Next, consider stacking of narrow-band images. We write the mean intensity I(R, z) of an ensemble of stacked narrow-band galaxy images as a function of radius R and redshift z as

$$I(R,z) = G_C(R) + \Theta(z)G_L(R) + I_R(z) \exp\left\{-\left[\tau_D(R) + \Theta(z)\tau_G(R)\right]\right\} + I_F(z), \tag{10}$$

where $G_L(R)$ is the target galaxy line intensity radial profile (contributed by fluorescence emission), $\tau_G(R)$ is the target galaxy gas optical depth radial profile, and $\Theta(z)$ is a function that takes on the value $\Theta(z) = 1$ if the target redshift is an "on-band" redshift that shifts a resonance transition into the filter bandpass and $\Theta(z) = 0$ if the target redshift is an "off-band" redshift that does not. In the optically-thin regime appropriate for the outskirts of galaxies,

$$I(R, z) \approx G_C(R) + \Theta(z)G_L(R) + I_B(z)[1 - \tau_D(R) - \Theta(z)\tau_G(R)] + I_F(z),$$
 (11)

Subtracting an adjacent off-band image from an on-band image and assuming that G(R), $I_B(z)$, and $I_F(z)$ vary slowly with wavelength leaves

$$I(R, z_{\rm on}) - I(R, z_{\rm off}) \approx G_L(R) - I_B(z)\tau_G(R), \tag{12}$$

The images and radial profiles of Fig. 5 show $I(R, z_{\rm on}) - I(R, z_{\rm off})$ and so may be interpreted directly in the context of equation (12). The radial profiles of Fig. 5 indicate that $I(R, z_{\rm on}) - I(R, z_{\rm off}) > 0$ at $R \lesssim 300$ kpc, from which we conclude

$$G_L(R) > I_B(z)\tau_G(R) \tag{13}$$

at z = 2.48, 1.73, and 0.51 for Ly α , C IV, and Mg II, respectively, and $R \lesssim 300$ kpc. If it is assumed that $G_L(R) \gg I_B(z)\tau_G(R)$, then equation (12) provides a direct measure of $G_L(R)$. But in general, the values of the radial profiles shown in Fig. 5 represent lower limits to $G_L(R)$.

We formed the stacked cutouts of broad- and narrow-band images using a list of redshifts of galaxies in and surrounding the COSMOS field derived from the SIMBAD4 v1.8 catalog ³².

Acknowledgments. This material is based upon work supported by the National Science Foundation under Grants 1910001, 2107954, 2108234, 2407763, and 2407764. We gratefully acknowledge the staff of Dark Sky New Mexico, including Michael Hensley and Diana Hensley for their outstanding logistical and technical support and Yuri Petrunin for crafting six superb instruments. This research has made use of the SIMBAD database, operated at CDS, Strasbourg, France.

Data Availability. All raw Condor data are available following an 18-month proprietary period. All raw and processed data described here, including the coadded narrow-band, luminance, and difference images, are available on the Condor web site https://condorarraytelescope.org/data_access/or by contacting the corresponding author.

Extended Data Fig. 5: Detected features of (1) high statistical significance and (2) large rest-frame equivalent width (for Ly α). Each panel shows small portions of (left to right) difference image, masked difference image, detection map, and luminance image. Images extend $2.8 \times 2.8 \text{ armin}^2$, which at redshift z = 2.4754 corresponds to 1.4 proper Mpc or 4.9 Mpc comoving Mpc on a side. North is up and east is to the left.

Extended Data Fig. 6: Distributions of parameter values obtained in 1000 resamplings for parameters \bar{x} , α , and x_0 of model of equation (2). Distributions of parameter values are bimodal, with values given in caption of Fig. 2 occurring in right-most peak in all cases.
