Graphical model estimation from modern multi-omics data requires a balance between statistical estimation performance and computational scalability. We introduce a novel pseudolikelihood-based graphical model framework that reparameterizes the target precision matrix while preserving sparsity pattern and estimates it by minimizing an ℓ_1 -penalized empirical risk based on a new loss function. The proposed estimator maintains estimation and selection consistency in various metrics under high-dimensional assumptions. The associated optimization problem allows for a provably fast computation algorithm using a novel operator-splitting approach and communicationavoiding distributed matrix multiplication. A high-performance computing implementation of our framework was tested in simulated data with up to one million variables demonstrating complex dependency structures akin to biological networks. Leveraging this scalability, we estimated partial correlation network from a dual-omic liver cancer data set. The co-expression network estimated from the ultrahighdimensional data showed superior specificity in prioritizing key transcription factors and co-activators by excluding the impact of epigenomic regulation, demonstrating the value of computational scalability in multi-omic data analysis.

1. Introduction. Omics technologies are essential discovery tools for the analysis of complex biological samples such as tissues and biofluids. Individual omics modalities can generate high-dimensional data (large p) for characterizing complex biological samples in a high-throughput manner (large $n \ll p$), and recently for deconvoluting molecular profiles of isolated single cells or spatially connected micrometer-sized regions over tissue sections (Vandereyken et al., 2023). Given the unprecedented opportunity to assemble multi-omic data as fine-resolution descriptors of gene expression regulation, cellular metabolism and signal transduction in a biological system, clinical and basic research studies routinely employ a combination of omics platforms to characterize joint variation in the genome, epigenome, transcriptome, proteome and metabolome (Hasin, Seldin and Lusis, 2017; Huang, Chaudhary and Garmire, 2017).

In biomedical applications, the method of choice for multi-omic data interpretation is to map experimental data over well-characterized biological networks, where the data features are linked by a directed graph representing gene expression regulatory

network, metabolic pathways or signaling cascades, or an undirected graph such as protein-6protein interaction network or gene co-expression network. Different networks facilitate human interpretation of molecular interactions in their respective biological context. However, a downside of this approach is that the network information biologically relevant to a given study may be unavailable in the literature, or the network information can be incomplete and thus fail to cover the molecules measured in a study. In other cases, the biological network of interest may be adaptive, and it is therefore susceptible to rewiring in specific conditions, rendering the available static network information inapplicable. For these reasons, it is often necessary to complement existing networks by estimating new ones directly from data so that a realistic snapshot of the relational structure among the variables is reflected in the downstream analysis or interpretation of the results.

In omics-scale analysis, biological network is typically represented as an adjacency matrix of data features based on marginal pairwise correlations. In the popular weighted gene co-expression network analysis (WGCNA, Zhang and Horvath, 2005), for example, Pearson correlation-based network modules are captured first and the initial network is refined by topological analysis. Despite the success of WGCNA and other extensions in identifying gene communities from omics data, the adjacency of two molecular features as determined by marginal correlations can be a byproduct of shared regulatory factors rather than direct biological interaction. Hence it is natural to estimate the co-expression network underlying a gene expression dataset with a graph representing the conditional dependencies, e.g., partial correlations. The same logic extends to the inference of other types of biological networks from multi-omic data such as metabolic pathways and signaling cascades.

It is well known that the precision matrix, or inverse covariance matrix, of a multivariate distribution encodes partial correlations. The most popular high-dimensional precision matrix estimation approach is the graphical lasso (Yuan and Lin, 2007; Friedman, Hastie and Tibshirani, 2008), which maximizes a multivariate Gaussian likelihood with an ℓ_1 -penalty. However, at the scale of modern multi-omics datasets, it is computationally infeasible to estimate desired networks using this strategy mainly due to the computational bottleneck, which is not easily resolved by using a more powerful computer. As we demonstrate later, our application data features close to 300,000 variables. On two high-performance computing (HPC) environments, the most scalable implementation of graphical lasso, BigQUIC (Hsieh et al., 2013), could complete the computation only for the trivial cases in which the computed precision matrix estimates were diagonal. Similarly, a fast implementation (Pang, Liu and Vanderbei, 2014) of CLIME (Cai, Liu and Luo, 2011), another popular methodology, was also not applicable on a HPC machine with 192GB of memory when the dataset dimension exceeded 30,000. In the next section, we discuss in detail that the inherent nature of the optimization problems from these popular methods makes it difficult to scale up to modern omics-scale problems.

Feature screening procedures, which reduces the number of variables before the network estimation step, have been proposed as a remedy to address the lack of scalability of methods mentioned above (Luo, Song and Witten, 2014; Zheng et al., 2020). Although feature screening could be suitable when a moderate dimensionality reduction is necessary, an order of magnitude reduction (300,000 or more to 30,000 or fewer features) precludes functionally important molecules from being considered for network estimation for computational tractability rather than a biologically motivated rationale. It is also difficult to discern essential variables and dispensable ones *a priori* solely based on numerical criteria chosen by an analyst, hence there is a clear merit in estimating the model with all possible input variables included from the start. Another category of graphical model structure learning approach is based on optimizing an ℓ_1 -penalized pseudolikelihood-based objective function (Peng et al., 2009; Khare, Oh and Rajaratnam, 2015). Although the structure of pseudolikelihood-based objectives can be advantageous from an optimization perspective (Koanantakool et al., 2018), existing estimators do not possess the statistical properties desirable for multiomics analyses, as we also discuss in the next section.

In summary, a statistical framework for partial correlation graph estimation scalable to contemporary multi-omics studies is currently lacking. To address this gap, we propose a new estimation framework called ACCORD that aims to strike a balance between computational scalability and statistical performance. In ACCORD, target precision matrix is reparameterized and estimated by minimizing the ℓ_1 -penalized empirical risk based on a new loss function. The associated optimization problem allows for a provably fast computation algorithm that is massively scalable, which is realized by a novel operator splitting algorithm and communication-avoiding distributed matrix multiplication. We then show that the ACCORD estimator possesses estimation consistency in ℓ_1 and ℓ_2 norms under standard high-dimensional assumptions and selection consistency under an irrepresentability condition. In this way, we balance between statistical performance and scalability of computation in massively large-scale settings.

We demonstrate that the HPC implementation of ACCORD, termed HP-ACCORD, scales well to handle dimensions up to one million. Leveraging on the scalability, we estimate a partial correlation network in the multi-omic liver cancer dataset from The Cancer Genome Atlas (TCGA). Using a combination of epigenomic and transcriptomic data sets with 285,358 variables in total, we successfully recapitulated local and global correlation structures of the variables within the same omics platform and identified a network of co-transcribed genes and DNA methylation events in upstream regulatory regions. More importantly, we show that the graph estimated from the ultrahigh-dimensional dual-omic data enabled us to identify *bona fide* transcription factors driving the co-expression network with greater specificity than and equivalent sensitivity to the alternative graph estimated from the transcriptomic data with 15,598 variables only. The analysis clearly highlights the merit of performing graph estimation in the whole feature space.

The organization of this paper is as follows. Section 2 explains the challenges that existing methods face when the scale of the problem becomes massively large. Section 3 introduces the ACCORD framework. In Section 4 we study the statistical properties of the ACCORD estimator. Section 5 is devoted to numerical experiments demonstrating the performance of the estimator and scalability of the algorithm. In Section 6, we showcase HP-ACCORD through graph estimation in a liver cancer data set with 285,358 multi-omic variables. The paper is concluded in Section 7.

2. Challenges. In this section we first describe the computational hurdles that current techniques for high-dimensional precision matrix estimation grapple with when dealing with extremely large scales.

Graphical lasso solves the convex optimization problem $\min_{\Theta \in \mathbb{S}^p} \{-\log \det \Theta + \operatorname{tr}(S\Theta) + \lambda \|\Theta\|_1\}, \ \lambda > 0$, in order to estimate the precision matrix Θ^* of a *p*-variate zero-mean distribution. Here \mathbb{S}^p is the space of $p \times p$ symmetric matrices, $S = (1/n)X^T X$ is the sample covariance matrix, where $X = [X_1, X_2, \cdots, X_n]^T$ with $X_i \in \mathbb{R}^p$ is the centered data matrix, and $\|\cdot\|_1$ is the vector ℓ_1 norm. The estimate is fully characterized by the Karush-Kuhn-Tucker (KKT) optimality condition

(2.1)
$$-\Theta^{-1} + S + \lambda Z = \mathbf{0}, \quad Z \in \partial \|\Theta\|_1,$$

where $\partial \|\Theta\|_1$ denotes the subdifferential of the convex function $X \mapsto \|X\|_1$ at Θ . The vast literature on the algorithms for graphical lasso, e.g., d'Aspremont, Banerjee and El Ghaoui (2008); Friedman, Hastie and Tibshirani (2008); Li et al. (2010); Hsieh et al. (2011, 2014), essentially reduces to how to solve the KKT equation (2.1) iteratively.

The computational culprit in (2.1) is the inverse of the $p \times p$ matrix variable Θ , which has to be computed every iteration. Inverting a $p \times p$ matrix using direct methods (e.g., Cholesky decomposition) costs $O(p^3)$ arithmetic operations in general, which becomes prohibitive if p is at the omics scale of a few hundreds of thousands. Storage requirements worsen the situation. The inverse Θ^{-1} is in general not sparse, requiring $O(p^2)$ memory space. For example if p = 300,000, then roughly 700GB of memory is needed, which calls for distributed computation. Being inherently sequential, however, matrix inversion is difficult to parallelize or distribute, meaning that direct methods are not so much scalable even with high-performance computing (HPC) systems with distributed memory.

Consequently, most existing algorithms resort to employing an (inner) iterative method to compute Θ^{-1} . For instance, Friedman, Hastie and Tibshirani (2008) invoke a *p*-dimensional lasso regression solver *p* times every (outer) iteration to compute one column of Θ^{-1} at a time, which becomes prohibitively expensive in omics-scale problems. BigQUIC (Hsieh et al., 2013) updates Θ by block coordinate descent and then computes Θ^{-1} column by column, by storing only a small fraction of the *p* columns of Θ^{-1} in a cache and recomputing the missing columns on demand; the recomputation solves a fraction of the *p* linear equations defining the inverse ($\Theta X = I_p$) by using conjugate gradient. Since this strategy is only successful if the cache miss rate is low, BigQUIC partitions Θ into a block matrix and permutes blocks to minimize the number of the off-block-diagonal elements. Therefore, the scalability of BigQUIC is limited by the maximum degree of the underlying graph. For more complex graph structures of interest, e.g., those that arise in multi-omics studies, computable dimensions are practically less than 100,000; see §5.

CLIME minimizes $\|\Theta\|_1$ subject to the constraint $\|S\Theta - I_p\|_{\infty} \leq \lambda$ over $\mathbb{R}^{p \times p}$, where $\|\cdot\|_{\infty}$ is the vector ℓ_{∞} norm. The optimization problem of CLIME can be decomposed into p independent, p-dimensional linear programming (LP) problems, each solving a column of Θ . While LP is the most extensively studied convex optimization problem, commercial LP solvers like Gurobi or Cplex, which utilize interior-point or simplex methods, struggle with scalability when handling hundreds of thousands of variables (Mazumder, Wright and Zheng, 2019). Exacerbating the situation, for omics-scale CLIME we are required to solve hundreds of thousands of large-scale LP problems. This remains an almost unattainable task despite the independence. As a result, fastclime (Pang, Liu and Vanderbei, 2014; Pang et al., 2017), which could not handle more than 30,000 variables in our problem instance, remains one of the most scalable implementations publicly available.

As the most scalable pseudolikelihood-based method up to date, CONCORD (Khare, Oh and Rajaratnam, 2015) solves the ℓ_1 -penalized minimization problem

(2.2)
$$\min_{\boldsymbol{\Theta} \in \mathbb{S}^p} \{ -\log \det \boldsymbol{\Theta}_D + (1/2) \operatorname{tr}(\boldsymbol{\Theta}^2 \boldsymbol{S}) + \lambda \| \boldsymbol{\Theta}_X \|_1 \},$$

where Θ_D denotes the diagonal and Θ_X denotes the off-diagonal parts of Θ . It is a convex amendment of a non-convex pseudolikelihood-based method SPACE (Peng et al., 2009), which in turn extends the node-wise regression approach by Meinshausen and Bühlmann (2006) to estimate Θ^* .¹ The associated KKT condition is

(2.3)
$$-\boldsymbol{\Theta}_D^{-1} + (1/2)(\boldsymbol{\Theta}\boldsymbol{S} + \boldsymbol{S}\boldsymbol{\Theta}) + \lambda \boldsymbol{Z} = \boldsymbol{0}, \quad \boldsymbol{Z} \in \partial \|\boldsymbol{\Theta}_X\|_1.$$

Compared with that for graphical lasso (2.1), KKT condition (2.3) only involves the inverse of the diagonal matrix Θ_D , which is trivial to compute. While the second term in (2.3) costs two $p \times p$ matrix-matrix multiplications with $O(p^3)$ operations, they are much easier to distribute and parallelize than matrix inversion. The sparsity of the optimization variable Θ imposed by the ℓ_1 penalty further reduces the complexity of the multiplication. Koanantakool et al. (2018) leverage these features to achieve massive scalability in distributed memory HPC systems. This HP-CONCORD implementation can handle 320,000 dimensional data drawn from a random graph structure resembling multi-omic networks.

Despite its computational success, a major drawback of CONCORD is its lack of statistical consistency in estimating Θ^* , which is important in downstream tasks in multi-omic analyses as it carries information on the strength of network edges. The objective function in (2.2) defines a loss function $L(\Theta, x) = -\log \det \Theta_D + \frac{1}{2} \operatorname{tr}(x^T \Theta^2 x)$ for a sample $x \in \mathbb{R}^p$. The population risk $R(\Theta) = \operatorname{E} L(\Theta, X)$ is minimized by a Θ satisfying the equation $\Theta_D^{-1} - \frac{1}{2}(\Theta\Sigma^* + \Sigma^*\Theta) = 0$, where $\Sigma^* = \Theta^{*-1}$ is the covariance matrix of random vector X. Unfortunately, the true precision matrix Θ^* does not minimize the risk unless Θ_D equals the identity. This is a very restrictive assumption indeed, and likely does not hold in many applications. Consequently, the currently available result on the consistency of the CONCORD estimator (Theorem 2, Khare, Oh and Rajaratnam, 2015) requires an accurate estimator $\widehat{\Theta}_D$ of Θ_D^* with a rate $\max_{i=1,\dots,p} |\widehat{\Theta}_{D,ii} - \Theta_{D,ii}^*| = O_P(\sqrt{\log n/n})$. Similarly, SPACE also requires a separate estimator of Θ_D^* with the same rate. Such a separate estimator is difficult to find in practice.

There is also an issue with the optimization method employed by HP-CONCORD. This CONCORD-ISTA algorithm (Oh et al., 2014) possesses an O(1/t) rate of convergence, where t is the number of iterations, and the convergence is measured in terms of the objective function value. In addition to the slow, sublinear convergence of the objective function, the variable iterate $\{\Theta^{(t)}\}$ may converge to the minimizer $\hat{\Theta}$ of (2.2) in an arbitrarily slow rate (Bauschke and Combettes, 2011). Since the algorithm has to be terminated within a finite number of iterations, statistical error of $\Theta^{(t)}$ (say $\|\Theta^{(t)} - \Theta^*\|$) may remain quite large compared to that of $\hat{\Theta}$ (say $\|\hat{\Theta} - \Theta^*\|$) even after a large number of iterations.

3. The ACCORD Estimator and HP-ACCORD.

3.1. ACCORD loss and estimator. For a matrix $\Omega \in \mathbb{R}^{p \times p}$, consider the following loss function

(3.1)
$$L(\mathbf{\Omega}, x) = -\log \det \mathbf{\Omega}_D + (1/2) \operatorname{tr}(x^T \mathbf{\Omega}^T \mathbf{\Omega} x).$$

The associated risk $R(\Omega) = \mathbf{E} L(\Omega, X) = -\log \det \Omega_D + \frac{1}{2} \operatorname{tr}(\Omega^T \Omega \Sigma^*)$ is minimized by $\Omega^* = \Theta_D^{*^{-1/2}} \Theta^*$ since it is the unique solution to the equation $\nabla R(\Omega) = \mathbf{0}$ and R is convex. The essential domain of R on which R is finite is $\operatorname{dom} R = \{(m_{ij}) \in \mathbb{R}^{p \times p} : m_{ii} > 0, i = 1, \ldots, p\} \cap \mathbb{R}^{p \times p}$. Then transformation $T : \Theta \mapsto \Theta_D^{-1/2} \Theta$ from $\operatorname{dom} R$ to

¹CLIME can be understood as an extension of the latter in a different direction, with the aforementioned scalability bottleneck.

itself is bijective with inverse $T^{-1}: \Omega \mapsto \Omega_D \Omega$. Obviously $\Omega^* = T(\Theta^*)$. In other words, the population risk is uniquely minimized by a one-to-one transformation T of the true precision matrix Θ^* . If $\hat{\Omega}$ minimizes the sample average of (3.1), then it consistently estimates Ω^* . Hence $T^{-1}(\hat{\Omega})$ consistently estimates $\Theta^* = T^{-1}(\Omega^*)$, as long as the dimension p is fixed.

In a high-dimensional setting, we can expect minimizing an ℓ_1 -penalized sample average of (3.1) estimates $\Omega^* = T(\Theta^*)$ consistently under the usual sparsity assumption on Θ^* :

(3.2)
$$\hat{\boldsymbol{\Omega}} = \arg\min_{\boldsymbol{\Omega} \in \mathbb{R}^{p \times p}} \left\{ -\log \det \boldsymbol{\Omega}_D + (1/2) \operatorname{tr}(\boldsymbol{\Omega}^T \boldsymbol{\Omega} \boldsymbol{S}) + \lambda \| \boldsymbol{\Omega} \|_1 \right\};$$

recall that \boldsymbol{S} is the sample covariance matrix. An important point here is that the transformation pair (T, T^{-1}) preserves the sparsity pattern of their respective arguments: if $\omega_{ij} = [T(\boldsymbol{\Theta})]_{ij}$ with $\boldsymbol{\Theta} = (\theta_{ij})$, then $\omega_{ij} = \theta_{ij}/\sqrt{\theta_{ii}}$ and $\theta_{ij} = \omega_{ii}\omega_{ij}$. Therefore, $\omega_{ij} = 0$ if and only if $\theta_{ij} = 0$, and $\boldsymbol{\Omega}^*$ shares the sparsity pattern with $\boldsymbol{\Theta}^*$. The ℓ_1 penalization on $\boldsymbol{\Omega}$ in (3.2) is thus justified. Since the downstream task is to analyze the partial correlations (ρ_{ij}^*) , using the relation $\rho_{ij}^* = -\theta_{ij}^*/\sqrt{\theta_{ii}^*\theta_{jj}^*}$ and $\theta_{ij}^* = \omega_{ii}^*\omega_{ij}^*$, we can consistently estimate ρ_{ij}^* by the formula $\hat{\rho}_{ij} = -(1/2)(\hat{\omega}_{ij}/\hat{\omega}_{jj} + \hat{\omega}_{ji}/\hat{\omega}_{ii})$, in which $\hat{\boldsymbol{\Omega}} = (\hat{\omega}_{ij})$.

The loss (3.1) and estimator (3.2) resemble those of CONCORD in §2. The critical difference is that the argument Ω is allowed to be asymmetric in our proposal. This simple change makes the estimator consistent (at least in the low-dimensional regime; high-dimensional results are presented in §4), a feature absent in CONCORD. For an obvious reason, we name the loss function (3.1) the ACCORD loss, and estimator (3.2) the ACCORD estimator, after Asymmetric ConCORD.

The KKT condition for the convex optimization problem for ACCORD (3.2) is

(3.3)
$$-\boldsymbol{\Omega}_D^{-1} + \boldsymbol{\Omega}\boldsymbol{S} + \lambda \boldsymbol{Z} = \boldsymbol{0}, \quad \boldsymbol{Z} \in \partial \|\boldsymbol{\Omega}\|_1,$$

which conserves the computational attraction of CONCORD; cf. (2.3). Furthermore, there is only one matrix multiplication in (3.3), suggesting simpler computation.

