Abstract

We study the properties of 26 PNe with PG1159-type central stars known till date and compare them with the properties of PNe having [WR], *wels* and hydrogen-rich central stars published earlier. We use archival photometric measurements of 2*MAS S* for near-IR analysis and *W IS E* and *IRAS* data for mid- and far-IR analysis and derive the IR properties of PG1159-PNe. We analyze the IR colour-colour diagrams of PG1159-PNe and compare them with the other three groups of PNe. Similar to the [WR]-PNe, many PG1159-PNe also show large amount of near-IR emission from the hot-dust component but their AGB dust is relatively cooler. We also report here the dust colour temperatures, dust masses, dust-to-gas mass ratios, IR luminosities and IR excess of PG1159-PNe and plot them against their surface Hβ brightness (age) and compare them with the distribution of other groups of PNe. The IR luminosity and dust temperature show strong correlation with surface Hβ brightness, however, the dust-to-gas mass ratio and IR excess do not show any trend. While the mean dust mass has a lower value for PG1159-PNe, in compared to other groups, the average dust-to-gas mass ratio is found to be marginally larger for PG1159-PNe. An analysis of the number distribution of different groups of PNe against surface Hβ brightness shows that a) younger [WR]-, *wels*- and normal-PNe have a similar distribution indicating that they all have evolved from the AGB in a similar way, b) while there is an overlap of surface Hβ brightness between [WR]- and PG1159-PNe, showing an evolutionary connection between them, there exists a significant gap between the values derived for *wels*- and PG1159-PNe.

Keywords: (ISM:) planetary nebulae ; stars: H-poor stars ; evolution− AGB and post−AGB stars

1. Introduction

The planetary nebula (PN; plural PNe) phase occurs when the low- and intermediate-mass stars with initial masses 0.8 to 8 *M*_{sun} evolve from the AGB phase before attaining white-dwarf configuration as the end product. Depending on the hydrogen content in their atmospheres, the central stars of PNe (CSPNe) was classified into hydrogen-rich or hydrogen-poor [\(Mendez](#page-19-0) [\[1991\]](#page-19-0)). While most CSPNe are hydrogen-rich (H-rich, normal-PNe hereafter; [Todt et al.](#page-19-1) [\[2006\]](#page-19-1), about 30% of the CSPNe belong to the

[∗]Corresponding author: Tel.: +91 80 25530672; fax: +91 80 25534043;

hydrogen-poor (H-poor) category, where hydrogen is depleted in their stellar atmospheres and they have helium and carbon as the most abundant elements. A sizeable number of CSPNe (about 7%) are known to exhibit Wolf-Rayet type spectrum [\[Crowther](#page-19-2), [2008\]](#page-19-2) (hereafter [WR] stars and the PNe with [WR] CSPNe are [WR]-PNe) which show H-poor atmospheres with strong and broad emission lines of highly ionized carbon, oxygen and helium. [WR] stars are also subdivided into the early type [WRE] and late type [WRL] [\[Acker and Neiner,](#page-18-0) [2003\]](#page-18-0). There is also a group of CSPNe which show H-poor atmosphere and weak and narrow emission lines at the same wavelengths as those shown by [WR] stars, which are called the 'weak emission lines stars' (*wels*; PNe with *wels* CSPNe are *wels*-PNe hereafter). PG1159 stars form another group of H-poor post-AGB stars with similar surface abundances to other H-poor CSPNe. While [WR] stars and *wels* stars are always surrounded by PNe; only a fraction of PG1159 stars have PNe around them, which are usually faint (PG1159-PNe hereafter).