For the ACCORD estimator (3.2) to be well-defined, a solution to (3.3) needs to be unique. A matrix $\mathbf{X} \in \mathbb{R}^{n \times p}$ $(p \ge n)$ is said to have columns in general position if the affine span of any *n* points $\{s_1 X_{i_1}, \dots, s_n X_{i_n}\}$, for arbitrary signs $s_1, \dots, s_n \in \{-1, 1\}$, does not contain any element of $\{\pm X_i : i \ne i_1, \dots, i_n\}$. General position occurs almost surely if \mathbf{X} is drawn from a continuous distribution (Tibshirani, 2013).

THEOREM 3.1. Suppose that the data matrix $\mathbf{X} \in \mathbb{R}^{n \times p}$ has columns in general position. Then, the ACCORD estimator (3.2) with $\mathbf{S} = (1/n)\mathbf{X}^T\mathbf{X}$ is unique.

3.2. ACCORD-FBS algorithm. For the computation of the ACCORD estimator, we use forward-backward splitting (FBS), also known as the proximal gradient method (Combettes and Pesquet, 2007, 2011). Let us split the ACCORD objective function f into f = g + h where

(3.4)
$$g(\boldsymbol{\Omega}) = (1/2) \operatorname{tr}(\boldsymbol{\Omega}^T \boldsymbol{\Omega} \boldsymbol{S}), \quad h(\boldsymbol{\Omega}) = -\log \det \boldsymbol{\Omega}_D + \lambda \|\boldsymbol{\Omega}\|_1.$$

and apply a forward step for $g: \mathbf{\Omega}^{(t+1/2)} = \mathbf{\Omega}^{(t)} - \tau_t \nabla g(\mathbf{\Omega}^{(t)})$, and a backward (proximal) step for $h: \mathbf{\Omega}^{(t)} = \arg \min_{\mathbf{\Omega} \in \mathbb{R}^{p \times p}} \{h(\mathbf{\Omega}) + \frac{1}{2\tau_t} \|\mathbf{\Omega} - \mathbf{\Omega}^{(t+1/2)}\|_F^2 \}$ to obtain a sequence of optimization variables $\{\mathbf{\Omega}^{(t)} = (\omega_{ij}^{(t)})\}$. At the element level, we have the following closed-form iteration:

(3.5)
$$\begin{aligned} \omega_{ii}^{(t+1)} &= (y - \tau_t \lambda + \sqrt{(y - \tau_t \lambda)^2 + 4\tau_t})/2, \quad y = \omega_{ii}^{(t)} - \tau_t [\mathbf{\Omega}^{(t)} \mathbf{S}]_{ii} \\ \omega_{ij}^{(t+1)} &= S_{\tau_t \lambda} (\omega_{ij}^{(t)} - \tau_t [\mathbf{\Omega}^{(t)} \mathbf{S}]_{ij}), \quad i \neq j, \end{aligned}$$

Algorithm 1 ACCORD-FBS

Input: sample covariance $S \in \mathbb{R}^{p \times p}$, minimum step size 1/L, initial step size τ_0 , line search parameter $0 < \beta < 1$, initial $\Omega^{(0)}$ for t in $0, 1, 2, \cdots$ do for τ_t in $\tau_0, \beta \tau_0, \beta^2 \tau_0, \cdots$ do $\nabla g(\Omega^{(t)}) \leftarrow \Omega^{(t)} S$ \succ Use Algorithm 2 for HP-ACCORD Update $\Omega^{(t)}$ according to (3.5) $\Delta \leftarrow \Omega^{(t+1)} - \Omega^{(t)}$ end for if $g(\Omega^{(t+1)}) \leq g(\Omega^{(t)}) + \langle \Delta, g(\Omega^{(t)}) \rangle + \frac{1}{2\tau_t} \|\Delta\|_F^2$ or $\tau_t \leq 1/L$ end for until converge Output: estimate $\hat{\Omega} \leftarrow \Omega^{(t+1)}$

where $S_a(x) = (|x| - a)_+ \operatorname{sign}(x)$ is the soft-thresholding operator.

Theory of FBS ensures that with the choice of the step size $\tau_t \in (0, 2/L)$, where $L = \sigma_{\max}(\mathbf{S})$ is the maximum singular value of \mathbf{S} , the iterate sequence $\{\mathbf{\Omega}^{(t)}\}$ converges to the target $\hat{\mathbf{\Omega}}$ (Bauschke and Combettes, 2011). The L coincides with the global Lipschitz constant of $\nabla g(\mathbf{\Omega}) = \mathbf{\Omega}\mathbf{S}$ in the Euclidean (Frobenius) norm. Backtracking line search adaptively finds a maximal step size τ_t for each iteration t in such a way the convergence is guaranteed (Beck and Teboulle, 2009). Algorithm 1, named ACCORD-FBS, describes both fixed step size and backtracking FBS algorithms for ACCORD. The step size satisfies $\tau_t \ge \min\{\tau_0, \beta/L\}$ for $\beta \in (0, 1)$ and the descent property $f(\mathbf{\Omega}^{(t+1)}) \le f(\mathbf{\Omega}^{(t)})$ is guaranteed by the majorization-maximization (MM) principle (Lange et al., 2022).

While the general convergence rate of FBS is O(1/t) in the objective value unless the objective is strongly convex (which is not the case in ACCORD), we can nevertheless show that ACCORD-FBS converges linearly in both the objective and variable iterates.

THEOREM 3.2. Assume the condition for Theorem 3.1, and that the iterate sequence $\{\Omega^{(t)}\}$ is generated by Algorithm 1 with the step size sequence $\{\tau_t\}$ satisfying either i) $\beta = 1, \tau_0 \in [\underline{\tau}, \overline{\tau}]$, where $0 < \underline{\tau} \leq \overline{\tau} < 2/L$, or ii) $0 < \beta < 1$. Then, the objective value sequence $\{f(\Omega^{(t)})\}$ converges to the minimum $f^* = f(\hat{\Omega})$ monotonically. Furthermore, if the initial iterate $\Omega^{(0)}$ is chosen such that $f(\Omega^{(0)}) \leq \operatorname{tr}(S)/2 + \lambda p$, then the following holds

(3.6)

$$f(\Omega^{(t)}) - f^{\star} \leq \left(\frac{1}{1+2a\sigma}\right)^{t} [f(\Omega^{(0)}) - f^{\star}], \quad t \geq 0,$$
$$\|\Omega^{(t)} - \hat{\Omega}\|_{F} \leq \left(\frac{1}{\sqrt{1+2a\sigma}}\right)^{t-1} \left(1 + \frac{1}{a\sigma\sqrt{1+1/(2a\sigma)}}\right) \sqrt{[f(\Omega^{(0)}) - f^{\star}]/a}, \quad t \geq 1,$$

where $a = 1/\bar{\tau} - L/2 > 0$, $\sigma = [4\kappa(1/\underline{\tau} + L)^2]^{-1}$ in case *i*, and $a = [2\tau_0]^{-1}$, $\sigma = [4\kappa(1/\tau_{\min} + L)^2]^{-1}$, $\tau_{\min} = \min\{\tau_0, \beta/L\}$ in case *ii*. The constant κ is explicit and depends only on S.

Splitting (3.4) is crucial for establishing linear convergence in that the global Lipschitz constant $L < \infty$ of ∇g exists, and 1/L > 0 serves as the lower bound of the step size that guarantees the descent property. Following CONCORD-ISTA (Oh et al., 2014), we may also split f into $\tilde{g}(\Omega) = -\log \det \Omega_D + (1/2) \operatorname{tr}(\Omega^T \Omega S)$ and $\tilde{h}(\Omega) = \lambda \|\Omega\|_1$ and

Algorithm 2 One-dimensionally distributed matrix multiplication (1DMM)

Input: Partition $\Omega = [\Omega_1^T, \dots, \Omega_P^T]^T$, $S = [S_1, \dots, S_P]$, where node k holds Ω_k and S_k for $k = 1, \dots, P$ simultaneously do for j in $1 \dots, P$ do send Ω_k to node k - j and recv Ω_{k+j} from node k + jCompute $\Omega_{k+j}S_k$ end for $G_k \leftarrow [(\Omega_1S_k)^T, \dots, (\Omega_PS_k)^T]^T$ end for Output: $G = [G_1, \dots, G_P]$, where node k holds G_k

call it ACCORD-ISTA. The problem with this splitting is that $\nabla \tilde{g}$ is not globally Lipschitz. The consequence is that the resulting step sizes satisfying the descent condition can be arbitrarily small, contributing to slow convergence of the iterates; see §2 and §5.

3.3. HP-ACCORD: HPC implementation of ACCORD. For its simplicity and linear convergence rate, the ACCORD-FBS algorithm (Algorithm 1) has an advantage in scaling up to handle massive-scale data. Note that the main computational components of ACCORD-FBS are: 1) sparse-dense matrix multiplication in computing the gradient $\nabla g(\mathbf{\Omega}^{(t)}) = \mathbf{\Omega}^{(t)} \mathbf{S}$ and 2) element-wise operations in computing (3.5); note that $\mathbf{\Omega}^{(t)}$ is sparse by construction. The latter is "embarassingly parallel." The former can also be easily parallelized in shared memory systems such as those employing graphical processing units (GPUs). However, if the size of the data becomes massive so that it does not fit into the system memory, employment of a distributed memory system becomes necessary. In distributed computation, communication cost becomes a major factor of the performance.

Our distributed-memory HPC implementation of ACCORD-FBS, termed HP-ACCORD, iteratively conducts the sparse-dense matrix multiplication for the gradient step as a special case of the SpDM³ algorithm (Koanantakool et al., 2018). This algorithm, named one-dimensionally distributed matrix multiplication (1DMM), is summarized in Algorithm 2. In HP-ACCORD, Ω and S are separated by columns (row-wise separation is also possible for Ω) and store each partition in different computational nodes. Then, the gradient $\nabla q(\mathbf{\Omega})$ is computed with 1DMM. While the standard method for distributed matrix-matrix multiplication on HPC systems is the scalable universal matrix multiplication algorithm (SUMMA, van de Geijn and Watts, 1997), this method partitions involved matrices by both rows and columns and allocates them across computational nodes, and completing each block of the product requires multiple rounds of broadcasting submatrices of both operands, which results in a major performance bottleneck. On the other hand, 1DMM sends and receives one-dimensional blocks of only one operand, i.e., Ω in Algorithm 2. Because of this difference, the communication cost of Algorithm 2 is smaller than SUMMA since Ω is sparse while S is dense (Koanantakool et al., 2016). Computation of the gradient can alternatively be conducted in two steps: $\boldsymbol{Y} = \boldsymbol{\Omega} \boldsymbol{X}^T$ and $\nabla q(\boldsymbol{\Omega}) = (1/n) \boldsymbol{Y} \boldsymbol{X}$, each of which can be computed with 1DMM. This strategy is advantageous when n is much smaller than p (Koanantakool et al., 2018).

3.4. Tuning. The choice of the regularization parameter λ impacts the practical performance of the ACCORD estimator. At the omics scale, sample reuse methods such as cross validation or neighborhood selection (Meinshausen and Bühlmann, 2010) are ruled out since they incur a nontrivial number of expensive passes of computing the

estimator. Following CONCORD and SPACE, which are also pseudolikelihood-based methods, we adopt a Bayesian information criterion (BIC)-type approach for tuning. Specifically, using the loss function part of (3.2), we choose λ minimizing

(3.7)
$$(2n)\left\{-\log\det\hat{\boldsymbol{\Omega}}_D + (1/2)\mathrm{tr}(\hat{\boldsymbol{\Omega}}^T\hat{\boldsymbol{\Omega}}\boldsymbol{S})\right\} + \|\hat{\boldsymbol{\Omega}}\|_0\log n + 4\gamma\|\hat{\boldsymbol{\Omega}}\|_0\log p,$$

where $\|\hat{\Omega}\|_0$ is the number of nonzero off-diagonal elements of the estimate $\hat{\Omega} = \hat{\Omega}(\lambda)$. The last term is taken from the extended BIC for graphical lasso (Foygel and Drton, 2010), proposed to promote further sparsity; $\gamma \in (0, 1]$ is a user-specified parameter. We may call quantity (3.7) an extended pseudo-BIC (epBIC).

3.5. Bias correction. Correcting the biases introduced by the ℓ_1 penalization by refitting is a common practice (Meinshausen, 2007; Candes and Tao, 2007; Cai, Liu and Luo, 2011). Following these approaches, we propose the following second-stage refitting procedure for ACCORD. If we let the support of the ACCORD estimate $\hat{\Omega}$ computed by solving (3.2) for an appropriate λ (e.g., epBIC of (3.7)) be \hat{S}_{λ} , then we refit by computing

(3.8)
$$\tilde{\boldsymbol{\Omega}} = \operatorname*{arg\,min}_{\boldsymbol{\Omega}:\,\boldsymbol{\Omega}_{S_{\boldsymbol{\lambda}}^{c}}=0} \left\{ -\log\det\boldsymbol{\Omega}_{D} + (1/2)\mathrm{tr}(\boldsymbol{\Omega}^{T}\boldsymbol{\Omega}\boldsymbol{S}) + \phi\boldsymbol{\lambda}\|\boldsymbol{\Omega}\|_{1} \right\}$$

where $0 \leq \phi \leq 1$. The refitted estimator $\tilde{\Omega} = (\tilde{\omega}_{ij})$ can be computed efficiently using Algorithm 1, by replacing the λ with $\phi \lambda$ for $(i, j) \in \hat{S}_{\lambda}$ and with ∞ for $(i, j) \notin \hat{S}_{\lambda}$.

4. Statistical Properties. In this section, we show that the ACCORD estimator can consistently estimate Ω^* , a one-to-one reparameterization of the true precision matrix Θ^* in various measures, under appropriate conditions. All the results provided here are non-asymptotic. In addition to the vector ℓ_1 and ℓ_{∞} norms introduced in §1, we use $|||\boldsymbol{M}|||$ to denote an operator norm of matrix $\boldsymbol{M} = (m_{ij})$ induced by the underlying vector norm. In particular, $|||\boldsymbol{M}|||_{\infty} = \max_{\boldsymbol{x}\neq 0} \frac{||\boldsymbol{M}\boldsymbol{x}||_{\infty}}{||\boldsymbol{x}||_{\infty}} = \max_i \sum_{j=1}^p |m_{ij}|$. The Frobenius norm $||\boldsymbol{M}||_F$ of \boldsymbol{M} is its vector ℓ_2 norm. For an $l \times m$ matrix $\boldsymbol{M}, A \subset [l] := \{1, \ldots, l\}$, and $B \subset [m]$, we denote by \boldsymbol{M}_{AB} the $|A| \times |B|$ submatrix of \boldsymbol{M} taking the rows and columns of \boldsymbol{M} with indices in A and B, respectively.

4.1. Estimation error bounds. We first provide finite-sample estimation error bounds in vector ℓ_1 and ℓ_2 norms. Recall that a zero-mean random vector Z is sub-Gaussian with parameter σ if $\mathbb{E}[\exp(tZ)] \leq \exp(\sigma^2 t^2/2)$ for all $t \in \mathbb{R}$. Let $\kappa_{\Omega^*} = |||\Omega^*|||_{\infty}$.

THEOREM 4.1. Suppose the data matrix $\mathbf{X} \in \mathbb{R}^{n \times p}$ is composed of n i.i.d. copies of zero-mean continuous random vector $X = (X_1, \ldots, X_p) \in \mathbb{R}^p$ with covariance matrix $\mathbf{\Sigma}^* = (\Sigma_{ij}^*) = \mathbf{\Theta}^{*-1}$ and each $X_j / \sqrt{\Sigma_{jj}^*}$ being sub-Gaussian with parameter σ . Also suppose that there exists $\alpha, \beta, \eta > 0$ such that $\mathbf{E}_X |\langle X, y \rangle|^2 \ge \alpha$ and $\mathbf{E}_X |\langle X, y \rangle|^{2+\eta} \le \beta^{2+\eta}$ for any $y \in \mathbb{R}^p$ with $||y||_2 = 1$. If we let $S = \{(i, j) \in [p] \times [p] : \theta_{ij}^* \ne 0\}$ be the support of $\mathbf{\Theta}^*$ (hence of $\mathbf{\Omega}^*$), then there exist positive constants κ, c_0, c_1 , and c_2 that explicitly depends on $\alpha, \beta, \eta, \sigma$, and $\max_{i \in [p]} \Sigma_{ii}^*$ such that $\lambda = 64(1 + 4\sigma^2)\kappa_{\Omega^*}(\max_{i \in [p]} \Sigma_{ii}^*)\sqrt{n^{-1}\log p}$ in (3.2) yields

 $\|\hat{\boldsymbol{\Omega}} - \boldsymbol{\Omega}^*\|_1 \leq 16\kappa^{-1}\lambda|S| \text{ and } \|\hat{\boldsymbol{\Omega}} - \boldsymbol{\Omega}^*\|_F \leq 4\kappa^{-1}\lambda\sqrt{|S|}$

with a probability at least $1 - c_1 e^{-c_2 n} - 4p^{-2}$, provided that $n > \max\{(64c_0^2/\kappa^2)|S|\log p, (1/16)\log p\}$.

REMARK 4.1. The consistency of $\hat{\Omega}$ in terms of $\|\cdot\|_1$ and $\|\cdot\|_F$ is obtained if σ^2 and κ_{Ω^*} are bounded, at the rate of $O_P(\sqrt{n^{-1}|S|\log p})$. The latter is bounded if, e.g., the graph implied by Θ^* has a finite maximum degree of $d = \max_{i \in [p]} |\{j \in [p] : \theta_{ij}^* \neq 0\}|$: since $|\theta_{ij}^*| \leq \sqrt{\theta_{ii}^* \theta_{jj}^*}$, $\kappa_{\Omega^*} = \max_{i \in [p]} \sum_{j=1}^p |\theta_{ij}^*| / \sqrt{\theta_{ii}^*} \leq d \max_{i \in [p]} \sqrt{\theta_{ii}^*} \leq d/\sqrt{\lambda_{\min}(\Sigma^*)}$, where $\lambda_{\min}(\Sigma^*) \geq \alpha$ is the minimum eigenvalue of Σ^* . This rate and the sample complexity of $n \geq |S| \log p$ match those for the graphical lasso (Wainwright, 2019, Proposition 11.9).

4.2. Edge selection and sign consistency. With further assumptions, the elementwise (ℓ_{∞}) error bound of $\hat{\Omega}$ can be controlled with which edge selection and sign consistency can be proved. The Hessian matrix of the population risk $R(\Omega)$ (see §3) with respect to the usual vectorization of Ω at Ω^* is

(4.1)
$$\Gamma^* = \Sigma^* \otimes \boldsymbol{I}_p + (\boldsymbol{\Omega}_D^{*-1} \otimes \boldsymbol{\Omega}_D^{*-1}) \boldsymbol{\Upsilon}_p$$

where \otimes is a Kronecker product and $\Upsilon = \sum_{i=1}^{p} e_i e_i^T \otimes e_i e_i^T$. It is positive definite since so is Σ^* . Let S be the support of Θ^* as stated in Theorem 4.1.

ASSUMPTION 4.1. We further assume the following properties on the data distribution.

- (A1) The maximum degree $d = \max_{i \in [p]} |\{j \in [p] : \theta_{ij}^* \neq 0\}| = \max_{i \in [p]} |\{j \in [p] | \omega_{ij}^* \neq 0\}|$ of the graph implied by Θ^* is bounded.
- (A2) (Irrepresentability condition) For some $\alpha \in [0, 1)$, the matrix Γ^* satisfies

(4.2)
$$\||\boldsymbol{\Gamma}_{S^c S}^* \boldsymbol{\Gamma}_{SS}^{*-1}|||_{\infty} \leq 1 - \alpha$$

Let us define the following associated quantities: $\kappa_{\Gamma^*} = \| (\Gamma^*_{SS})^{-1} \|_{\infty}, \kappa_{\Sigma^*} = \| \Sigma^* \|_{\infty}, \gamma_1 = \| \Omega^{*-1}_D \|_{\infty}.$ Recall $\kappa_{\Omega^*} = \| \Omega^* \|_{\infty}.$

THEOREM 4.2. Suppose the data matrix $\mathbf{X} \in \mathbb{R}^{n \times p}$ is composed of n i.i.d. copies of zero-mean continuous random vector $X = (X_1, \ldots, X_p) \in \mathbb{R}^p$ with covariance matrix $\mathbf{\Sigma}^* = (\Sigma_{ij}^*) = \mathbf{\Theta}^{*-1}$ and each $X_j / \sqrt{\Sigma_{jj}^*}$ being sub-Gaussian with parameter σ . If further Assumption 4.1 holds, then for $\lambda = 80\sqrt{2}(1+4\sigma^2)(\max_{i \in [p]} \Sigma_{ii}^*)\kappa_{\Omega^*}\alpha^{-1}\sqrt{(\tau \log p + \log 4)/n}, \tau > 2$,

- (a) there holds $\|\hat{\boldsymbol{\Omega}} \boldsymbol{\Omega}^*\|_{\infty} \leq 24\sqrt{2}(1+4\sigma^2)(\max_{i\in[p]}\sum_{i=1}^{*})\kappa_{\Gamma^*}\kappa_{\Omega^*}(1+10/\alpha)\sqrt{(\tau\log p + \log 4)/n};$
- (b) the estimated support $\hat{S} = \{(i, j) \in [p] \times [p] : \hat{\omega}_{ij} \neq 0\}$ is contained in the true support S and includes all edges (i, j) with $|\omega_{ij}^*| > 24\sqrt{2}(1 + 4\sigma^2)(\max_{i \in [p]} \Sigma_{ii}^*)\kappa_{\Gamma^*}\kappa_{\Omega^*}(1 + 10/\alpha)\sqrt{(\tau \log p + \log 4)/n}$,

with a probability no smaller than $1 - p^{-(\tau-2)}$, provided $n > 128(1 + \sigma^2)^2 (\max_{i \in [p]} \sum_{ii}^*)^2 \delta^{-2}(\tau \log p + \log 4)$ where

$$\delta = \min\left\{\frac{\min\left\{\frac{1}{3\gamma_1}, \frac{1}{3\gamma_1^3\kappa_{\Gamma^*}}, \frac{\kappa_{\Omega^*}}{3d}\right\}}{3\kappa_{\Gamma^*}\kappa_{\Omega^*}\left(1+10/\alpha\right)}, \frac{2}{27\gamma_1^3\kappa_{\Gamma^*}^2\kappa_{\Omega^*}\left(1+10/\alpha\right)^2}, 8(1+4\sigma^2)(\max_{i\in[p]}\Sigma_{ii}^*)\right\}.$$

REMARK 4.2. With other quantities held fixed, the sample size required to achieve the rate $\|\hat{\Omega} - \Omega^*\|_{\infty} = O_P(\sqrt{(\tau \log p)/n})$ is $n \gtrsim d^2 \tau \log p$. It can be also shown that for data distributions with a bounded 4*m*-th moment, the error rate is $O_P(\sqrt{p^{\tau/m}/n})$ for $n \gtrsim d^2 p^{\tau/m}$; see Supplementary Material A.6. These sample complexities and rates of convergence match those of graphical lasso, obtained by Ravikumar et al. (2011) under similar conditions. Part (b) of Theorem 4.2 only states that the ACCORD estimator can exclude all false edges and find true edges with large enough ω_{ij}^* 's. Exploiting it further, the sign consistency on all edges can be declared. For $\hat{S} = S$, let $\omega_{\min} = \min_{(i,j) \in S} |\omega_{ij}^*|$:

THEOREM 4.3. Assume the same conditions as Theorem 4.2. If the sample size satisfies

$$n > 128(1+4\sigma^2)^2 (\max_{i \in [p]} \Sigma_{ii}^*)^2 (\tau \log p + \log 4) / \min\{\omega_{\min} / [6\kappa_{\Gamma^*} \kappa_{\Omega^*} (1+10/\alpha)], \delta\}^2$$

where σ and δ are as defined in Theorem 4.2, then the event {sign (ω_{ij}^*) = sign $(\hat{\omega}_{ij})$ for all $(i, j) \in S$ } occurs with a probability no smaller than $1 - p^{-(\tau-2)}$.

5. Numerical Experiments.

5.1. Linear convergence of ACCORD-FBS. We provide empirical evidences of the guaranteed descent property and linear convergence exhibited by ACCORD-FBS (Algorithm 1). The merit of the novel operator splitting utilized by the latter is demonstrated by comparing it with ACCORD-ISTA (see the last paragraph of §3.2). Firstly, we generated two Erdos-Renyi graphs of size p = 1000 with a sparsity level of 15%. To construct a ground truth precision matrix, we employed the following procedure. The edge weights were selected from a uniform distribution on [0.5, 1] and their signs were flipped with a probability of 0.5. To ensure symmetry and positive definiteness, the resulting matrix was added to its transpose and its diagonal entries are set to be 1.5 times the absolute sum of the off-diagonal entries of the corresponding rows. This matrix was scaled by pre- and post-multiplying a diagonal matrix such that all the diagonal entries are equal to one. Finally, variation among the diagonal entries was introduced by performing another pre- and post-multiplications with a diagonal matrix with uniformly distributed entries on $[1, \sqrt{3}]$. Using this precision matrix, multivariate Gaussian data with a sample size of n = 500 were generated.

ACCORD-FBS was investigated with two variants: one with a constant step size of $\tau = 1/L$ and the other employing backtracking line search with $\tau = 1/L$ as a lower bound. In contrast, a grid of constant step sizes, $\tau \in \{0.25, 0.6, 0.75\}$, along with backtracking, were chosen for ACCORD-ISTA to demonstrate its convergence behavior.

The convergence behavior of the iterate $\{\Omega^{(t)}\}\$ and the objective value $\{\ell(\Omega^{(t)})\}\$ is illustrated in Figure 1. Here, $\hat{\Omega}$ denotes the final iterate obtained by executing ACCORD-FBS until termination, with the criterion of $\|\Omega^{(t+1)} - \Omega^{(t)}\| < 10^{-15}$. In Figure 1, ACCORD-FBS exhibits linear convergence for both variants, while backtracking shows a faster rate. On the other hand, the convergence behavior of ACCORD-ISTA varies significantly across different constant step sizes, ranging from slow convergence to divergence. Moreover, the iterates from ACCORD-ISTA with backtracking encounters a plateau at an early stage. These observations underscore the challenges associated with the selection of an appropriate step size in ACCORD-ISTA.

5.2. Scalability of HP-ACCORD. We next investigate the scalability of HP-ACCORD (§3.3) using simulated data of dimension p up to one million. At this scale, even simulating multivariate Gaussian samples becomes a nontrivial task (Vono, Dobigeon and Chainais, 2022). We took a similar approach to the numerical experiments in Li et al. (2010): generate a sparse $p \times p$ unit lower triangular matrix \boldsymbol{L} taking values in [-1,1] and compute $\boldsymbol{y} = \boldsymbol{L}^{-T} \boldsymbol{x}, \, \boldsymbol{x} \sim N(\boldsymbol{0}, \boldsymbol{I}_p)$, by backsubstitution so that \boldsymbol{y} follows

Fig 1: Convergence comparison between ACCORD-FBS and ACCORD-ISTA.

 $N(0, (\boldsymbol{L}\boldsymbol{L}^T)^{-1})$. The location of off-diagonal non-zero entries of \boldsymbol{L} were uniformly selected so that the graph implied by the precision matrix $\boldsymbol{L}\boldsymbol{L}^T$ had an average degree of 10.3 for each p, and the maximum degree ranged from 42 to 66.

We employed the Nurion supercomputer at the Korea Institute of Science and Technology Information (KISTI) National Supercomputing Center (KSC) for the scalability experiment. Nurion is a Cray CS500 system with 8,305 Intel Xeon Phi 7250 1.4GHz manycore (KNL) computational nodes with 96GB of memory per node, featuring 25.3 petaflops of peak performance. As a benchmark, we compared HP-ACCORD with BigQUIC.² and fastclime.³ Note that fastclime is an R package with a single-core-oriented implementation of CLIME in C at its heart. Both BigQUIC and HP-ACCORD perform multi-core computations written in C++. However, BigQUIC's scalability is limited to a single node as a shared-memory algorithm. In contrast, HP-ACCORD can run on multiple nodes simultaneously utilizing distributed memory in supercomputing environments (§3.3).

We report the results in Figure 2. Since the memory of a single KNL node (96GB) was not enough for the computation with dimensions greater than or equal to 100,000. an appropriate number of nodes that can handle the input size data was used for HP-ACCORD, showcasing the scalability of the algorithm. The supercomputing center imposed a 48-hour restriction on the running time of a single job. Thus we only report accurate timing for the processes finished within this limit. In panel (a), the regularization parameter λ was set large enough so that the resulting precision matrix estimate $\hat{\Theta}$ becomes diagonal. In panel (b), λ was adjusted so that the numbers of nonzero entries of $\hat{\Theta}$ have a similar scale to their true precision matrices. Note that fastclime had to use the time near the limit to estimate a precision matrix to compute estimate for two λ 's for p = 10,000, and it could not run with data that has p = 30,000 and above due to the memory limit. Also, for the both panel, we could observe that HP-ACCORD outperforms BigQUIC in terms of computation time, even when only a single node is employed. By adopting multiple computational nodes, HP-ACCORD was able to deliver the estimate within the time budget in all scenarios. On the contrary, BigQUIC could not finish the process on time when the dimension exceeds 100,000 and the λ is chosen so that the estimate is non-diagonal. Internally, BigQUIC tries to find a permuted partition $\{B_1, \dots, B_k\}$ of the p coordinates using a graph clustering algorithm

²Available at https://bigdata.oden.utexas.edu/software/1035/.

³Available at https://cran.r-project.org/src/contrib/Archive/fastclime/.

Fig 2: Scalability comparison between HP-ACCORD and other methods. The horizontal red lines indicate the 48-hour limit of the supercomputer system.

(Karypis and Kumar, 1998; Dhillon, Guan and Kulis, 2007) so that most of the coordinate updates are performed in the diagonal blocks $(B_1, B_1), \dots, (B_k, B_k)$. However, the size of each partition is limited due to the memory limit of a single computational node (about 20,000 in the Nurion environment in which each node has 96GB of memory), and clustering with such a limited block size bares many off-block diagonal edges in our simulated data. In consequence, the conjugate gradient method employed to compute the off-diagonal blocks are hardly skipped, causing the algorithm to run extremely slowly. Even when λ is so large that the estimate should be diagonal, BigQUIC failed to complete the computation if the dimension reached one million.

5.3. Edge detection and estimation error. We examine the edge detection and parameter estimation performance of ACCORD on simulated data, comparing it with CONCORD, graphical lasso (GLASSO), SPACE, CLIME. Following the hub graph setting in Peng et al. (2009), we generated a graph with 10 clusters each having 100 nodes and 90 edges and connected 100 randomly chosen node pairs from adjacent clusters. The clusters had either a hub network or scale-free graph structure. A hub network was generated by (1) constructing an Erdös-Rényi graph with 97 nodes and 45 edges, and (2) consecutively adding 3 hub nodes, each connected to random 15 nodes. A scale-free graph was generated so that the degree k of the nodes has a probability $P(k) \sim k^{-2.3}$. We additionally considered a simple Erdös-Rényi graph with 1,000 nodes and 1,000 edges without the clustered structure. The partial correlation matrix corresponding to the graph was chosen so that the matrix has minimum eigenvalue of at least 0.2, and each nonzero entries have absolute value of 0.1 at least. Model selection was carried out using epBIC (3.7) for ACCORD and CONCORD for an evenly spaced grid of λ 's in logarithmic scale, while extended Gaussian BIC was used for GLASSO and CLIME. Although cross validation was used to select the λ in the original paper of CLIME (Cai. Liu and Luo, 2011), we used BIC instead to avoid the repetitive parameter fitting. For SPACE, we used "BIC-type criterion" defined in Peng et al. (2009). For CONCORD, the matrix $\hat{\Theta}$ minimizing (2.2) was treated as a precision matrix despite the possible inconsistency (see §2). This procedure was repeated 50 times. For ACCORD, we also considered debiasing procedure (3.8).

Graph	Method	AUPRC	# TP edges	# FP edges	
Hub Network	ACCORD	0.843 (0.011)	732(18.6)	55(17.0)	
	CONCORD	0.837(0.011)	715(18.1)	50(16.5)	
	GLASSO	0.835(0.010)	706(20.5)	63(11.3)	
	SPACE	0.813(0.011)	768(13.8)	321 (33.0)	
	CLIME	0.835(0.010)	734 (13.8)	64(17.5)	
Scale-free	ACCORD	0.882 (0.008)	810 (13.9)	77 (18.7)	
	CONCORD	0.882 (0.008)	797(17.4)	67(16.2)	
	GLASSO	0.874(0.008)	808(14.4)	110(16.9)	
	SPACE	0.864(0.008)	831(13.8)	321 (33.0)	
	CLIME	0.879 (0.009)	813 (15.8)	85 (22.4)	
Erdös-Rényi	ACCORD	0.884 (0.009)	811 (14.5)	74(16.9)	
	CONCORD	0.885 (0.008)	802(14.7)	70(14.5)	
	GLASSO	0.874(0.009)	809(16.0)	114(12.7)	
	SPACE	0.868(0.009)	836(10.9)	369(28.3)	
	CLIME	0.882(0.009)	817(13.5)	88 (19.3)	
TABLE 1					

Edge detection performance, mean (standard deviation) over 50 replications.

Table 1 reports the area under the precision-recall curve (AUPRC) and number of edges selected. In terms of AUPRC (and Matthews correlation coefficient; see Supplementary Material B), ACCORD performed slightly better than or similarly to other methods. The trend of the precision-recall curves did not particularly vary among replications. In all cases, the penalty selected from each selection method yielded reasonable number of selected edges. We could observe that BIC-type methods with the extended term drastically reduces false positive (FP) edges in the expense of few true positive (TP) edges.

Table 2 reports the total squared error of the estimated precision matrix Θ and its reparameterization Ω by ACCORD and CONCORD, along with their debiased refit. Compared to CONCORD, ACCORD estimates clearly showed better result for both $\hat{\Theta}$ and $\hat{\Omega}$ in terms of the estimate error. The debiased refit also clearly improves the estimating performance. For more details about the impact of the debiased refit, see Supplementary Material B.

6. Case Study: Integrative Analysis of Multi-Omics data in Liver Cancer.

6.1. HP-ACCORD to delineate complex mechanisms in gene expression regulation. In this section, we show that HP-ACCORD enables complex biological inference using ultrahigh-dimensional multi-omic data through the example of the LIver Hepatocellular Carcinoma (LIHC) cohort (n=365) of TCGA. In this analysis, we aim to identify the determinants of mRNA-level expression regulation of individual genes across the tumor samples and compare the strength of different regulatory drivers, particularly between the activity of transcription factors (TF) and the repressive potential of epigenomic regulators using partial correlations as the metric of independent contribution. Since the partial correlation between the mRNA expression level of a gene and the level of each regulatory factor given all other data features deconvolutes the strength of each source of direct regulation, this analysis, if computation is scalable to the entirety of the multi-omic data, will dissect relative contributions of individual regulatory mechanisms to the observed gene expression variation, and the causal graph mirroring the regulatory network is expected to be embedded within the reported (undirected) graph structure.

Estimation		Graph	Total Squared Error $(\hat{\Theta})$	Total Squared Error $(\hat{\boldsymbol{\Omega}})$
ACCORD	Biased	Hub Network Scale-free Erdös-Rényi	$194.6 (10.7) \\ 202.6 (8.5) \\ 201.0 (8.1)$	$\begin{array}{c} 73.7 \ (3.3) \\ 68.1 \ (2.2) \\ 69.7 \ (2.1) \end{array}$
	Debiased	Hub Network Scale-free Erdös-Rényi	37.7 (1.4) 36.2 (2.2) 35.4 (1.6)	19.7 (0.6) 16.5 (1.0) 16.3 (0.8)
CONCORD	Biased	Hub Network Scale-free Erdös-Rényi	$\begin{array}{c} 392.3 \ (18.0) \\ 433.6 \ (21.5) \\ 437.5 \ (19.7) \end{array}$	$108.0 (3.7) \\ 107.9 (3.8) \\ 110.8 (3.0)$
	Debiased	Hub Network Scale-free Erdös-Rényi	206.6 (11.0) 226.6 (13.9) 231.0 (13.5)	$\begin{array}{c} 44.2 \ (1.4) \\ 43.6 \ (1.8) \\ 44.8 \ (1.8) \end{array}$

Table 2

MSE of biased and debiased ACCORD and CONCORD in partial correlation, mean (standard deviation) over 50 replications.

We used the LIHC dataset consisting of expression data of 15,598 protein-coding genes (mRNAs), expression data of 364 microRNAs (miRNAs) and DNA methylation levels (β -values) at 269,396 CpG islands positioned in the upstream regulatory regions of genes. These are a subset of variables provided in the original data from the TCGA data portal (Ally et al., 2017), where only the DNA methylation probes in regulatory regions or gene bodies of annotated genes were included. Since DNA hypoand hyper-methylation status tends to be correlated locally in genomic neighborhoods and those probesets for methylation status make up a majority of the variables in the data, the underlying graph is expected to reflect a sparse precision matrix with a large number of small block diagonals if the variables were ordered by chromosomes and by within-chromosomal genomic coordinates. Most causally implicated correlations between methylation probes and mRNAs are also likely to be local with the exception of DNA methyltransferase genes and the likes, and they would not alter the presumed network topology described above. The same logic also applies to mRNA-mRNA correlations, but these correlations can be local and global across genomic locations. However, these latter correlations tend to form block diagonal patterns by their upstream TF regulators and the target precision matrix will still remain within a structure amenable to consistent estimation.

We performed this analysis on two HPC systems: Nurion at KSC (see §5.2) and the Cori system at the National Energy Research Scientific Computing Center (NERSC), which is a Cray XC40 system with more than 2,000 computational nodes that are equipped with dual-socket 16-core Intel Xeon Processor E5-2698 (Haswell) and 128GB of memory for each node. On both systems, the shared-memory, multi-core implementation of BigQUIC was the only working alternative for comparison. However, BigQUIC was not able to complete the computation of the precision matrix for a wide range of the regularization parameter λ , except for those that yielded diagonal matrices; this observation is consistent with the results from the numerical studies in §5.2.

In the next two sections, we first describe the overall partial correlation patterns within and across the two omics data. Using the precision matrix estimate and partial correlations, we aim to tease apart the impact of active TF-driven co-regulation of target genes from that of DNA methylation-mediated gene expression repression in the promoter regions. To show the advantage of this analysis, we compare the mRNAmRNA network from the two analyses, and show that the analysis accounting for the

Fig 3: Summary of intra-modality and inter-modality correlations. (A) Barplots show the total number of edges with non-zero correlations in each of the six edge categories. (B) Estimated partial correlations against genomic distances between connected nodes. Gray dots represent all edges and they are shown in panels. Black dots show the data pertaining to the edge category in each panel. (C) Gene ontology terms enriched in the nodes (genes) with positive and negative methylation-mRNA partial correlations.

methylation-mediated regulation recovers experimentally validated regulatory actions of TFs with comparable sensitivity and better specificity. To the best of our knowledge, the effort to deconvolute the effects of two or more types of gene expression regulation using graphical models has not been attempted due to the computational bottleneck we address in this work.

6.2. Network structure of epigenomics and transcriptomics data. We estimated partial correlations by solving (3.2) at $\lambda = 0.45$ selected by epBIC (3.7) and then applying the debiasing procedure (3.8). We extracted non-zero partial correlations to form edges and calculated the frequency of intra-modality and inter-modality pairs. Figure 3A shows the frequency of each type of inter- and intra-modality edges, with separate positive and negative edge counts.