PG1159 stars represent post-AGB evolution with the hottest known H-poor atmospheres (T_{eff} up to 200,000 K)[\[Werner and Herwig](#page-20-0), [2006,](#page-20-0) Löbling et al., [2019\]](#page-19-3). They are named after the proto-type star PG1159-035, a faint blue object of magnitude 14.5 by [Winget et al.](#page-20-1) [\[1985](#page-20-1)] in the Palomar green survey [\[Green et al.,](#page-19-4) [1986\]](#page-19-4). In the H-R diagram, PG1159 stars occupy a region with low luminosity and high surface temperature[\[Werner and Herwig](#page-20-0), [2006](#page-20-0), [De Marco,](#page-19-5) [2008\]](#page-19-5). Their optical spectrum is dominated by He II and C IV absorption lines [\[Werner](#page-20-2), [1993\]](#page-20-2). It is believed that PG1159 stars have experienced re-ignition of helium, resulting in helium flash (thermal pulse [Catelan et al.](#page-19-6) [\[1996\]](#page-19-6)), which dredged up the stellar atmospheres with the inter-shell abundance of carbon and oxygen metals, like other H-poor stars [Górny and Tylenda, [2000](#page-19-7)]. Hence, H-poor CSPNe are the test beds of helium-burning CSPNe models [Górny et al., [2001\]](#page-19-8). Some of these PG1159 stars might still be fusing helium. There is also a sub-group of PG1159 CSPNe called hybrid PG1159 [\[Schoenberner and Napiwotzki,](#page-19-9) [1990](#page-19-9)] which show hydrogen in absorption. With the high surface temperature and gravity, PG1159 remained a unique stellar object until it was discovered that the central star of the PN K 1-16 is a pulsating variable star similar to PG1159-035. Subsequently, more objects which are similar to PG1159-035 and K 1-16 were discovered with an extended Palmoar survey, resulting in a new class of extremely hot pulsators. Other characteristics of PG1159 stars are that they are non-radial g-mode pulsators with varying pulsation periods and are given a sub-class of GW Variable stars (or GW Vir), for example, SDSS J0349-0059 [\[Woudt et al.,](#page-20-3) [2012\]](#page-20-3). In his work, [Werner](#page-20-2) [\[1993](#page-20-2)] has introduced multiple sub-classes in the PG1159 class of stars based on these variable pulsations.

The evolutionary path of low- and intermediate-mass stars which give birth to H-poor CSPNe should have some difference with the path followed by H-rich CSPNe. How and when their evolutionary paths differ is not yet well understood. Importantly, the evolutionary connections between different types of H-poor CSPNe are not fully known. PNe around H-rich and H-poor CSPNe should have this information imprinted with them; hence their properties must be probed in detail. The chemical composition and other properties of 30 [WR]-PNe and 18 *wels*-PNe were studied and compared to a sample of normal-PNe by [Girard et al.](#page-19-10) [\[2007\]](#page-19-10) . Górny et al. [\[2001\]](#page-19-8) analyzed the IR properties of 49 [WR]-PNe and addressed their dust content using near- and mid-IR photometric and spectroscopic observations gathered from the literature. A recent study on the physical properties of [WR]-PNe with its sub-types can also be seen in [Awad and Ali](#page-18-1) [\[2023\]](#page-18-1) . A uniform IR analysis of known PNe surrounding 99 [WR]- and 67 *wels*central stars was made by [Muthumariappan and Parthasarathy](#page-19-11) [\[2020\]](#page-19-11) (MP20, hereafter), and their properties were compared with a randomly selected sample of 100 PNe with H-rich central stars. Nebular and dust properties derived by them using *IRAS* , *W IS E* and *Akari* data showed several differences from which they addressed the evolutionary connections between different groups of PNe. They argued that [WR]-PNe and *wels*-PNe are two different groups of PNe, and they do not form an evolutionary sequence, though they share many similar properties. Their study also found very old PNe only in the normal-PNe group and [WR]- and

wels-PNe are not seen as very old PNe, suggesting that they evolve to group of PNe with different type of H-poor central stars, possibly PG1159.

Though it is believed that [WR] stars can turn into PG1159, possible evolutionary link(s) between PG-1159 stars and [WR] and *wels* stars are still unknown. It is essential to study the infrared and other related properties of all known PG1159-PNe and compare them with the [WR]- and *wels*-PNe properties in order to address the evolutionary links between different H-poor CSPNe. We aim to do this by investigating the IR properties of PG1159-PNe and their relation with the IR properties derived for [WR]and *wels*-PNe by MP20 and also aim to make an age analysis for different groups of H-poor PNe. Nebulae around many PG1159 stars were dispersed into the ISM, and this study can be made with the limited number of PNe around these stars. We compile 26 known PNe with PG1159 central stars, and we use the IR colour-colour diagrams of PG1159-PNe derived using photometry at 2*MAS S* , *IRAS* and *W IS E* bands and also derive their nebular and dust properties from *IRAS* fluxes at 25- and 60µm bands. We also invoke a statistical analysis of Hβ surface brightness distribution of all groups of PNe to constrain the origin of H-poor PNe and to understand the evolutionary connection of PG1159 stars with the [WR] and *wels* stars in their journey towards white dwarf. Though the interest of the community is further enhanced by the presence of pulsations in PG1159 CSPNe to study their internal structure, it is beyond the scope of this work, and hence it is not addressed here.