Since the DNA methylation probes outnumbered both mRNA- and miRNA-level expression variables in the input data, the majority of the selected edges were the intra-modality correlations between methylation probes (>99%), which showed predominantly positive partial correlations (98%) even at long genomic distances. The second most frequent edges were between mRNAs and between miRNAs, where the vast majority showed positive partial correlations (96%), and the correlations were close to zero for the pairs associated with negative partial correlations. This observation clearly reaffirms that physically proximal protein coding genes and non-coding RNAs are often co-transcribed. Among the small number of non-zero inter-modality correlations, the most pronounced category was that of edges between DNA methylation probes and mRNA expression (total transcript level per gene); the signs of the partial correlations were evenly split between positive and negative (Figure 3A).

When we further examined the genomic distances between connected nodes across the six categories, positive inter-modality correlations were from the data features located on the same chromosomes and within 200 kilobase distance of one another (Figure 3B). The edges connecting mRNAs and miRNAs showed exclusively positive partial correlations within a 100 kilobase distance only, hinting at high local specificity of cotranscription. Last but not least, the edges connecting mRNAs and DNA methylation probes showed both positive and negative partial correlations. A closer examination revealed that most large negative partial correlations were between mRNAs and DNA methylation probes within a 1 kbp distance (from TSS), consistent with the established role of methylation for gene expression repression in regulatory regions.

When we further investigated biological functions enriched in the genes with negative correlation between DNA methylation and mRNA expression, those were mostly the genes encoding subunits of enzymes involved in small molecule metabolism and redox reaction regulation (Figure 3C), suggesting that epigenomic regulation actively corepresses the expression levels of metabolic enzymes in liver tumors.

6.3. Dissecting active regulatory contribution of TFs and repressive epigenomic regulation. Upon understanding the overall structure of the graph, we investigated the regulatory impact of DNA methylation on the expression levels of adjacent genes and dissected the regulatory contribution of TFs on their target gene expression and the repressive effects of hypermethylation in regulatory regions. To this end, we estimated another graph of mRNA expression variables using only the mRNA expression data as input, thereby establishing a reference network which does not exclude the impact of epigenomic regulation. We then compared the resulting mRNA-mRNA network against the one estimated earlier. For the comparison, we removed edges with absolute partial correlation smaller than 0.02 in the network visualization, an arbitrary threshold determined from the histogram of non-zero partial correlation estimates, to minimize the impact of false positive edges as mentioned in $\S5$.

The new mRNA-mRNA network contained 104,599 edges at $\lambda = 0.30$ based on ep-BIC. We observed that the graph estimated without the DNA methylation data, called unadjusted network hereafter, contained 84.5% of the edges from the graph estimated with the DNA methylation data, called adjusted network (Figure 4A). In those edges appearing in both networks, the magnitude of partial correlation estimates in the unadjusted network between mRNA pairs was greater than the one in the adjusted network, as expected (Figure 4B). Overall, the data clearly show that a significant portion of

Fig 4: (A) Comparison of the two partial correlation networks of mRNA expression data estimated with and without miRNA and DNA methylation data. (B) Comparison of partial correlation estimates for 110,787 edges appearing in the two mRNA-mRNA networks. (C) The network estimated with DNA methylation data. The able on the right side shows the biological processes and TFs enriched in each area.

the conditional dependence relationship between two mRNA nodes can be explained away by DNA methylation levels, highlighting the contribution of epigenomic elements in the co-expression patterns.

Since the impact of methylation-driven co-repression of mRNA expression was accounted for, the adjusted network data allows us to infer active co-regulation driven by TFs and co-activators without potential confounding by epignomic regulation. We thus visualized the adjusted network using the Cytoscape software (Shannon et al., 2003) and selected six subnetworks of high connectivity (Figure 4C). We performed hypergeometric probability-based tests for enrichment of biological functions and TFs potentially implicated in each subnetwork of genes. Indeed, the subnetworks showed highly specific enrichment of widely-known cancer associated biological processes, ranging from the extracellular matrix remodeling in the parenchymal environment, immune response and signal transduction, cell cycle and protein translation, and small molecular metabolism with previously well characterized TFs in various cellular processes.

By contrast, the unadjusted network showed a higher degree of connectivity between the nodes (visualization not shown due to lack of legibility) and the overall network lacked clear separation of subnetworks. Interestingly, the network had a large number of nodes with one or two edges connecting to others only. To investigate the quality of the two networks in terms of the recovery of well-validated TF-target relationships, we queried the selected mRNA-mRNA edges in the two networks against *bona fide* TF-target regulatory network compiled from credible sources (Koh et al., 2019). Upon mapping the two mRNA-mRNA networks, 32% and 30% of the edges involved genes encoding a TF or a co-activator in the adjusted and unadjusted networks, respectively. However, while 19% of the reported edges were experimentally validated TF-target pairs in the adjusted network, only 9% of the edges were validated in the unadjusted network. Given the unadjusted network is about 2.6 times larger than the adjusted network, the result implies that the adjusted network recovers the known TF-target regulatory relationships with comparable sensitivity and greater specificity.

In summary, the assessment clearly shows that the network derived from the ultrahigh-dimensional dual-omic data represents more robust relational hypotheses than the network derived from the transcriptomic data alone. With the capability to estimate conditional dependence structure from ultrahigh-dimensional data, spurious associations can be screened out and the results enables subsequent inference of regulatory relationships, which would have been otherwise impossible.

7. Discussion. In discovery-oriented clinical and basic research applications, technological advances in molecular modalities have steadily increased the number of variables to analyze. Typical dimensionality of data sets exceeds tens or hundreds of thousands, as shown in the motivating dual-omic dataset. The latest technological advances also push sample sizes to thousands, best evidenced by the number of cells analyzed using single-cell resolution omics technologies. When making inference from these truly big data, striking a balance between statistical performance and computational scalability is therefore essential.

The analysis in §6 is a testament to this trade-off. Although the validity of individual edges should be confirmed by experimental means, we verified that the mRNA co-expression network estimated from the ultrahigh-dimensional dual-omic data was largely nested within the network obtained from mRNA expression variables alone, not deviating to a completely distinct result. Moreover, the former network excluding the epigenomic regulation allowed us to recover *bona fide* TF-target relationships validated in human cells with greater specificity and without loss of sensitivity.

The analysis of dual-omic data presented in this paper would have been impossible without the scalable computation for estimating the underlying graphical model. In an era with new omics modalities added to the multi-omic repertoire and declining cost to produce such data, graphical model estimation in ultrahigh dimensional space will be in increasing demand and computational scalability will thus be as essential as ever. We believe HP-ACCORD paves the way to meeting the demand for graphical model estimation in the modern multi-omic studies and encourages development of related statistical frameworks having scalability in their backbone.

SUPPLEMENTARY MATERIAL

APPENDIX A: PROOFS

A.1. Proof of Theorem 3.1. Recall that $X \in \mathbb{R}^{n \times p}$ $(p \ge n)$ has columns in general position if the affine span of any n points $\{\sigma_1 X_{i_1}, \dots, \sigma_n X_{i_n}\}$, for arbitrary signs $\sigma_1, \dots, \sigma_n \in \{-1, 1\}$, does not contain any element of $\{\pm X_i : i \ne i_1, \dots, i_n\}$, where X_i is the *i*-th column of X.

The objective function of the ACCORD estimation problem (3.2) can be expressed as

(A.1)
$$\tilde{f}(\tilde{\boldsymbol{X}}\operatorname{vec}(\boldsymbol{\Omega}^T)) := \sum_{i=1}^p \{ \tilde{g}(\tilde{\boldsymbol{X}}^i \boldsymbol{\Omega}_i^T) + \lambda \| \boldsymbol{\Omega}_i^T \|_1 \},$$

where Ω_i^T is *i*-th column of Ω^T , $\tilde{\boldsymbol{X}}^i := [e_i, \boldsymbol{X}^T]^T$, $\tilde{g}([a, b^T]^T) := -\log(a) + \frac{1}{2n} \|b\|_2^2$, and $\tilde{\boldsymbol{X}} = \operatorname{diag}(\tilde{\boldsymbol{X}}^1, \cdots, \tilde{\boldsymbol{X}}^p)$. Here, we see that \tilde{g} is strictly convex on its natural domain.

LEMMA A.1. For any $S = \frac{1}{n} X^T X$ and $\lambda \ge 0$, solutions to problem (3.2) have the following properties:

- 1. there is either a unique solution or an (uncountably) infinite number of solutions;
- 2. every solution $\hat{\Omega}$ has the same values of $\hat{\Omega}_D$ and $\tilde{X} \operatorname{vec}(\hat{\Omega}^T)$;
- 3. if $\lambda > 0$, then every solution $\hat{\Omega}$ has the same ℓ_1 norm $\|\hat{\Omega}\|_1$.

PROOF. Since the objective function (A.1) is a convex coercive function, a solution always exists. Denote the optimal value of \tilde{f} as f^* . If there exists two distinct solutions $\Omega^{(1)}$ and $\Omega^{(2)}$, then $\alpha \Omega^{(1)} + (1 - \alpha) \Omega^{(2)}$ is also a solution for any $0 < \alpha < 1$ since all the level set of f is convex. Then, we have

$$\begin{split} f^{\star} &= \tilde{f} \left(\tilde{\boldsymbol{X}} \operatorname{vec} \left(\alpha \boldsymbol{\Omega}^{(1)^{T}} + (1 - \alpha) \boldsymbol{\Omega}^{(2)^{T}} \right) \right) \\ &= \sum_{i=1}^{p} \left\{ \tilde{g} \left(\tilde{\boldsymbol{X}}^{i} \left(\alpha \Omega_{i}^{(1)^{T}} + (1 - \alpha) \Omega_{i}^{(2)^{T}} \right) \right) \right\} + \lambda \| \alpha \boldsymbol{\Omega}^{(1)} + (1 - \alpha) \boldsymbol{\Omega}^{(2)} \|_{1} \\ &\leq \alpha \sum_{i=1}^{p} \left\{ \tilde{g} (\tilde{\boldsymbol{X}}^{i} \Omega_{i}^{(1)^{T}}) + \lambda \| \Omega_{i}^{(1)^{T}} \|_{1} \right\} + (1 - \alpha) \sum_{i=1}^{p} \{ \tilde{g} (\tilde{\boldsymbol{X}}^{i} \Omega_{i}^{(2)^{T}}) + \lambda \| \Omega_{i}^{(2)^{T}} \|_{1} \} \\ &= \alpha \tilde{f} (\tilde{\boldsymbol{X}} \operatorname{vec}(\boldsymbol{\Omega}^{(1)^{T}})) + (1 - \alpha) \tilde{f} (\tilde{\boldsymbol{X}} \operatorname{vec}(\boldsymbol{\Omega}^{(2)^{T}})) = \alpha f^{\star} + (1 - \alpha) f^{\star} = f^{\star}. \end{split}$$

Thus the inequality must hold with equality. Note that this inequality arises from the strict convexity of \tilde{g} , thus equality holds if and only if $\tilde{X} \operatorname{vec}({\Omega^{(1)}}^T) = \tilde{X} \operatorname{vec}({\Omega^{(2)}}^T)$, which implies $\Omega_D^{(1)} = \Omega_D^{(2)}$ and $X \Omega_i^{(1)T} = X \Omega_i^{(2)T}$, $i = 1, \dots, p$. It then follows that $\|\Omega^{(1)}\|_1 = \|\Omega^{(2)}\|_1$.

The Karush-Kuhn-Tucker (KKT) optimality condition for (3.2) can be written as

(A.2)
$$\hat{\boldsymbol{\Omega}}_D^{-1} - n^{-1} \boldsymbol{X}^T \boldsymbol{X} \hat{\boldsymbol{\Omega}}^T = \lambda \boldsymbol{Z},$$

where

(A.3)
$$z_{ij} \in \begin{cases} \{\operatorname{sign}(\hat{\omega}_{ij})\} & \text{if } \hat{\omega}_{ij} \neq 0, \\ [-1,1] & \text{if } \hat{\omega}_{ij} = 0, \end{cases}$$

for $\hat{\Omega} = (\hat{\omega}_{ij})$ and $\mathbf{Z} = (z_{ij})$. Note that z_{ii} is always 1 as $\hat{\omega}_{ii}$ is always positive for all $i = 1, \ldots, p$. Let r_i be the *i*-th column of $n^{-1} \mathbf{X} \hat{\mathbf{\Omega}}^T$. We define the equicorrelation set \mathcal{E} bv

$$\mathcal{E} = \bigcup_{i=1}^{r} \{ (j,i) : j \in \mathcal{E}_i \}, \quad \mathcal{E}_i = \{ j \in (1, \cdots, p) : |X_j^T r_i| = \lambda \} \cup \{i\}.$$

The KKT condition (A.2)–(A.3) implies that $\hat{\omega}_{ji} = 0$ if $(j,i) \notin \mathcal{E}$, and thus problem (3.2) is equivalent to finding a minimizer of $\sum_{i=1}^{p} \left\{ \tilde{g}(\tilde{\boldsymbol{X}}_{\mathcal{E}_{i}}^{i}\Omega_{i,\mathcal{E}_{i}}^{T}) + \lambda \|\Omega_{i,\mathcal{E}_{i}}^{T}\|_{1} \right\}$, where $\tilde{\boldsymbol{X}}_{\mathcal{E}_{i}}^{i}$ is a submatrix consisting of columns of $\tilde{\boldsymbol{X}}^i$ with column indices in \mathcal{E}_i and $\Omega_{i,\mathcal{E}_i}^T$ is a vector consisting of ω_{ij} for $j \in \mathcal{E}_i$. In light of the proof of Lemma A.1, we see that if $\operatorname{null}(\tilde{X}_{\mathcal{E}_i}^i) = \{0\}$ for every *i*, then the minimizer is unique. In order to find a sufficient condition for this to hold, suppose the case where $\operatorname{null}(\tilde{X}_{\mathcal{E}_i}) \neq \{0\}$ for some *i*. Then, there exists $\mathcal{D} \subset \mathcal{E}_i$ with at most *n* elements such that

$$X_j = \sum_{k \in \mathcal{D} \setminus \{j\}} c_k X_k$$

for some $j \in \mathcal{D}$ and $c_k \in \mathbb{R} \setminus \{0\}$. Note that $i \notin \mathcal{D}$ as $\tilde{\boldsymbol{X}}_i^i = [1, X_i^T]^T$ cannot be spanned by the columns of $\tilde{\boldsymbol{X}}_{-i}^{i} = [0, \boldsymbol{X}_{-i}^{T}]^{T}$. Taking the inner product with r_{i} on both sides of the equation above yields

$$s_{ij}\lambda = \sum_{k \in \mathcal{D} \setminus \{j\}} s_{ik}c_k\lambda = \sum_{k \in \mathcal{D} \setminus \{j\}} (s_{ik}s_{ij}c_k)(s_{ij}\lambda)$$

where $s_{ik} \in \{-1, 1\}$ for $k \in \mathcal{D}$, since $|X_j^T r_i| = \lambda$ for $j \in \mathcal{E}_i \setminus \{i\}$. So for $\lambda > 0$, we have $\sum_{k \in \mathcal{D} \setminus \{j\}} (s_{ik}s_{ij}c_k) = 1$. In other words, X_j is an affine combination of $\pm X_k$'s, $k \in \mathcal{D} \setminus \{j\}$. Thus, we conclude that if there exist more than one solutions, the columns of X are not in the general position.

A.2. Proof of Theorem 3.2. Recall (3.4) that the ACCORD objective function is $f(\boldsymbol{\Omega}) = g(\boldsymbol{\Omega}) + h(\boldsymbol{\Omega})$ where $g(\boldsymbol{\Omega}) = (1/2) \operatorname{tr}(\boldsymbol{\Omega}^T \boldsymbol{\Omega} \boldsymbol{S})$ and $h(\boldsymbol{\Omega}) = -\log \det \boldsymbol{\Omega}_D + \lambda \|\boldsymbol{\Omega}\|_1$.

Convergence of $\{\Omega^{(t)}\}$ to $\hat{\Omega}$ is a standard result in the operator splitting literature; see, e.g., Bauschke and Combettes (2011), Ko, Yu and Won (2019), and Ko and Won (2019). Monotone convergence of $\{f(\Omega^{(t)})\}$ to $f^{\star} = \min_{\Omega} f(\Omega)$ follows from the continuity of f and the descent property of the algorithm.

In order to establish the rate of convergence, we first prove a Łojasiewicz error bound (Lojasiewicz, 1958). Recall the expression (A.1). Let $y = \mathbf{vec}(\Omega^T) \in \mathbb{R}^{p^2}$ and write

$$\bar{g}(\boldsymbol{Z}) = \sum_{i=1}^{p} \tilde{g}(z_i), \quad \bar{h}(\boldsymbol{\Omega}) = \bar{h}(y) = \lambda \|y\|_1$$
$$\tilde{f}(\boldsymbol{\Omega}) = \tilde{f}(\tilde{\boldsymbol{X}}\boldsymbol{\Omega}^T) = \bar{g}(\tilde{\boldsymbol{X}}y) + \bar{h}(y),$$

where $\boldsymbol{Z} = [z_1^T, \dots, z_p^T]^T$ for $z_i \in \mathbb{R}^{n+1}$; \tilde{g} and $\tilde{\boldsymbol{X}}$ are defined in (A.1). The smooth part \bar{g} is a proper closed convex function and strongly convex on any compact convex subset in its natural domain $\{\boldsymbol{Z} \in \mathbb{R}^{(n+1)p} : \boldsymbol{Z}_{i,1} > 0\}$. The nonsmooth part \bar{h} , with $\operatorname{dom} \bar{h} = \mathbb{R}^{p^2}$, is piece-wise linear, thus its epigraph is polyhedral. Let $y^{\star} = \mathbf{vec}(\hat{\boldsymbol{\Omega}}^T)$ be the unique minimizer of f. Then, $f(y^{\star}) \leq f(\mathbf{vec}(\boldsymbol{I})) = \operatorname{tr}(\boldsymbol{S})/2 + \lambda p$ and $L_0 = \{y \in \mathbb{R}^{p^2} : f(y) \leq \operatorname{tr}(\boldsymbol{S})/2 + \lambda p\}$ is nonempty, compact, and convex. Obviously, $y^{\star} \in L_0$. Now let

$$R = \max\{\|y\|_1 : y \in L_0\} \in (0,\infty)$$

so that $||y||_1 \leq R$ whenever $y \in L_0$. $||y^*||_1 \leq R$ also holds. We also split y into y_D and y_X , where each corresponds to the elements of Ω_D and Ω_X . Let P a permutation matrix such that

$$y = \boldsymbol{P}[y_D^T, y_X^T]^T.$$

Then,

$$\begin{split} \min_{y \in \mathbb{R}^{p^2}} f(y) &= \min\{\bar{g}(\tilde{X}y) + \bar{h}(y) : y \in L_0\} \\ &= \min\{\bar{g}(\tilde{X}y) + \lambda \|y\|_1 : \|y\|_1 \leqslant R\} \\ &= \min\left\{\bar{g}\left(\tilde{X}P[y_D^T, y_X^{+T} - y_X^{-T}]^T\right) + \lambda(\mathbf{1}^T y_D + \mathbf{1}^T y_X^{+} + \mathbf{1}^T y_X^{-}) \\ &\quad : \mathbf{1}^T y_D + \mathbf{1}^T y_X^{+} + \mathbf{1}^T y_X^{-} \leqslant R, \mathbf{y}_D \geqslant 0, y_X^{+} \geqslant 0, y_X^{-} \geqslant 0 \right\} \\ &= \min\{\bar{g}(\boldsymbol{E}\tilde{y}) + b^T\tilde{y} : \boldsymbol{A}\tilde{y} \leqslant a\}, \end{split}$$

where $b = \lambda 1$, $\boldsymbol{E} = \tilde{\boldsymbol{X}} \boldsymbol{P} \tilde{\boldsymbol{E}}$, and

$$\tilde{y} = \begin{bmatrix} y_D \\ y_X^+ \\ y_X^- \end{bmatrix}, \quad \tilde{\boldsymbol{E}} = \begin{bmatrix} \boldsymbol{I} \ \boldsymbol{0} \ \boldsymbol{0} \\ \boldsymbol{0} \ \boldsymbol{I} - \boldsymbol{I} \end{bmatrix}, \quad \boldsymbol{A} = \begin{bmatrix} 1^T & 1^T & 1^T \\ -\boldsymbol{I} & \boldsymbol{0} & \boldsymbol{0} \\ \boldsymbol{0} & -\boldsymbol{I} & \boldsymbol{0} \\ \boldsymbol{0} & \boldsymbol{0} & -\boldsymbol{I} \end{bmatrix}, \quad \boldsymbol{a} = \begin{bmatrix} R \\ 0 \end{bmatrix},$$

and where 0's and 1's denote entries of zeros and ones with an appropriate size. Note the constraint set $\tilde{Y} = \{\tilde{y} \in \mathbb{R}^{4p^2} : A\tilde{y} \leq a\}$ is a compact polyhedron in which \bar{g} is strongly convex with parameter

$$\nu(\tilde{Y}) := \min\left\{\frac{1}{\max_{\tilde{y}\in\tilde{Y}}\|\tilde{y}_D\|_{\infty}^2}, \frac{1}{2n}\right\}$$

Now, let us define the diameters and radii of the sets

$$D = \max\{\|\tilde{y}_1 - \tilde{y}_2\|_2 : \tilde{y}_1, \tilde{y}_2 \in \tilde{Y}\} < \infty,$$

$$D_E = \max\{\|\boldsymbol{E}\tilde{y}_1 - \boldsymbol{E}\tilde{y}_2\|_2 : \tilde{y}_1, \tilde{y}_2 \in \tilde{Y}\} \leqslant \|\|\boldsymbol{E}\|\|_2 D,$$

$$G = \max\{\|\boldsymbol{E}\tilde{y}\|_2 : \tilde{y} \in \tilde{Y}\} \leqslant \|\|\boldsymbol{E}\|\|_2 D,$$

where $|||\mathbf{E}|||_r = \sup_{v \neq 0} ||\mathbf{E}v||_r / ||v||_r$ is the operator *r*-norm. We also let $\tilde{Y}^{\star} = \arg \min_{\tilde{y} \in \tilde{Y}} \{\bar{g}(\mathbf{E}\tilde{y}) + b^T \tilde{y}\}$, which is a nonempty and compact set. Then, by Beck and Shtern (2017, Lemma 2.5), for any $\tilde{y} \in \tilde{Y}$,

(A.4)
$$\operatorname{dist}^{2}(\tilde{y}, \tilde{Y}^{\star}) \leq \kappa [\bar{g}(\boldsymbol{E}\tilde{y}) + b^{T}\tilde{y} - \min_{\bar{y}\in\tilde{Y}} \{\bar{g}(\boldsymbol{E}\bar{y}) + b^{T}\bar{y}\}],$$

where $\operatorname{dist}(p, S) = \inf_{s \in S} \|p - s\|_2$ and

(A.5)
$$\kappa = \theta^2 (\|b\|_2 D + 3GD_E + 2(G^2 + 1)/\nu(\tilde{Y}))$$

for the Hoffman constant θ that only depends on A and E (Hoffman, 1952). This constant is characterized as

$$\theta = \max_{\boldsymbol{B} \in \mathcal{B}} 1/\lambda_{\min}(\boldsymbol{B}\boldsymbol{B}^T),$$

where λ_{\min} denotes the smallest eigenvalue and \mathcal{B} is the set of matrices constructed by linearly independent rows of $[\mathbf{E}^T, \mathbf{A}^T]^T$, and can be estimated from \mathbf{A} and \mathbf{E} (Zualinescu, 2003).

Going back to the original variable, observe that for any $y \in \mathbb{R}^{p^2}$ such that $||y||_1 \leq R$ and $y_D \geq 0$, there exists $\tilde{y} \in \tilde{Y}$ such that

$$y = \boldsymbol{P}\tilde{\boldsymbol{E}}\tilde{y}, \quad f(y) = \tilde{f}(\tilde{\boldsymbol{X}}y) = \bar{g}(\tilde{\boldsymbol{X}}\boldsymbol{P}\tilde{\boldsymbol{E}}\tilde{y}) + b^T\tilde{y} = \bar{g}(\boldsymbol{E}\tilde{y}) + b^T\tilde{y},$$

and vice versa. Denote \tilde{y}^{\star} as the projection of \tilde{y} onto \tilde{Y}^{\star} . Since y^{\star} , the minimizer of f, is unique, we also have $y^{\star} = P\tilde{E}\tilde{y}^{\star}$. It also holds that

$$f^{\star} := \min_{\boldsymbol{y} \in \mathbb{R}^{p^2}} f(\boldsymbol{y}) = f(\boldsymbol{y}^{\star}) = \bar{g}(\boldsymbol{E}\tilde{\boldsymbol{y}}^{\star}) + b^T \tilde{\boldsymbol{y}}^{\star} = \min_{\bar{\boldsymbol{y}} \in \tilde{Y}} \{ \bar{g}(\boldsymbol{E}\bar{\boldsymbol{y}}) + b^T \bar{\boldsymbol{y}} \}.$$

Then,

$$\|y - y^{\star}\|_{2} \leq \|\|\tilde{\boldsymbol{E}}\|_{2} \|\tilde{y} - \tilde{y}^{\star}\|_{2} = \sqrt{2}\operatorname{dist}(\tilde{y}, Y^{\star})$$

It follows from the inequality (A.4) that for any $\Omega \in \mathbb{R}^{p \times p}$ such that $\|\Omega\|_1 \leq R$,

$$\|\mathbf{\Omega} - \hat{\mathbf{\Omega}}\|_F^2 \leq 2\kappa [f(\mathbf{\Omega}) - f^*]_{\mathbf{R}}$$

i.e., the Łojasiewicz error bound inequality holds. Then, from Bolte et al. (2017, Theorem 5), the KL inequality

(A.6)
$$\varphi'(f(\mathbf{\Omega}) - f^{\star})\operatorname{dist}(0, \partial f(\mathbf{\Omega})) \ge 1$$

holds with $\varphi(s) = 2\sqrt{2\kappa s}$ for all Ω such that $\|\Omega\|_1 \leq R$ and $f(\Omega) > f^*$. The inverse $\psi: [0, \infty) \ni y \mapsto y^2/(8\kappa)$ of φ satisfies Assumption (A) of Bolte et al. (2017).

Now consider the proposed splitting (3.4). If $\tau_t \in [\underline{\tau}, \overline{\tau}]$ with $0 < \underline{\tau} \leq \overline{\tau} < 2/L$, then Bolte et al. (2017, Proposition 13) asserts that Assumptions (H1) and (H2) of Bolte et al. (2017) are satisfied with $a = 1/\overline{\tau} - L/2$ and $b = 1/\underline{\tau} + L$. The non-asymptotic complexity bound (3.6) follows immediately from Bolte et al. (2017, Corollary 20).

If τ_t is chosen by the line search, then we have

$$g(\mathbf{\Omega}^{(t+1)}) \leq g(\mathbf{\Omega}^{(t)}) + \langle \nabla g(\mathbf{\Omega}^{(t)}), \mathbf{\Omega}^{(t+1)} - \mathbf{\Omega}^{(t)} \rangle + \frac{1}{2\tau_t} \|\mathbf{\Omega}^{(t+1)} - \mathbf{\Omega}^{(t)}\|_F^2.$$

where

$$\mathbf{\Omega}^{(t+1)} = \operatorname*{arg\,min}_{\mathbf{\Omega}} \left\{ \langle \nabla g(\mathbf{\Omega}^{(t)}), \mathbf{\Omega} - \mathbf{\Omega}^{(t)} \rangle + \frac{1}{2\tau_t} \|\mathbf{\Omega} - \mathbf{\Omega}^{(t)}\|_F^2 + h(\mathbf{\Omega}) \right\}.$$

From the convexity of h, the latter is equivalent to

(A.7)
$$-\nabla g(\mathbf{\Omega}^{(t)}) - \tau_t^{-1}(\mathbf{\Omega}^{(t+1)} - \mathbf{\Omega}^{(t)}) \in \partial h(\mathbf{\Omega}^{(t+1)}),$$

which implies

$$\begin{split} h(\boldsymbol{\Omega}^{(t)}) &\geq h(\boldsymbol{\Omega}^{(t+1)}) + \langle -\nabla g(\boldsymbol{\Omega}^{(t)}) - \tau_t^{-1}(\boldsymbol{\Omega}^{(t+1)} - \boldsymbol{\Omega}^{(t)}), \boldsymbol{\Omega}^{(t)} - \boldsymbol{\Omega}^{(t+1)} \rangle \\ &= h(\boldsymbol{\Omega}^{(t+1)}) + \langle \nabla g(\boldsymbol{\Omega}^{(t)}), \boldsymbol{\Omega}^{(t+1)} - \boldsymbol{\Omega}^{(t)} \rangle + \tau_t^{-1} \| \boldsymbol{\Omega}^{(t+1)} - \boldsymbol{\Omega}^{(t)} \|_F^2 \end{split}$$

Combining the above two inequalities yields

$$g(\mathbf{\Omega}^{(t+1)}) + h(\mathbf{\Omega}^{(t+1)}) + \frac{1}{2\tau_t} \|\mathbf{\Omega}^{(t+1)} - \mathbf{\Omega}^{(t)}\|_F^2 \leq g(\mathbf{\Omega}^{(t)}) + h(\mathbf{\Omega}^{(t)}).$$

Since $\tau_t \leq \tau_0$ for all t, Assumption (H1) of Bolte et al. (2017) is satisfied with $a = 1/(2\tau_0)$. Now from the condition (A.7) there is $s^{(t+1)} \in \partial h(\Omega^{(t+1)})$ such that $s^{(t+1)} + \nabla g(\Omega^{(t)}) + \tau_t^{-1}(\Omega^{(t+1)} - \Omega^{(t)}) = 0$. This entails

$$\begin{split} \|s^{(t+1)} + \nabla g(\mathbf{\Omega}^{(t+1)})\|_{F} &\leq \|s^{(t+1)} + \nabla g(\mathbf{\Omega}^{(t)})\|_{F} + \|\nabla g(\mathbf{\Omega}^{(t)}) - \nabla g(\mathbf{\Omega}^{(t+1)}\|_{F} \\ &\leq \tau_{t}^{-1} \|\mathbf{\Omega}^{(t+1)} - \mathbf{\Omega}^{(t)}\|_{F} + L \|\mathbf{\Omega}^{(t)} - \mathbf{\Omega}^{(t+1)}\|_{F} \\ &\leq (\tau_{\min}^{-1} + L) \|\mathbf{\Omega}^{(t+1)} - \mathbf{\Omega}^{(t)}\|_{F}, \end{split}$$

since $\tau_t \geq \tau_{\min}$. Invoking that $s^{(t+1)} + \nabla g(\mathbf{\Omega}^{(t+1)}) \in \partial f(\mathbf{\Omega}^{(t+1)})$, we see that Assumption (**H2**) of Bolte et al. (2017) is satisfied with $b = \tau_{\min}^{-1} + L$. The non-asymptotic complexity bound (3.6) follows again from Bolte et al. (2017, Corollary 20).

A.3. Proof of Theorem 4.1. Recall that the empirical ACCORD risk is $\ell(\Omega) = -\log \det \Omega_D + (1/2) \operatorname{tr}(\Omega^T \Omega S)$ and the ACCORD estimator (3.2) is defined as a minimizer of $\ell(\Omega) + \lambda \|\Omega\|_1$ for $\lambda \ge 0$. The Hessian matrix of the loss is

(A.8)
$$\nabla^2 \ell(\mathbf{\Omega}) = \mathbf{S} \otimes \mathbf{I}_p + \sum_{i=1}^p \omega_{ii}^{-2} (e_i e_i^T \otimes e_i e_i^T) = \mathbf{S} \otimes \mathbf{I}_p + (\mathbf{\Omega}_D^{-1} \otimes \mathbf{\Omega}_D^{-1}) \mathbf{\Upsilon},$$

where $\Upsilon = \sum_{i=1}^{p} e_i e_i^T \otimes e_i e_i^T$, if the matrix variable Ω is vectorized in column-major order, i.e., by $\operatorname{vec}(\Omega) = (\omega_{11}, \ldots, \omega_{p1}, \ldots, \omega_{1p}, \ldots, \omega_{pp})$; \otimes is the Kronecker product.

To prove the claimed error bounds, we follow the proof of Theorem 9.36 in Wainwright (2019). First define the error function

(A.9)
$$\mathcal{E}(\mathbf{\Delta}) := \ell(\mathbf{\Omega}^* + \mathbf{\Delta}) - \ell(\mathbf{\Omega}^*) - \langle \nabla \ell(\mathbf{\Omega}^*), \mathbf{\Delta} \rangle,$$

and verify its restricted strong convexity

(A.10)
$$\mathcal{E}(\mathbf{\Delta}) \ge \kappa \|\mathbf{\Delta}\|_F^2, \quad \kappa > 0, \ \mathbf{\Delta} \in \mathbb{C}(S)$$

where S is the support of Ω^* and $\mathbb{C}(S) := \{\Delta : \|\Delta_{S^c}\|_1 \leq 3 \|\Delta_S\|_1\}$. Then, the claimed error bounds are achieved in the event of $G(\lambda) = \{\|\nabla \ell(\Omega^*)\|_{\infty} \leq \lambda/2\}$, which is a sufficient condition for $\hat{\Delta} = \hat{\Omega} - \Omega^* \in \mathbb{C}(S)$.

A.3.1. Verifying restricted strong convexity.

THEOREM A.1 (Restricted strong convexity of the ACCORD loss). Suppose the data matrix $\mathbf{X} \in \mathbb{R}^{n \times p}$ is composed of n i.i.d. copies of zero-mean continuous random vector $X = (X_1, \ldots, X_p) \in \mathbb{R}^p$ with covariance matrix $\mathbf{\Sigma}^* = (\Sigma_{ij}^*) = \mathbf{\Theta}^{*-1}$ and each $X_j/\sqrt{\Sigma_{jj}^*}$ being sub-Gaussian with parameter σ . Also, suppose that there exist $\alpha, \beta, \eta > 0$ such that $\mathbf{E}_X |\langle X, y \rangle|^2 \ge \alpha$ and $\mathbf{E}_X |\langle X, y \rangle|^{2+\eta} \le \beta^{2+\eta}$ for any $y \in \mathbb{R}^p$ with $||y||_2 = 1$. Let $S = \{(i, j) \in [p] \times [p] : \theta_{ij}^* \ne 0\}$ be the support of $\mathbf{\Theta}^*$ (hence of $\mathbf{\Omega}^*$). and each $X_j/\sqrt{\Sigma_{jj}^*}$ is sub-Gaussian with parameter σ . Then, for the error function \mathcal{E} (A.9), the inequality

(A.11)
$$\mathcal{E}(\mathbf{\Delta}) \ge \kappa \|\mathbf{\Delta}\|_F^2 - c_0 \sqrt{\frac{\log p}{n}} \|\mathbf{\Delta}\|_F \|\mathbf{\Delta}\|_1,$$

holds with a probability of at least $1 - c_1 e^{-c_2 n}$, for some positive constants κ, c_0, c_1 , and c_2 that explicitly depends on $\alpha, \beta, \eta, \sigma$, and $\max_{i \in [p]} \sum_{ii}^*$.

REMARK A.1. If (A.11) holds, then the restricted strong convexity condition

(A.12)
$$\mathcal{E}(\mathbf{\Delta}) \ge \left(\kappa - 4c_0 \sqrt{|S| \frac{\log p}{n}}\right) \|\mathbf{\Delta}\|_F^2 \ge \frac{\kappa}{2} \|\mathbf{\Delta}\|_F^2,$$

holds for $\mathbf{\Delta} \in \mathbb{C}(S)$ as $\|\mathbf{\Delta}\|_1 = \|\mathbf{\Delta}_S\|_1 + \|\mathbf{\Delta}_{S^c}\|_1 \leq 4\|\mathbf{\Delta}_S\|_1 \leq 4\sqrt{|S|}\|\mathbf{\Delta}\|_F$, provided that $\sqrt{n^{-1}|S|\log p} \leq \kappa/(8c_0)$.

PROOF. Let $X^i \in \mathbb{R}^p$ be the *i*-th observation of the data matrix X and $y_j \in \mathbb{R}^p$ be the *j*-th column of Δ^T . Using Taylor's remainder theorem and the expression (A.8) of the Hessian of ℓ , we have

$$\mathcal{E}(\boldsymbol{\Delta}) = \mathbf{vec}(\boldsymbol{\Delta})^T \nabla^2 \ell(\boldsymbol{\Omega}^* + t\boldsymbol{\Delta}) \, \mathbf{vec}(\boldsymbol{\Delta}) \geqslant \mathbf{vec}(\boldsymbol{\Delta})^T (\boldsymbol{S} \otimes \boldsymbol{I}_p) \, \mathbf{vec}(\boldsymbol{\Delta}) = \frac{1}{n} \sum_{i=1}^n \sum_{j=1}^p |\langle X^i, y_j \rangle|^2$$

for some 0 < t < 1. Define a truncating function

$$\varphi_K(x) = \begin{cases} |x|^2, & \text{if } |x| \leq K, \\ K^2, & \text{if } |x| > K, \end{cases}$$

for some K > 0. Here, it suffices to prove that for any $y \in \mathbb{R}^p$ with $||y||_2 = 1$,

(A.13)
$$\frac{1}{n}\sum_{i=1}^{n}\varphi_{K}(\langle X^{i}, y\rangle) \ge c_{3} - c_{4}\sqrt{\frac{\log 2p}{n}} \|y\|_{1}$$

holds for some K, c_3 , and c_4 with a probability at least $1 - c_1 e^{-c_2 n}$. To see this, let $\|y_j\|_2 = t_j$. Without loss of generality, assume that $t_j > 0$ for all j. If (A.13) holds for all y with $\|y\|_2 = 1$, then since $\|y_j/t_j\|_2 = 1$, it follows that

$$\begin{aligned} \frac{1}{n} \sum_{i=1}^{n} \varphi_{t_{j}K}(\langle X^{i}, y_{j} \rangle) &= \frac{1}{n} \sum_{i=1}^{n} t_{j}^{2} \varphi_{K}(\langle X^{i}, y_{j}/t_{j} \rangle) \stackrel{(A.13)}{\geqslant} c_{3}t_{j}^{2} - c_{4}\sqrt{\frac{\log 2p}{n}} \|y_{j}\|_{1}t_{j} \\ \Rightarrow \mathcal{E}(\mathbf{\Delta}) &\geq \frac{1}{n} \sum_{j=1}^{p} \sum_{i=1}^{n} \varphi_{t_{j}K}(\langle X^{i}, y_{j} \rangle) \geq c_{3} \sum_{j=1}^{p} t_{j}^{2} - 2c_{4}\sqrt{\frac{\log p}{n}} \sum_{j=1}^{p} \|y_{j}\|_{1}t_{j} \\ &\geq c_{3} \sum_{j=1}^{p} t_{j}^{2} - 2c_{4}\sqrt{\frac{\log p}{n}} \sqrt{\sum_{j=1}^{p} \|y_{j}\|_{1}^{2}} \sqrt{\sum_{j=1}^{p} t_{j}^{2}} \geq c_{3} \|\mathbf{\Delta}\|_{F}^{2} - 2c_{4}\sqrt{\frac{\log p}{n}} \|\mathbf{\Delta}\|_{1} \|\mathbf{\Delta}\|_{F}, \end{aligned}$$

i.e., (A.11) with $\kappa = c_3$ and $c_0 = 2c_4$, due to the Cauchy-Schwarz inequality and that $\sum_{j=1}^{p} \|y_j\|_1^2 \leq (\sum_{j=1}^{p} \|y_j\|_1)^2$. To show (A.13), define

$$Z(r) := \inf_{\|y\|_2 = 1, \|y\|_1 \leqslant r} \left\{ \frac{1}{n} \sum_{i=1}^n \varphi_K(\langle X^i, y \rangle) - \mathbf{E}_X[\varphi_K(\langle X, y \rangle)] \right\}$$
$$= -\sup_{\|y\|_2 = 1, \|y\|_1 \leqslant r} \left\{ \frac{1}{n} \sum_{i=1}^n -\varphi_K(\langle X^i, y \rangle) - \mathbf{E}_X[-\varphi_K(\langle X, y \rangle)] \right\}$$

Note that if

(A.14)
$$\mathbf{E}_{X}[\varphi_{K}(\langle X, y \rangle)] \ge \frac{3}{4}\alpha,$$

and

(A.15)
$$Z(r) \ge -\alpha/2 - c'_4 r \sqrt{\frac{\log 2p}{n}}$$

holds for some $c'_4 > 0$, then

$$\frac{1}{n}\sum_{i=1}^{n}\varphi_{K}(\langle X^{i}, y\rangle) \ge \mathbf{E}_{X}[\varphi_{K}(\langle X, y\rangle)] - \alpha/2 - c_{4}'r\sqrt{\frac{\log 2p}{n}} \ge \alpha/4 - c_{4}'r\sqrt{\frac{\log 2p}{n}}$$

and thus (A.13) with the $||y||_1$ replaced by r holds with $c_3 = \alpha/4$ and $c_4 = c'_4$, provided that $||y||_1 \leq r$.