We organize the paper in the following way: Section [2](#page-2-0) provides the data sample and computation of IR properties; Section [3](#page-3-0) presents the results we obtained from the i) colour-colour diagrams in the near and mid-IR bands for [WR]-,*wels*-, PG1159- and normal-PNe, ii) gas and dust properties derived for these groups of PNe, iii) statistical analysis of *S_{Hβ}* for different groups of PNe with H-poor central stars. A discussion on the dust-to-gas mass ratios in PNe and on the origin of PNe with H-rich and H-poor central stars are given in Section [4.](#page-15-0) Our conclusions are listed in Section [5.](#page-18-2)

2. Data Sample and computation of IR parameters

We used the IR photometric data obtained from the archives for this study. The *Two Micron All Sky Survey* (2*MASS*) [\[Skrutskie et al.](#page-19-12), [2006](#page-19-12)] data was used to compute the near-IR fluxes from the magnitude measurements available at different wavebands. Mid- and far-IR fluxes were computed from the stellar magnitudes obtained from the *Wide* − *f ield In f rared S urvey Explorer* (*WIS E*; [Wright et al.](#page-20-4) [\[2010\]](#page-20-4), [Cutri](#page-19-13) [\[2012\]](#page-19-13)) at 3.4-, 4.2-, 12- and 22 μ m bands and the fluxes at 12-, 25-, 60- and 100 μ m bands of *In f raRed Astronomical S atellite* (*IRAS* ; [Neugebauer et al.](#page-19-14) [\[1984\]](#page-19-14)). The IR data taken for this study are available at the NASA/IPAC Infrared Science Archive ^{*a*}. *Akari* data were not available for most of the sources, and we don't use them here as they form poor statistics. All the archival data we have used for this study have definite error measurements. They were used to estimate the errors associated with the derived parameters.

We searched for the confirmed candidate of PG1159 stars with PNe around them in the literature. There are 67 objects which were classified as PG1159 stars; among them 26 sources (39%) have PNe. A list of 22 PG1159-PNe and 4 hybrid PG1159-PNe are given in Table 1, which makes our sample (WeSb 3 is a doubtful PG1159-PN hence it is not included [\[Weidmann and Gamen,](#page-19-15) [2011\]](#page-19-15)). Most of them come from the catalogue of spectral classification of CSPNe given by [Weidmann and Gamen](#page-19-15) [\[2011\]](#page-19-15). References for PN candidates which have hybrid-PG1159 central stars are given in the table. We have used the nebular *H*β fluxes and electron densities of PNe, required for our investigation given in Stasińska and Szczerba [\[1999a\]](#page-19-16). Optical size of the nebula the values of *E*(*B* − *V*) and the distances for all the PG1159-PNe in our sample are from [Frew et al.](#page-19-17) [\[2016\]](#page-19-17). Though distances for some sources are also given at Gaia DR3 release, they are not available for all objects, and as discussed in MP20 Gaia distances match reasonably well with the values derived by [Frew et al.](#page-19-17) [\[2016](#page-19-17)]. Some objects in our sample do not have IR data in some bands and/or they do not have the nebular *H*β flux and/or density and/or distance measurements. However, the available data on the PG1159-PNe in our sample are maximally utilized: a study is performed for an object in the following sections if the required data for that particular study is available with measurement error. The 2*MAS S* photometric fluxes were corrected for interstellar extinction using the relations given by [Whitelock](#page-20-5) [\[1985\]](#page-20-5) and the *E*(*B* − *V*) values given in Table 1. The nebular and dust properties of PG1159- and hybrid PG1159-PNe were computed using the methodology discussed in detail by MP20 (section 4.3); which we brief here:

The characteristic temperature of thermal equilibrium dust in a PN can be derived using its far-IR continuum fluxes at *IRAS* 25 and 60 μ m bands, where the contribution from dust emission features and atomic line emission are minimal. These far-IR fluxes were fitted with a modified blackbody function assuming an emissivity exponent of 1.0 [\[Muthumariappan et al.,](#page-19-18) [2006\]](#page-19-18). PNe are optically thin at far-IR wavelengths which makes the determination of T_d easy. The dust temperature of a PN derived in this way is also called the dust colour temperature (T_d) ; Stasinska and Szczerba [\[1999a\]](#page-19-16)). We derive the dust colour temperatures of our sample PNe for which the *IRAS* 25- and 60μ fluxes are known with the data quality flag 3. The distance-independent parameter, the nebular Hβ surface brightness (*S_{Hβ}*; Stasińska and Szczerba [\[1999a\]](#page-19-16), Górny and Tylenda [\[2000\]](#page-19-7), MP20), was derived from the Hβ flux and the optical size of the nebula. *S* $_{Hβ}$ is a good indicator of the age of a PN: as the nebula evolves, it expands and the *S* $_{Hβ}$ value decreases [Stasińska and Szczerba, [1999a\]](#page-19-16).