To show the expectation bound (A.14), observe that

$$\mathbf{E}_{X}[\varphi_{K}(\langle X, y \rangle)] \ge \mathbf{E}_{X}[|\langle X, y \rangle|^{2} \cdot I(|\langle X, y \rangle| \leqslant K)]$$
$$\ge \alpha - \mathbf{E}_{X}[|\langle X, y \rangle|^{2} \cdot I(|\langle X, y \rangle| > K)],$$

so that it suffices to show that the last term is at most $\alpha/4$. From the given conditions, we have

$$\Pr(|\langle X, y \rangle| > K) \leq \mathbf{E}_X[|\langle X, y \rangle|^{2+\eta}]/K^{2+\eta} \leq \beta^{2+\eta}/K^{2+\eta}$$

by Markov's inequality. Hence, the Hölder's inequality yields

$$\mathbf{E}_{X}[|\langle X, y \rangle|^{2} \cdot I(|\langle X, y \rangle| > K)] \leq (\mathbf{E}[|\langle X, y \rangle|^{2+\eta}])^{\frac{2}{2+\eta}} (\Pr(|\langle X, y \rangle| > K))^{\frac{\eta}{2+\eta}} \leq \beta^{2+\eta} / K^{\eta}.$$

Thus, $K^{\eta} = 4\beta^{2+\eta}/\alpha$ results in (A.14). In the sequel, we assume $K = (4\beta^{2+\eta}/\alpha)^{\frac{1}{\eta}}$.

To prove the tail bound (A.15), we need the following lemmas regarding a supremum of a functional on \mathcal{F} , a class of integrable real-valued functions with domain \mathbb{R}^p .

LEMMA A.2 (Functional Hoeffding inequality; Wainwright, 2019, Theorem 3.26). Suppose that every $f \in \mathcal{F}$ is uniformly bounded in [a,b], i.e., $f(x) \in [a,b]$. Then, for $Z = -\sup_{f \in \mathcal{F}} \{\frac{1}{n} \sum_{i=1}^{n} f(X^i)\}$, where all X^i 's are independent random variables, we have

$$\Pr(Z \leq \mathbf{E}[Z] - \delta) \leq \exp\left(-\frac{n\delta^2}{4(b-a)^2}\right).$$

for any $\delta \ge 0$.

LEMMA A.3 (Wainwright, 2019, Proposition 4.11). Let (X^1, \dots, X^n) be an *i.i.d.* sequence of some distribution, and let $(\epsilon_1, \dots, \epsilon_n)$ be an *i.i.d.* sequence of Rademacher variables, *i.e.*, random variables uniformly distributed in $\{-1, 1\}$. Then, we have

$$\mathbf{E}_{X} \sup_{f \in \mathcal{F}} \left[\frac{1}{n} \sum_{i=1}^{n} f(X^{i}) - \mathbf{E}_{X} f(X) \right] \leq 2 \mathbf{E}_{X,\epsilon} \left[\sup_{f \in \mathcal{F}} \frac{1}{n} \sum_{i=1}^{n} \epsilon_{i} f(X^{i}) \right].$$

LEMMA A.4 (Ledoux-Talagrand contraction inequality). Suppose that $\phi_i : \mathbb{R} \to \mathbb{R}$ is a L-Lipschitz continuous function. Also, let $\epsilon_1, \dots, \epsilon_n \in \{-1, 1\}$ be an i.i.d. sequence of Rademacher variables. Then, we have

$$\mathbf{E}_{x,\epsilon}\left[\sup_{f\in\mathcal{F}}\sum_{i=1}^{n}\epsilon_{i}(\phi_{i}\circ f)(X^{i})\right] \leqslant L \mathbf{E}_{x,\epsilon}\left[\sup_{f\in\mathcal{F}}\sum_{i=1}^{n}\epsilon_{i}f(X^{i})\right]$$

LEMMA A.5 (Expected ℓ_{∞} -norm of sub-Gaussian). Let $X = (X_1, \dots, X_p)$ be a vector of sub-Gaussian random variables with parameter ν , where each random variable is not necessarily independent of each other. Then,

$$\mathbf{E}_X[\max_i |X_i|] \leq \nu \sqrt{2\log 2p}.$$

Note that φ_K is a 2K-Lipschitz continuous function, and all X_1, \dots, X_p are sub-Gaussian random variables with parameter $\nu := \sigma \sqrt{\max_{i \in [p]} \Sigma_{ii}^*}$. Then, we have the following inequality for the for the expectation of Z(r).

$$\mathbf{E}[Z(r)] = -\mathbf{E}_{X} \sup_{\|y\|_{2}=1, \|y\|_{1} \leqslant r} \left\{ \frac{1}{n} \sum_{i=1}^{n} -\varphi_{K}(\langle X^{i}, y \rangle) - \mathbf{E}_{X}[-\varphi_{K}(\langle X, y \rangle)] \right\}$$

$$\geq -2 \mathbf{E}_{X,\epsilon} \left[\sup_{\|y\|_{2}=1, \|y\|_{1} \leqslant r} \frac{1}{n} \sum_{i=1}^{n} \epsilon_{i} \varphi_{K}(\langle X^{i}, y \rangle) \right] \quad \text{(Lemma A.3)}$$

$$\geq -4K \mathbf{E}_{X,\epsilon} \left[\sup_{\|y\|_{2}=1, \|y\|_{1} \leqslant r} \frac{1}{n} \sum_{i=1}^{n} \epsilon_{i} \langle X^{i}, y \rangle \right] \quad \text{(Lemma A.4)}$$

$$\geq -4Kr \mathbf{E}_{X,\epsilon} \left\| \frac{1}{n} \sum_{i=1}^{n} \epsilon_{i} X^{i} \right\|_{\infty} \quad \text{(Hölder's inequality)}$$

$$\geq -4\sqrt{2}K\nu r \sqrt{\frac{\log 2p}{n}} \quad \text{(Lemma A.5).}$$

The last inequality holds because each element of $n^{-1}\sum_{i=1}^{n} \epsilon_i X^i$ is sub-Gaussian with parameter ν/\sqrt{n} .

On the other hand, since the value of φ_K is nonnegative and bounded above by K^2 , the range of $\varphi_K(\langle \cdot, y \rangle) - \mathbf{E}_X[\varphi_K(\langle X, y \rangle)]$ is bounded within $[-K^2, K^2]$. Hence, Lemma A.2 yields

Thus (A.15) holds with a probability at least $1 - e^{-\frac{r^2 \log 2p}{16K^4} - \frac{\alpha^2}{64K^4}n}$, for $c'_4 = 1 + 4\sqrt{2}K\nu$. Then, it follows that for all $y \in \mathbb{R}^p$ with $\|y\|_2 = 1$, $\|y\|_1 \leq r$, (A.13) with $\|y\|_1$ replaced by r holds with a probability at least $1 - e^{-\frac{r^2 \log 2p}{16K^4} - \frac{\alpha^2}{64K^4}n}$, for $c_3 = \alpha/4$, and $c_4 = c'_4$. In other words,

$$\begin{aligned} \text{(A.18)} \\ &\Pr\left(\exists y \text{ with } \|y\|_{2} = 1, \|y\|_{1} \leqslant r \text{ such that } \frac{1}{n} \sum_{i=1}^{n} \varphi_{K}(\langle X^{i}, y \rangle) < \frac{\alpha}{4} - c_{4}' \sqrt{\frac{\log 2p}{n}} r \right) \\ &= \Pr\left(\inf_{y:\|y\|_{2} = 1, \|y\|_{1} \leqslant r} \frac{1}{n} \sum_{i=1}^{n} \varphi_{K}(\langle X^{i}, y \rangle) - \frac{3}{4}\alpha < -\frac{\alpha}{2} - c_{4}' \sqrt{\frac{\log 2p}{n}} r \right) \\ &\leqslant \Pr\left(Z(r) < -\frac{\alpha}{2} - c_{4}' \sqrt{\frac{\log 2p}{n}} r\right) \leqslant \exp\left(-\frac{r^{2} \log 2p}{16K^{4}} - \frac{\alpha^{2}}{64K^{4}}n\right), \quad c_{4}' = 1 + 4\sqrt{2}K\nu \end{aligned}$$

To complete the proof, we need to show that (A.13) holds with a high probability independent of $||y||_1$ for some c_3 and c_4 . To see this, let us choose $c_3 = \alpha/4$ and $c_4 = 2c'_4$ in (A.13) and \mathcal{V} be the event that (A.13) with this choice is violated. That is,

$$\mathcal{V} = \left\{ \frac{1}{n} \sum_{i=1}^{m} \varphi_K(\langle X^i, y \rangle) < \frac{\alpha}{4} - 2c'_4 \sqrt{\frac{\log 2p}{n}} \|y\|_1 \text{ for some } y \in \mathbb{R}^p \text{ with } \|y\|_2 = 1 \right\}.$$

Suppose $\hat{y} \in \mathbb{R}^p$ violates (A.13), with $\|\hat{y}\|_2 = 1$. If we define $A_m = \{y \in \mathbb{R}^p : \|y\|_2 = 1, 2^{m-1} \leq \|y\|_1 < 2^m\}$ for $m = 1, 2, \ldots$, then, since $1 = \|y\|_2 \leq \|y\|_1 \leq \sqrt{p}$, we have $\hat{y} \in A_m$ for some m. Thus

$$\inf_{y:\|y\|_2=1,\|y\|_1\leqslant 2^m} \frac{1}{n} \sum_{i=1}^n \varphi_K(\langle X^i, y \rangle) \leqslant \frac{1}{n} \sum_{i=1}^n \varphi_K(\langle X^i, \hat{y} \rangle) < \alpha/4 - c_4' 2^m \sqrt{(\log 2p)/n}.$$

Therefore,

$$\Pr(\mathcal{V}) \leq \sum_{m=1}^{\infty} \Pr\left(\inf_{\substack{y: \|y\|_2 = 1, \|y\|_1 \leq 2^m}} \frac{1}{n} \sum_{i=1}^n \varphi_K(\langle X^i, y \rangle) < \frac{\alpha}{4} - c_4' \sqrt{\frac{\log 2p}{n}} 2^m\right)$$

$$\stackrel{(A.18)}{\leq} \sum_{m=1}^{\infty} \exp\left(-\frac{4^m \log 2p}{16K^4} - \frac{\alpha^2}{64K^4}n\right)$$

$$\leq \sum_{m=1}^{\infty} \exp\left(-\frac{4^{m-3}}{K^4}\right) \exp\left(-\frac{\alpha^2}{64K^4}n\right) = c_1 \exp(-c_2 n),$$

where $c_1 = \sum_{m=1}^{\infty} \exp\left(-\frac{4^{m-3}}{K^4}\right) = \sum_{m=1}^{\infty} \exp\left(-\frac{4^{m-3}}{(4\beta^{2+\eta}/\alpha)^{4/\eta}}\right) < \infty$ and $c_2 = \frac{\alpha^2}{64K^4} = \alpha^{2+4/\eta}/[64(4\beta^{2+\eta})^{4/\eta}]$. Thus, (A.13) holds with probability $\Pr(\mathcal{V}^c) \ge 1 - c_1 e^{-c_2 n}$ for $c_3 = \alpha/4$ and $c_4 = 2(1 + 4\sqrt{2}(4\beta^{2+\eta}/\alpha)^{1/\eta}\nu)$, as desired. It follows that (A.11) holds with $\kappa = \alpha/4$ and $c_0 = 4(1 + 4\sqrt{2}(4\beta^{2+\eta}/\alpha)^{1/\eta}\nu)$ with the same probability. \Box

A.3.2. Verifying the event $G(\lambda)$. We need an upper probability bound for the event

$$G(\lambda)^{c} = \{ \|\nabla \ell(\boldsymbol{\Omega}^{*})\|_{\infty} > \lambda/2 \} = \left\{ \| - \boldsymbol{\Omega}_{D}^{*-1} + \boldsymbol{\Omega}^{*}\boldsymbol{S} \|_{\infty} > \lambda/2 \right\}$$

Recall that $\Theta^* = \Omega_D^* \Omega^*$, which implies $\Omega_D^* {}^{-1} = \Omega^* \Theta^{*-1} = \Omega^* \Sigma^*$. Therefore,

$$\Pr(G(\lambda)^c) \leq \Pr(\|\mathbf{\Omega}^*(-\mathbf{\Sigma}^* + \mathbf{S})\|_{\infty} \ge \lambda/2) \leq \Pr(\|\mathbf{\Omega}^*\|_{\infty} \|\mathbf{S} - \mathbf{\Sigma}^*\|_{\infty} \ge \lambda/2).$$

From Ravikumar et al. (2011, Lemma 1), we know that

$$\Pr(\|\boldsymbol{S} - \boldsymbol{\Sigma}^*\|_{\infty} \ge t) \le 4 \exp\left\{-\frac{nt^2}{128(1+4\sigma^2)^2(\max_{i \in [p]} \boldsymbol{\Sigma}^*_{ii})^2} + 2\log p\right\}$$

for $0 < t < 8(1 + 4\sigma^2) \max_{i \in [p]} \sum_{i=1}^{*} \Sigma_{ii}^{*}$. Thus, letting

$$\lambda = (2 \| \mathbf{\Omega}^* \|_{\infty}) \cdot 16(1 + 4\sigma^2) (\max_{i \in [p]} \Sigma_{ii}^*) (\sqrt{n^{-1} \log p} + \delta)$$

upper-bounds $P(G(\lambda)^c) = 1 - P(G(\lambda))$ by $4 \exp(-2n\delta^2)$ for the sample size *n* such that $\sqrt{n^{-1}\log p} + \delta < 1/2$.

A.3.3. Putting things together. We conclude that, by Wainwright (2019, Theorem 9.19), if the event $\mathcal{V}^c \cap G(\lambda)$ occurs, then there holds

$$\|\hat{\boldsymbol{\Omega}} - \boldsymbol{\Omega}^*\|_F \leq 4\kappa^{-1}\lambda\sqrt{|S|} \quad \text{and} \quad \|\hat{\boldsymbol{\Omega}} - \boldsymbol{\Omega}^*\|_1 \leq 4\sqrt{|S|}\|\hat{\boldsymbol{\Omega}} - \boldsymbol{\Omega}^*\|_F \leq 16\kappa^{-1}\lambda|S|.$$

The probability of this event is bounded by

$$1 - \Pr(\mathcal{V} \cup G(\lambda)^{c}) \ge 1 - c_1 e^{-c_2 n} - 4e^{-2n\delta^2},$$

provided that $\sqrt{n^{-1}|S|\log p} \leq \kappa/(8c_0)$ and $\sqrt{n^{-1}\log p} + \delta < 1/2$. Choosing $\delta = \sqrt{n^{-1}\log p}$ yields the desired result.

A.4. Proof of Theorem 4.2. We prove the theorem by proving an umbrella theorem under a more general tail condition.

DEFINITION A.1 (Tail condition; Ravikumar et al., 2011, Definition 1). Random vector X with covariance matrix $\Sigma^* = (\Sigma_{ij}^*)$ satisfies tail condition $\mathcal{T}(f, v_*)$ if there exists a constant $v_* \in (0, \infty]$ and a function $f : \mathbb{N} \times (0, \infty) \to (0, \infty)$, which is monotonically increasing in either argument, such that for any $(i, j) \in [p] \times [p]$ and sample estimate $S = (s_{ij})$ of Σ^* :

(A.19)
$$P[|s_{ij} - \Sigma_{ij}^*| \ge \delta] \le 1/f(n,\delta), \quad \forall \delta \in (0, 1/v_*].$$

We adopt the convention $1/0 = +\infty$, so that the value $v^* = 0$ indicates that inequality (A.19) holds for any $\delta \in (0, \infty)$. Define inverses of f

$$\bar{n}_f(\delta, r) = \arg \max\{n : f(n, \delta) \leq r\}$$
 and $\delta_f(n, r) = \arg \max\{\delta : f(n, \delta) \leq r\}.$

It follows that $n > \bar{n}_f(\delta, r)$ for some $\delta > 0$ implies $\bar{\delta}_f(n, r) \leq \delta$.

THEOREM A.2. Suppose that the data matrix \mathbf{X} consists of n i.i.d. copies of zeromean continuous random vector $X \in \mathbb{R}^p$ satisfying the tail condition $\mathcal{T}(f, v_*)$ of Definition A.1. Also suppose that the covariance matrix Σ^* of X satisfies Assumption 4.1. Let $\mathbf{S} = \frac{1}{n} \mathbf{X}^T \mathbf{X}$ and $\hat{\mathbf{\Omega}}$ be the unique solution to the ACCORD problem in (3.2) with $\lambda = \lambda_n = (10\kappa_{\Omega^*}/\alpha)\overline{\delta}_f(n, p^{\tau})$ for some $\tau > 2$. If the sample size n is such that

(A.20)
$$n > \bar{n}_f \left(\min\left\{ \frac{\min\left\{\frac{1}{3\gamma_1}, \frac{1}{3\gamma_1^3 \kappa_{\Gamma^*}}, \frac{\kappa_{\Omega^*}}{3d}\right\}}{3\kappa_{\Gamma^*}\kappa_{\Omega^*} \left(1 + \frac{10}{\alpha}\right)}, \frac{2}{27\gamma_1^3 \kappa_{\Gamma^*}^2 \kappa_{\Omega^*} \left(1 + \frac{10}{\alpha}\right)^2}, \frac{1}{v_*} \right\}, p^\tau \right),$$

then for $C = 3\kappa_{\Gamma^*}\kappa_{\Omega^*} (1+10/\alpha)$ and with a probability no smaller than $1-p^{-(\tau-2)}$, (a) there holds

(A.21)
$$\|\hat{\boldsymbol{\Omega}} - \boldsymbol{\Omega}^*\|_{\infty} \leqslant C \,\overline{\delta}_f(n, p^{\tau});$$

(b) the estimated support set $S(\hat{\Omega}) = \{(i, j) \in V \times V : \hat{\omega}_{ij} \neq 0, i \neq j\}$ is contained in the true support S and includes all coordinates (i, j) with $|\omega_{ij}^*| > C \,\overline{\delta}_f(n, p^{\tau})$.

PROOF. Let

(A.22)
$$\tilde{\boldsymbol{\Omega}} = \underset{\boldsymbol{\Omega}_{S^c}=0}{\operatorname{arg\,min}} \left\{ -\log \det \boldsymbol{\Omega}_D + \frac{1}{2} \operatorname{tr}(\boldsymbol{\Omega}^T \boldsymbol{\Omega} \boldsymbol{S}) + \lambda \|\boldsymbol{\Omega}\|_1 \right\}$$

be the oracle solution, where S denotes the support of Ω^* (hence of $\Theta^* = \Sigma^{*-1}$). This solution is also unique under the general position condition. We want to find a condition such that $\hat{\Omega} = \tilde{\Omega}$ with a high probability.

The KKT optimality condition for (3.2) is

(A.23)
$$-\boldsymbol{\Omega}_D^{-1} + \boldsymbol{\Omega} \boldsymbol{S} + \lambda \boldsymbol{Z} = 0, \quad \exists \boldsymbol{Z} \in \partial \|\boldsymbol{\Omega}\|_1$$

where $\partial \|\mathbf{\Omega}\|_1 = \{(z_{ij}) : z_{ij} = \operatorname{sign}(\omega_{ij}) \text{ if } \omega_{ij} \neq 0, \ z_{ij} \in [-1,1] \text{ if } \omega_{ij} = 0\}$. Thus if we let $\tilde{\mathbf{Z}} = (\tilde{z}_{ij}) = \frac{1}{\lambda} (\tilde{\mathbf{\Omega}}_D^{-1} - \tilde{\mathbf{\Omega}} \mathbf{S})$ and verify that

(A.24)
$$\|\tilde{\boldsymbol{Z}}_{S^c}\|_{\infty} = \max_{(i,j)\in S^c} |\tilde{z}_{ij}| < 1,$$

then the pair $(\hat{\Omega}, \tilde{Z})$ satisfies condition (A.23) and $\tilde{\Omega}$ minimizes the objective function in (3.2). By the uniqueness of the solution, we have $\hat{\Omega} = \tilde{\Omega}$. The rest of the proof is to find a condition under which (A.24) holds. In order to do this, we need the following lemmas, proved in Appendix A.7.

LEMMA A.6 (Control of the oracle estimation error). Suppose

$$r := 3\kappa_{\Gamma^*}(\kappa_{\Omega^*} \| \boldsymbol{W} \|_{\infty} + \lambda) \leqslant \min\left\{\frac{1}{3\gamma_1}, \frac{1}{3\gamma_1^3 \kappa_{\Gamma^*}}, \frac{\kappa_{\Omega^*}}{3d}\right\},$$

where $\boldsymbol{W} = \boldsymbol{S} - \boldsymbol{\Sigma}^*$. Then, $\|\tilde{\boldsymbol{\Omega}} - \boldsymbol{\Omega}^*\|_{\infty} \leq r$.

LEMMA A.7 (Control of remainder). For $\Delta = \tilde{\Omega} - \Omega^*$, let

$$R(\boldsymbol{\Delta}_D) = -\boldsymbol{\Omega}_D^{*-1} \left[\sum_{k=2}^{\infty} (-\boldsymbol{\Delta}_D \boldsymbol{\Omega}_D^{*-1})^k \right].$$

If $\|\mathbf{\Delta}\|_{\infty} \leq \frac{1}{3\gamma_1}$, then $\|R(\mathbf{\Delta}_D)\|_{\infty} \leq \frac{3}{2}\gamma_1^3 \|\mathbf{\Delta}\|_{\infty}^2$.

LEMMA A.8 (Strict dual feasibility). For the primal solution $\tilde{\Omega}$ to the oracle problem (A.22), let $\Delta = \tilde{\Omega} - \Omega^*$. Suppose

$$\|R(\boldsymbol{\Delta}_D)\|_{\infty} + \kappa_{\Omega^*} \|\boldsymbol{W}\|_{\infty} + d\|\boldsymbol{W}\|_{\infty} \|\boldsymbol{\Delta}\|_{\infty} \leq \alpha \lambda/4.$$

Then under the irrepresentability assumption (4.2), the dual optimum $\tilde{\mathbf{Z}}$ for the oracle problem (A.22) satisfies (A.24), i.e., $\|\mathbf{Z}_{S^c}\|_{\infty} < 1$, and therefore, $\hat{\mathbf{\Omega}} = \tilde{\mathbf{\Omega}}$.

Putting all things together, we now complete the main proof. The lower bound (A.20) of the sample size implies

(A.25)
$$\bar{\delta}_f(n, p^{\tau}) \leqslant \min\left\{\frac{\min\left\{\frac{1}{3\gamma_1}, \frac{1}{3\gamma_1^3\kappa_{\Gamma^*}}, \frac{\kappa_{\Omega^*}}{3d}\right\}}{3\kappa_{\Gamma^*}\kappa_{\Omega^*}\left(1 + \frac{10}{\alpha}\right)}, \frac{2}{27\gamma_1^3\kappa_{\Gamma^*}^2\kappa_{\Omega^*}\left(1 + \frac{10}{\alpha}\right)^2}, \frac{1}{v_*}\right\}.$$

The inequality (A.25) implies $\bar{\delta}_f(n, p^{\tau}) \leq 1/v_*$. Then the event (A.26) $\{ \| \boldsymbol{W} \|_{\infty} \leq \bar{\delta}_f(n, p^{\tau}) \}$ occurs with a probability of at least $1 - p^{-(\tau-2)}$ (Ravikumar et al., 2011, Lemma 8). In the sequel, we condition on the event (A.26).

Recall that we have chosen $\lambda = \frac{10\kappa_{\Omega^*}}{\alpha} \bar{\delta}_f(n, p^{\tau})$. Then,

(A.27)
$$\kappa_{\Omega^*} \| \boldsymbol{W} \|_{\infty} \leqslant \frac{\alpha}{10} \lambda$$

and $r = 3\kappa_{\Gamma^*}(\kappa_{\Omega^*} \| \boldsymbol{W} \|_{\infty} + \lambda) \leq 3\kappa_{\Gamma^*}(\alpha/10 + 1)\lambda = 3\kappa_{\Gamma^*}\kappa_{\Omega^*}(1 + 10/\alpha)\bar{\delta}_f(n, p^{\tau})$. Now Lemma A.6 combined with the inequality (A.25) yields

(A.28)
$$\|\mathbf{\Delta}\|_{\infty} \leqslant r \leqslant 3\kappa_{\Gamma*}\kappa_{\Omega*} \left(1 + 10/\alpha\right) \bar{\delta}_f(n, p^{\tau}) \leqslant \min\left\{\frac{1}{3\gamma_1}, \frac{1}{3\gamma_1^3\kappa_{\Gamma*}}, \frac{\kappa_{\Omega*}}{3d}\right\}.$$

It then follows from Lemma A.7 that

(A.29)
$$\|R(\mathbf{\Delta}_{D})\|_{\infty} \leq \frac{3}{2}\gamma_{1}^{3}\|\mathbf{\Delta}\|_{\infty}^{2} \leq \frac{3}{2}\gamma_{1}^{3}r^{2}$$
$$\leq \frac{3}{2}\gamma_{1}^{3} \cdot 9\kappa_{\Gamma^{*}}^{2}\kappa_{\Omega^{*}}^{2} (1+10/\alpha)^{2} \bar{\delta}_{f}^{2}(n,p^{\tau})$$
$$= \frac{27}{2}\gamma_{1}^{3}\kappa_{\Gamma^{*}}^{2}\kappa_{\Omega^{*}}^{2} (1+10/\alpha)^{2} \bar{\delta}_{f}(n,p^{\tau}) \frac{\alpha}{10\kappa_{\Omega^{*}}} \lambda$$
$$\leq \frac{\alpha}{10} \lambda,$$

since from (A.25), n satisfies $\frac{27}{2}\gamma_1^3\kappa_{\Gamma^*}^2\kappa_{\Omega^*}^2(1+10/\alpha)^2\bar{\delta}_f(n,p^{\tau}) \leq \kappa_{\Omega^*}$. Finally, from (A.27),

(A.30)
$$d\|\mathbf{\Delta}\|_{\infty}\|\mathbf{W}\|_{\infty} \leq dr\|\mathbf{W}\|_{\infty} \leq d\frac{\kappa_{\Omega^*}}{3d}\|\mathbf{W}\|_{\infty} \leq \frac{1}{3}\frac{\alpha}{10}\lambda = \frac{\alpha}{30}\lambda.$$

Combining (A.27), (A.29), and (A.30),

$$\|R(\boldsymbol{\Delta}_D)\|_{\infty} + \kappa_{\Omega^*} \|\boldsymbol{W}\|_{\infty} + d\|\boldsymbol{\Delta}\|_{\infty} \|\boldsymbol{W}\|_{\infty} \leq \frac{\alpha}{10}\lambda + \frac{\alpha}{10}\lambda + \frac{\alpha}{30}\lambda < \frac{\alpha}{4}\lambda,$$

and the condition for Lemma A.8 is satisfied. Consequently, $\hat{\Omega} = \tilde{\Omega}$ and $\Delta = \hat{\Omega} - \Omega^*$. Then, conclusion (A.21) holds by (A.28). That $S(\hat{\Omega}) \subset S$ also follows since $\hat{\Omega}_{S^c} = \tilde{\Omega}_{S^c} = \Omega_{S^c}^* = \Omega_{S^c}^* = 0$. Furthermore, if

$$|\omega_{ij}^*| > 3\kappa_{\Gamma^*}\kappa_{\Omega^*} (1+10/\alpha) \,\overline{\delta}_f(n, p^\tau),$$

then $\hat{\omega}_{ij} \neq 0$ since otherwise $|\hat{\omega}_{ij} - \omega_{ij}^*| > 3\kappa_{\Gamma^*}\kappa_{\Omega^*} (1 + 10/\alpha) \,\overline{\delta}_f(n, p^{\tau})$, contradicting (A.21).

PROOF OF THEOREM 4.2. The conclusion of Theorem 4.2 follows by noting that each normalized coordinate variable $X_i/\sqrt{\Sigma_{ii}^*}$ is sub-Gaussian with parameter σ and satisfies the tail condition $\mathcal{T}(f, v_*)$ with $v_* = [(\max_{i \in [p]} \Sigma_{ii}^*)8(1 + 4\sigma^2)]^{-1}$ and

$$f(n,\delta) = \frac{1}{4} \exp(c_* n \delta^2), \quad c_* = [128(1+4\sigma^2)^2 \max_{i \in [p]} (\Sigma_{ii}^*)^2]^{-1},$$

$$\bar{\delta}_f(n,r) = \sqrt{\frac{\log(4r)}{c_* n}}, \qquad \bar{n}_f(\delta,r) = \frac{\log(4r)}{c_* \delta^2}$$

(Ravikumar et al., 2011, §2.3) and applying Theorem A.2.

A.5. Proof of Theorem 4.3. Again we prove a more general result:

THEOREM A.3 (Model selection and sign consistency). Under the conditions of Theorem A.2, suppose that the sample size n is such that

$$n > \bar{n}_f \left(\min\left\{ C^{-1}\omega, \delta \right\}, p^\tau \right)$$

for some $0 < \omega < \omega_{\min}$. Then, the event

$$\{\operatorname{sign}(\omega_{ij}^*) = \operatorname{sign}(\hat{\omega}_{ij}) \text{ for all } (i,j) \in S\}$$

occurs with a probability no smaller than $1 - p^{-(\tau-2)}$.

PROOF. Following the procedures of proving Theorem A.2, we can show that with probability not smaller than $1 - p^{-(\tau-2)}$, $\hat{\Omega}_{S^c} = \tilde{\Omega}_{S^c} = 0$, which indicates that the ACCORD solution is the same as the oracle solution. Thus, all edges outside the true edge set S are excluded. Then, using Lemma A.6, we have

$$\|\widehat{\boldsymbol{\Omega}}_S - \boldsymbol{\Omega}_S^*\|_{\infty} \leqslant C\delta_f(n, p^{\tau}) \leqslant \omega < \omega_{\min}$$

since $n > \bar{n}_f \left(\min \{ C^{-1}\omega, \delta \}, p^{\tau} \right)$ implies $\bar{\delta}_f(n, p^{\tau}) \leq C^{-1}\omega$. Then, we can conclude that for every $(i, j) \in S$, $\hat{\omega}_{ij}$ has the same sign as ω_{ij}^* , because otherwise, $\omega_{\min} > |\hat{\omega}_{ij} - \omega_{ij}^*| = |\hat{\omega}_{ij}| + |\omega_{ij}^*| \geq |\omega_{ij}^*|$, which violates the definition of ω_{\min} .

PROOF OF THEOREM 4.3. The conclusion of Theorem 4.3 follows from Theorem A.3 by specifying $f(n,\delta)$, v_* , c_* , $\bar{\delta}_f(n,r)$, and $\bar{n}_f(\delta,r)$ as in the proof of Theorem 4.2 and setting $\omega = \omega_{\min}/2$.

A.6. Results for polynomial tails. It can be shown that a zero-mean random vector $X \in \mathbb{R}^p$ with covariance matrix Σ^* where each coordinate variable X_i has a bounded 4*m*-th moment satisfies the tail condition with $v_* = 0$ and has a polynomial-type tail. Specifically, if

$$\mathbb{E}\left[\left(X_i/\sqrt{\Sigma_{ii}^*}\right)^{4m}\right] \leqslant K_m < \infty$$

for some $K_m > 0$, then

$$f(n,\delta) = c_* n^m \delta^{2m}, \quad c_* = [m^{2m+1} 2^{2m} (\max_i \Sigma_{ii}^*)^{2m} (K_m + 1)]^{-1}$$

and

$$\bar{\delta}_f(n,r) = \frac{(r/c_*)^{1/2m}}{\sqrt{n}}, \quad \bar{n}_f(\delta,r) = \frac{(r/c_*)^{1/m}}{\delta^2}$$

(Ravikumar et al., 2011, §2.3). In this case, Theorem A.2 and Theorem A.3 incarnate as the following.

COROLLARY A.1 (Elementwise error). Suppose the data matrix $\mathbf{X} \in \mathbb{R}^{n \times p}$ is composed of n i.i.d. copies of zero-mean continuous random vector $X = (X_1, \ldots, X_p) \in \mathbb{R}^p$ with covariance matrix $\mathbf{\Sigma}^* = (\Sigma_{ij}^*) = \mathbf{\Theta}^{*-1}$ and each X_j satisfies $\mathbf{E}(X_j/\sqrt{\Sigma_{jj}^*})^{4m} \leq K_m < \infty$ for a positive integer m. Let $\sigma^2 = \max_{j \in [p]} \Sigma_{jj}^*$. If further Assumption 4.1 holds, then for $\lambda = 20m^{1+1/(2m)}(K_m + 1)^{1/(2m)}\sigma^2\kappa_{\Omega^*}\alpha^{-1}p^{\tau/(2m)}/\sqrt{n}, \tau > 2$,

1. there holds $\|\hat{\mathbf{\Omega}} - \mathbf{\Omega}^*\|_{\infty} \leq 6m^{1+1/(2m)}(K_m + 1)^{1/(2m)}\sigma^2\kappa_{\Gamma^*}\kappa_{\Omega^*}(1 + 10/\alpha)p^{\tau/2m}/\sqrt{n};$

2. the estimated support set $\hat{S} = \{(i, j) \in [p] \times [p] : \hat{\omega}_{ij} \neq 0\}$ is contained in the true support S and includes all edges (i, j) with

$$|\omega_{ij}^*| > 6m^{1+1/(2m)} (K_m + 1)^{1/(2m)} \sigma^2 \kappa_{\Gamma^*} \kappa_{\Omega^*} (1 + 10/\alpha) p^{\tau/2m} / \sqrt{n}$$

with a probability no smaller than $1 - p^{-(\tau-2)}$, provided that $n > 4m^{2+1/m}(K_m + 1)^{1/m}\sigma^4\delta^{-2}p^{\tau/m}$ where

$$\delta = \min\left\{\frac{\min\left\{\frac{1}{3\gamma_1}, \frac{1}{3\gamma_1^3 \kappa_{\Gamma^*}}, \frac{\kappa_{\Omega^*}}{3d}\right\}}{3\kappa_{\Gamma^*}\kappa_{\Omega^*}\left(1+10/\alpha\right)}, \frac{2}{27\gamma_1^3\kappa_{\Gamma^*}^2\kappa_{\Omega^*}\left(1+10/\alpha\right)^2}\right\}.$$

COROLLARY A.2 (Edge selection and sign consistency). Assume the same conditions as Corollary A.1. If the sample size satisfies

$$n > 4\sigma^4 (K_m + 1)^{1/m} p^{\tau/m} / \min\{\omega_{\min} / [6\kappa_{\Gamma^*} \kappa_{\Omega^*} (1 + 10/\alpha)], \delta\}^2$$

where σ and δ are as defined in Corollary A.1, then the event

$$\{\operatorname{sign}(\omega_{ij}^*) = \operatorname{sign}(\hat{\omega}_{ij}) \text{ for all } (i,j) \in S\}$$

occurs with a probability no smaller than $1 - p^{-(\tau-2)}$.

A.7. Proofs of technical lemmas. Throughout, it is convenient to note (A.31) $\operatorname{vec}(ABC) = (C^T \otimes A) \operatorname{vec}(B).$

PROOF OF LEMMA A.4. Fix the sample (X^1, \dots, X^n) , and rewrite the left side of the inequality as

$$\begin{aligned} \mathbf{E}_{\epsilon} \left[\sup_{f \in \mathcal{F}} \sum_{i=1}^{n} \epsilon_{i} (\phi_{i} \circ f)(X^{i}) \right] &= \mathbf{E}_{\epsilon_{1}, \cdots, \epsilon_{n-1}} \mathbf{E}_{\epsilon_{n}} \sup_{f \in \mathcal{F}} \left[m_{n-1}(f) + \epsilon_{n} (\phi_{n} \circ f)(X^{n}) \right] \\ &= \frac{1}{2} \mathbf{E}_{\epsilon_{1}, \cdots, \epsilon_{n-1}} \sup_{f \in \mathcal{F}} \left[m_{n-1}(f) + (\phi_{n} \circ f)(X^{n}) \right] \\ &+ \frac{1}{2} \mathbf{E}_{\epsilon_{1}, \cdots, \epsilon_{n-1}} \sup_{f \in \mathcal{F}} \left[m_{n-1}(f) - (\phi_{n} \circ f)(X^{n}) \right], \end{aligned}$$

where $m_{n-1}(f) = \sum_{i=1}^{n-1} \epsilon_i(\phi_i \circ f)(X^i)$. For fixed $\epsilon_1, \dots, \epsilon_{n-1}$, note that there exists f_1, f_2 such that

$$\frac{1}{2} \sup_{f \in \mathcal{F}} \left[m_{n-1}(f) + (\phi_n \circ f)(X^n) \right] + \frac{1}{2} \sup_{f \in \mathcal{F}} \left[m_{n-1}(f) - (\phi_n \circ f)(X^n) \right] - \delta$$

$$\leq \frac{1}{2} \left[m_{n-1}(f_1) + (\phi_n \circ f_1)(X^n) \right] + \frac{1}{2} \left[m_{n-1}(f_2) - (\phi_n \circ f_2)(X^n) \right],$$

for some arbitrary $\delta > 0$. Let $s = sign(f_1(X^n) - f_2(X^n))$. Then, we have

$$\begin{aligned} \mathbf{E}_{\epsilon_n} \sup_{f \in \mathcal{F}} \left[m_{n-1}(f) + \epsilon_n (\phi_n \circ f)(X^n) \right] &- \delta \\ &\leq \frac{1}{2} \left[m_{n-1}(f_1) + m_{n-1}(f_2) + Ls(f_1(X^n) - f_2(X^n)) \right] \quad (L\text{-Lipschitz}) \\ &\leq \frac{1}{2} \sup_{f \in \mathcal{F}} \left[m_{n-1}(f) + Lsf(X^n) \right] + \frac{1}{2} \sup_{f \in \mathcal{F}} \left[m_{n-1}(f) - Lsf(X^n) \right] \\ &= \mathbf{E}_{\epsilon_n} \sup_{f \in \mathcal{F}} \left[m_{n-1}(f) + L\epsilon_n f(X^n) \right]. \end{aligned}$$

Since the inequality holds for arbitrary $\delta > 0$, we have

$$\mathbf{E}_{\epsilon_n} \sup_{f \in \mathcal{F}} \left[m_{n-1}(f) + \epsilon_n (\phi_n \circ f)(X^n) \right] \leq \mathbf{E}_{\epsilon_n} \sup_{f \in \mathcal{F}} \left[m_{n-1}(f) + L\epsilon_n f(X^n) \right],$$

and repeating this step proves the lemma by induction.

PROOF OF LEMMA A.5. By Jensen's inequality, for any t > 0,

$$\exp(t \mathbf{E}_X[\max_i |X_i|]) \leq \mathbf{E}_X \max_i \exp(t|X_i|)$$
$$\leq \sum_{i=1}^p \{\mathbf{E}_X \exp(tX_i) + \mathbf{E}_X \exp(-tX_i)\} \leq 2p \exp(t^2 \sigma^2/2),$$

Therefore, $\mathbf{E}_X[\max_i |X_i|] \leq \frac{\log 2p}{t} + \frac{t\sigma^2}{2}$, and setting $t = \sqrt{2\log 2p}/\sigma$ proves the inequality.