IR luminosity (L_{IR}) of a PN was estimated from its *IRAS* fluxes at 25- and 60 μ m bands, which was fitted by a modified blackbody flux distribution function. The curve was then integrated above 1μ m to find the total L_{IR} from continuum dust, taking the distance into account. We estimated the values of *LIR* and their errors for PG1159- and hybrid PG1159-PNe (the errors mainly come from the distance measurements). The IR excess (IRE) and their errors were estimated from the *LIR* values and their reddening corrected nebular Hβ fluxes and using the relation (equation 6) given by Stasińska and Szczerba [\[1999a\]](#page-19-16). IRE were calculated for PNe if they have both *IRAS* far-IR and $H\beta$ fluxes available with their uncertainties.

The dust mass m_d and the dust-to-gas mass ratios m_d/m_g were estimated by assuming an optically thin limit for PNe in the midand far-IR region. For a given distance, the dust mass was derived using the continuum flux at *IRAS* 60μ band and the T_d value. The values of T_d , *IRAS* 60 μ flux, H β flux and the electron density taken from the literature were used to obtain the dust-to-gas mass ratio. Errors associated with m_d and m_d/m_g were also estimated.

3. Results

Using the archival photometric fluxes and other nebular parameters collected from the literature, we investigate the IR colours of PG1159- and hybrid PG1159-PNe and derive their physical properties.

3.1. IR Colour-colour Diagrams analysis

The IR colour-colour diagrams (CCDMs) of PNe are useful tools to study their IR properties. The IR-CCDMs were derived for PG1159- and hybrid PG1159-PNe using their photometric measurements at 2*MAS S* , *W IS E* and *IRAS* bands. The IR emission

Table 1: List of PG1159-PNe and Hybrid-PG1159-PNe. Origin of the sources: 1) [Weidmann et al.](#page-19-19) [\[2023](#page-19-19)], 2) [Bond et al.](#page-18-3) [\[2023\]](#page-18-3), 3) [Werner et al.](#page-20-6) [\[2004](#page-20-6)]. Other sources are taken from [Weidmann and Gamen](#page-19-15) [\[2011](#page-19-15)]. Diameter (θ), distances and E(B-V) values are from [Frew et al.](#page-19-17) [\[2016\]](#page-19-17). F*H*^β and *n^e* are from Stasińska and Szczerba [\[1999a](#page-19-16)]

(a) IR data available at <https://irsa.ipac.caltech.edu/frontpage/>

arising from different components of a PN was discussed in MP20 and we use here the same methodology followed by them to obtain the CCDMs, hence they are not discussed here. IR CCDMS of [WR]-,*wels*- and normal-PNe and their mean values of colours, which are used to make a comparison study, are all from MP20. However, we resolve the distribution of [WRL]- and [WRE]-PNe in IR CCDMs to show the evolutionary connection.

3.1.1. Near-IR colour analysis

Near-IR radiation of PNe comprises the emission from atoms and free-free and free-bound emission of electrons in the gaseous nebula. The hot dust component of PNe with temperatures ∼1000K - 2000K can also radiate significantly in the near-IR waveband [\[Whitelock,](#page-20-5) [1985,](#page-20-5) [Leene and Pottasch,](#page-19-20) [1988\]](#page-19-20). We used the near-IR CCDM to analyze the dominant source of radiation at this waveband for PG1159- and hybrid PG1159-PNe and compare them with the other groups of PNe. 2*MAS S* photometric measurements were used for all sources in Table 1, as available, to have uniformity in the analysis with other groups of PNe done by MP20.

The extinction corrected near-IR CCDM of PG1159 and hybrid PG1159-PNe between 2*MAS S* bands [*J* − *H*]⁰ and [*H* − *K*]⁰ is shown in Fig. 1. Also shown in the figure are the regions dominated by emission from stellar component (S-region, this could be a companion to CSPN or field star(s)), nebular hot dust component (D-region) and from nebular atomic, free-free and free-bound emission (N-region). Contribution from both stellar and nebular components are seen in the 'NS' region and from both nebular and dust components are seen in the 'ND' region. More details on different emitting regions in the plot can be seen in Section 3.1 of MP20. The errors associated with the colours are computed from the errors in the photometric measurements and the errors in the *E*(*B* − *V*) values. Fig. 1 also shows the extinction corrected colours of [WRL]-,[WRE]- *wels*- and normal-PNe in 2*MAS S* bands, which are over-plotted for comparison. We find larger errors in the near-IR colours of many of the PG1159 and its hybrid type PNe, when compared to the other groups of PNe, due to the larger errors in their photometric measurements.

There are 15 PG1159- and hybrid PG1159-PNe for which the 2*MAS S* data and *E*(*B* − *V*) values are available, and we have calculated the near-IR CCDMs for them. Out of these 15 sources, five PG1159-PNe (including one hybrid type) are located in the 'S' region (∼ 33%) and in the 'NS' region there are five PG1159-PNe (∼