PROOF OF LEMMA A.6. The optimality conditions for the oracle problem (A.22) are

(A.32a)
$$[-\boldsymbol{\Omega}_D^{-1} + \boldsymbol{\Omega}\boldsymbol{S} + \lambda \boldsymbol{Z}]_S = 0, \quad \exists \boldsymbol{Z} \in \partial \|\boldsymbol{\Omega}\|_1,$$

(A.32b)
$$\mathbf{\Omega}_{S^c} = 0$$

For any $\Omega \in \mathbb{R}^{p \times p}$ satisfying (A.32b), write $\Omega = \Omega^* + \Delta$. Then $\Omega = \Omega_S = \Omega_S^* + \Delta_S$, $\Omega_D = \Omega_D^* + \Delta_D$, and $\Delta_{S^c} = 0$, $\Delta = \Delta_S$. Then,

$$\begin{split} [-\Omega_D^{-1} + \Omega S + \lambda Z]_S &= -[\Omega_D^{-1}]_S + [\Omega S]_S + \lambda Z_S \\ &= -[(\Omega_D^* + \Delta_D)^{-1}]_S + [(\Omega^* + \Delta)(\Sigma^* + W)]_S + \lambda Z_S \\ &= -[(\Omega_D^* + \Delta_D)^{-1}]_S + [\Omega^* \Theta^{*-1} + \Delta \Sigma^* + \Omega^* W + \Delta W]_S + \lambda Z_S \\ &= -[(\Omega_D^* + \Delta_D)^{-1}]_S + [\Omega_D^{*-1} + \Delta \Sigma^* + \Omega^* W + \Delta W]_S + \lambda Z_S \\ &= [-(\Omega_D^* + \Delta_D)^{-1} + \Omega_D^{*-1}]_S + [\Delta \Sigma^*]_S + [\Omega^* W]_S + [\Delta W]_S + \lambda Z_S \\ &= [-(\Omega_D^* + \Delta_D)^{-1} + \Omega_D^{*-1}]_S + [\Delta_S \Sigma^*]_S + [\Omega^* W]_S + [\Delta_S W]_S + \lambda Z_S \\ &= : G(\Delta_S). \end{split}$$

But

(

$$\begin{split} \Omega_D^* + \boldsymbol{\Delta}_D)^{-1} &= \left[(\boldsymbol{I}_p + \boldsymbol{\Delta}_D \Omega_D^{*-1}) \Omega_D^* \right]^{-1} \\ &= \Omega_D^{*-1} (\boldsymbol{I} + \boldsymbol{\Delta}_D \Omega_D^{*-1})^{-1} \\ &= \Omega_D^{*-1} \left[\sum_{k=0}^{\infty} (-\boldsymbol{\Delta}_D \Omega_D^{*-1})^k \right] \\ &= \Omega_D^{*-1} [\boldsymbol{I} - \boldsymbol{\Delta}_D \Omega_D^{*-1} + \sum_{k=2}^{\infty} (-\boldsymbol{\Delta}_D \Omega_D^{*-1})^k] \\ &= \Omega_D^{*-1} - \Omega_D^{*-1} \boldsymbol{\Delta}_D \Omega^{*-1} + \underbrace{\Omega_D^{*-1} [\sum_{k=2}^{\infty} (-\boldsymbol{\Delta}_D \Omega_D^{*-1})^k]}_{= -R(\boldsymbol{\Delta}_D)} < \infty, \end{split}$$

provided that the series converges.

16

Observing that $\mathbf{\Delta}_D = \sum_{i=1}^p e_i e_i^T \mathbf{\Delta} e_i e_i^T$, it follows that

$$G(\boldsymbol{\Delta}_{S}) = [\boldsymbol{\Omega}_{D}^{*-1}\boldsymbol{\Delta}_{D}\boldsymbol{\Omega}_{D}^{*-1} + \boldsymbol{\Delta}\boldsymbol{\Sigma}^{*}]_{S} + R(\boldsymbol{\Delta}_{D}) + [\boldsymbol{\Omega}^{*}\boldsymbol{W}]_{S} + [\boldsymbol{\Delta}_{S}\boldsymbol{W}]_{S} + \lambda \boldsymbol{Z}_{S}$$
$$= [\sum_{i=1}^{p} \boldsymbol{\Omega}_{D}^{*-1}e_{i}e_{i}^{T}\boldsymbol{\Delta}e_{i}e_{i}^{T}\boldsymbol{\Omega}_{D}^{*-1} + \boldsymbol{\Delta}_{S}\boldsymbol{\Sigma}^{*}]_{S} + R(\boldsymbol{\Delta}_{D}) + [\boldsymbol{\Omega}^{*}\boldsymbol{W}]_{S}$$
$$+ [\boldsymbol{\Delta}_{S}\boldsymbol{W}]_{S} + \lambda \boldsymbol{Z}_{S}.$$

Consider a vectorization of $G(\Delta_S)$:

(A.33)
$$g(\boldsymbol{\Delta}_{S}) = [\operatorname{vec} G(\boldsymbol{\Delta}_{S})]_{S}$$
$$= \Gamma_{SS}^{*} \operatorname{vec}(\boldsymbol{\Delta}_{S})_{S} + \operatorname{vec} R(\boldsymbol{\Delta}_{D})_{S} + \operatorname{vec}(\boldsymbol{\Omega}^{*}\boldsymbol{W})_{S} + \operatorname{vec}(\boldsymbol{\Delta}_{S}\boldsymbol{W})_{S}$$
$$+ \lambda \operatorname{vec}(\boldsymbol{Z}_{S})_{S}.$$

We recall (4.1), (A.31), and

$$\sum_{i=1}^{p} \mathbf{\Omega}_{D}^{*-1} e_{i} e_{i}^{T} \otimes \mathbf{\Omega}_{D}^{*-1} e_{i} e_{i}^{T} = (\mathbf{\Omega}_{D}^{*-1} \otimes \mathbf{\Omega}_{D}^{*-1}) \mathbf{\Upsilon}.$$

If we let $F : \mathbb{R}^{|S|} \to \mathbb{R}^{|S|}$ be

$$F(\mathbf{\Delta}_S) = \mathbf{vec}(\mathbf{\Delta}_S)_S - \mathbf{\Gamma}_{SS}^{*-1}g(\mathbf{\Delta}_S),$$

then $F(\Delta_S) = \mathbf{vec}(\Delta_S)_S$ if and only if either $G(\Delta_S) = 0$ or (A.32a) is satisfied.

Thus, if a fixed point of the map F exists, then it yields a solution to (A.32), which must be unique. It follows from (4.1) that

$$F(\boldsymbol{\Delta}_S) = \boldsymbol{\Gamma}_{SS}^{*-1} [-\operatorname{vec} R(\boldsymbol{\Delta}_D) - \operatorname{vec}(\boldsymbol{\Omega}^* \boldsymbol{W})_S - \operatorname{vec}(\boldsymbol{\Delta}_S \boldsymbol{W})_S - \lambda \operatorname{vec}(\boldsymbol{Z}_S)_S],$$

and

$$\begin{split} \|F(\boldsymbol{\Delta}_{S})\|_{\infty} &\leqslant \kappa_{\Gamma} * (\|R(\boldsymbol{\Delta}_{D})\|_{\infty} + \|\boldsymbol{\Omega}^{*}\|_{\infty} \|\boldsymbol{W}\|_{\infty} + \|\boldsymbol{W}\boldsymbol{\Delta}_{S}\|_{\infty} + \lambda). \\ &= \kappa_{\Gamma} * (\|R(\boldsymbol{\Delta}_{D})\|_{\infty} + \|\boldsymbol{\Delta}_{S}\|_{\infty} \|\boldsymbol{W}\|_{\infty} + \kappa_{\Omega} * \|\boldsymbol{W}\|_{\infty} + \lambda) \\ &\leqslant \kappa_{\Gamma} * (\|R(\boldsymbol{\Delta}_{D})\|_{\infty} + d\|\boldsymbol{\Delta}_{S}\|_{\infty} \|\boldsymbol{W}\|_{\infty} + \kappa_{\Omega} * \|\boldsymbol{W}\|_{\infty} + \lambda). \end{split}$$

This is because $\Delta = \Delta_S$ has at most d non-zeroes per row or column, and thus $\||\Delta_S||_{\infty} \leq d\|\Delta_S\|_{\infty}$. For any Δ_S such that $\|\Delta_S\|_{\infty} \leq r$ for some $r \in (0, 1/\gamma_1)$ (recall $\gamma_1 = 1/(\min_{i=1,\dots,p} \omega_{ii}^*) > 0$), we see

$$\|R(\boldsymbol{\Delta}_D)\|_{\infty} = \left\|\boldsymbol{\Omega}_D^{*-1} \sum_{k=2}^{\infty} (-\boldsymbol{\Delta}_D \boldsymbol{\Omega}_D^{*-1})^k\right\|_{\infty}$$
$$\leq \sum_{k=2}^{\infty} \|\boldsymbol{\Omega}_D^{*-1} (\boldsymbol{\Delta}_D \boldsymbol{\Omega}_D^{*-1})^k\|_{\infty} = \sum_{k=2}^{\infty} \max_{i=1,\dots,p} |\omega_{ii}^{*-1} (\delta_{ii}/\omega_{ii}^*)^k$$
$$\leq \sum_{k=2}^{\infty} \gamma_1 (\gamma_1 r)^k = \gamma_1^3 \frac{r^2}{1-\gamma_1 r} < \infty.$$

Thus, the series converges for the range of r claimed. If $r \leq \min\left\{\frac{1}{3\gamma_1}, \frac{1}{3\gamma_1^3\kappa_{\Gamma^*}}\right\}$, then

(A.34)
$$\kappa_{\Gamma^*} \| R(\mathbf{\Delta}_D) \|_{\infty} \leq \kappa_{\Gamma^*} \gamma_1^3 \frac{r^2}{1 - 1/3} = \kappa_{\Gamma^*} \frac{3}{2} \gamma_1^3 r^2 \leq \frac{3\gamma_1^3 \kappa_{\Gamma^*}}{2} \frac{1}{3\gamma_1^3 \kappa_{\Gamma^*}} r = \frac{r}{2}$$

Now equate $r = 3\kappa_{\Gamma^*}(\kappa_{\Omega^*} \| \boldsymbol{W} \|_{\infty} + \lambda)$. If further $r \leq \frac{\kappa_{\Omega^*}}{3d}$, then

$$\kappa_{\Gamma^*} d \| \boldsymbol{W} \|_{\infty} \| \boldsymbol{\Delta}_S \|_{\infty} \leq \kappa_{\Gamma^*} d \| \boldsymbol{W} \|_{\infty} r \leq \kappa_{\Gamma^*} d \| \boldsymbol{W} \|_{\infty} \frac{\kappa_{\Omega^*}}{3d}$$
$$= \frac{1}{3} \kappa_{\Gamma^*} \kappa_{\Omega^*} \| \boldsymbol{W} \|_{\infty} \leq \frac{1}{3} \kappa_{\Gamma^*} (\kappa_{\Omega^*} \| \boldsymbol{W} \|_{\infty} + \lambda) = \frac{r}{9}.$$

Thus from (A.34),

$$\|F(\mathbf{\Delta}_S)\|_{\infty} \leqslant \frac{r}{2} + \frac{r}{9} + \frac{r}{3} \leqslant r$$

and F maps $B(r) = \{\Delta_S : \|\Delta_S\|_{\infty} \leq r\}$ to itself. Then, by Brouwer's fixed point theorem, F has a fixed point $\bar{\Delta}_S$ in B(r). It follows that $\bar{\Omega}_S = \Omega_S^* + \bar{\Delta}_S$ satisfies (A.32). By the uniqueness of the solution, we have $\tilde{\Omega} = \bar{\Omega}_S$, and

$$\|\bar{\boldsymbol{\Delta}}_S\|_{\infty} = \|\tilde{\boldsymbol{\Omega}} - \boldsymbol{\Omega}^*\|_{\infty} \leqslant r := 3\kappa_{\Gamma^*}(\kappa_{\Omega^*}\|\boldsymbol{W}\|_{\infty} + \lambda),$$

provided that

$$r \leq \min\left\{\frac{1}{3\gamma_1}, \frac{1}{3\gamma_1^3 \kappa_{\Gamma^*}}, \frac{\kappa_{\Omega^*}}{3d}\right\}.$$

PROOF OF LEMMA A.7. It follows immediately from the derivation of inequality (A.34) in the proof of Lemma A.6.

PROOF OF LEMMA A.8. From (A.32) and (A.33),

$$\operatorname{vec}(\Delta)_{S} = -\Gamma_{SS}^{*-1}[\operatorname{vec} R(\Delta_{D})_{S} + \operatorname{vec}(\Omega^{*}W)_{S} + \operatorname{vec}(\Delta W)_{S} + \lambda \operatorname{vec}(\tilde{Z})_{S}],$$

 $0 = \Gamma_{S^{c}S}^{*} \operatorname{vec}(\Delta)_{S} + [\operatorname{vec} R(\Delta_{D}) + \operatorname{vec}(\Omega^{*}W) + \operatorname{vec}(\Delta_{S}W) + \lambda \operatorname{vec}(\tilde{Z})]_{S^{c}}.$

Therefore,

$$\begin{split} \mathbf{vec}(\tilde{\boldsymbol{Z}}_{S^c}) = & \frac{1}{\lambda} \boldsymbol{\Gamma}_{S^c S}^* \boldsymbol{\Gamma}_{SS}^{*-1} [\mathbf{vec} \, R(\boldsymbol{\Delta}_D)_S + \mathbf{vec}(\boldsymbol{\Omega}^* \boldsymbol{W})_S + \mathbf{vec}(\boldsymbol{\Delta} \boldsymbol{W})_S \\ & + \lambda \, \mathbf{vec}(\tilde{\boldsymbol{Z}})_S] - \frac{1}{\lambda} [\mathbf{vec} \, R(\boldsymbol{\Delta}_D)_{S^c} + \mathbf{vec}(\boldsymbol{\Omega}^* \boldsymbol{W})_{S^c} + \mathbf{vec}(\boldsymbol{\Delta}_S \boldsymbol{W})_{S^c}] \\ & = & \frac{1}{\lambda} \boldsymbol{\Gamma}_{S^c S}^* \boldsymbol{\Gamma}_{SS}^{*-1} [\mathbf{vec} \, R(\boldsymbol{\Delta}_D)_S + \mathbf{vec}(\boldsymbol{\Omega}^* \boldsymbol{W})_S + \mathbf{vec}(\boldsymbol{\Delta} \boldsymbol{W})_S] \\ & + \boldsymbol{\Gamma}_{S^c S}^* \boldsymbol{\Gamma}^{*-1} \, \mathbf{vec}(\tilde{\boldsymbol{Z}})_S - \frac{1}{\lambda} [\mathbf{vec} \, R(\boldsymbol{\Delta}_D)_{S^c} + \mathbf{vec}(\boldsymbol{\Omega}^* \boldsymbol{W})_{S^c} \\ & + \mathbf{vec}(\boldsymbol{\Delta}_S \boldsymbol{W})_{S^c}], \end{split}$$

which entails

$$\begin{split} \|\tilde{\boldsymbol{Z}}_{S^{c}}\|_{\infty} &\leq \frac{1}{\lambda} \|\|\boldsymbol{\Gamma}_{S^{c}S}^{*}\boldsymbol{\Gamma}_{SS}^{*-1}\|\|_{\infty} [\|R(\boldsymbol{\Delta}_{D})_{S}\|_{\infty} + \|(\boldsymbol{\Omega}^{*}\boldsymbol{W})_{S}\|_{\infty} + \|(\boldsymbol{\Delta}\boldsymbol{W})_{S}\|_{\infty}] \\ &+ \|\|\boldsymbol{\Gamma}_{S^{c}S}^{*}\boldsymbol{\Gamma}_{SS}^{*-1}\|\|_{\infty} \|\operatorname{vec}(\tilde{\boldsymbol{Z}})_{S}\|_{\infty} + \frac{1}{\lambda} (\|R(\boldsymbol{\Delta}_{D})_{S^{c}}\|_{\infty} + \|(\boldsymbol{\Omega}^{*}\boldsymbol{W})_{S^{c}}\|_{\infty} \\ &+ \|(\boldsymbol{\Delta}_{S}\boldsymbol{W})_{S^{c}}\|_{\infty}) \\ &\leq \frac{1}{\lambda} (1-\alpha) [\|R(\boldsymbol{\Delta}_{D})_{S}\|_{\infty} + \|(\boldsymbol{\Omega}^{*}\boldsymbol{W})_{S}\|_{\infty} + \|(\boldsymbol{\Delta}\boldsymbol{W})_{S}\|_{\infty}] \end{split}$$

Fig S1: Edge detection performance comparison with various regularization parameter.

$$+1-\alpha + \frac{1}{\lambda} (\|R(\boldsymbol{\Delta}_D)_{S^c}\|_{\infty} + \|(\boldsymbol{\Omega}^*\boldsymbol{W})_{S^c}\|_{\infty} + \|(\boldsymbol{\Delta}_S\boldsymbol{W})_{S^c}\|_{\infty})$$

$$\leq \frac{2-\alpha}{\lambda} [\|R(\boldsymbol{\Delta}_D)\|_{\infty} + \|\boldsymbol{\Omega}^*\boldsymbol{W}\|_{\infty} + \|\boldsymbol{\Delta}\boldsymbol{W}\|_{\infty}] + 1-\alpha$$

$$\leq \frac{2-\alpha}{\lambda} [\|R(\boldsymbol{\Delta}_D)\|_{\infty} + \|\|\boldsymbol{\Omega}^*\|\|_{\infty} \|\boldsymbol{W}\|_{\infty} + \|\|\boldsymbol{\Delta}\|\|_{\infty} \|\boldsymbol{W}\|_{\infty}] + 1-\alpha$$

$$\leq \frac{2-\alpha}{\lambda} [\|R(\boldsymbol{\Delta}_D)\|_{\infty} + \kappa_{\Omega^*} \|\boldsymbol{W}\|_{\infty} + d\|\boldsymbol{\Delta}\|_{\infty} \|\boldsymbol{W}\|_{\infty}] + 1-\alpha$$

$$\leq \frac{2-\alpha}{\lambda} \frac{\alpha\lambda}{4} + 1-\alpha \leq \frac{\alpha}{2} + 1-\alpha < 1.$$

The second inequality is due to the irrepresentability assumption (4.2). The fifth inequality holds since Δ has at most d non-zeroes per row or column, and thus $\||\Delta|\|_{\infty} \leq d\|\Delta\|_{\infty}$.

APPENDIX B: ADDITIONAL FIGURES FROM NUMERICAL EXPERIMENTS

B.1. Edge detection. Figure S1 shows Matthews correlation coefficient (MCC) and precision-recall curves generated by varying regularization parameter λ , where each point represents averaged value of 50 replications in same λ . Overall, the mean edge detection performance of ACCORD was slightly better compared to CONCORD, CLIME and SPACE; this gap was bigger in Hub Network and Scale-free graph, which are more complex structures. Compared with graphical LASSO, ACCORD showed better MCC when the estimates are sparsely selected. In the precision-recall curves, ACCORD showed the best AUC in Hub Network and Scale-free graph, as shown in

Fig S2: Distributions of partial correlation estimates of ACCORD

Table 1. Also, we marked the most frequently selected model among all λ grid in Figure S1 for different criteria. The models selected by the plain pseudo-BIC or Gaussian BIC were denser than the models selected by extended pseudo-BIC. The sparser estimates selected with extended pseudo-BIC showed better results in terms of MCC. Hence, these results shows practical merit of using the extended pseudo-BIC in terms of tuning parameter selection; the selected models retain estimates with far less false positive edges in the expense of few true positive edges.

B.2. Parameter estimation. The impact of debiasing refit in ACCORD is demonstrated in Figure S2 for the suggested simulation settings. Each plot is a histogram showing the true partial correlations (T) and estimated partial correlations. Different colors are used to distinguish the estimated values at correctly detected nonzero locations (true positives or TP) and falsely detected nonzero locations (false positives or FP). The results clearly indicate that debiasing (3.8) consistently improves the accuracy of the estimates at TP locations while effectively controlling the magnitude of the FP, ensuring it remains relatively small.
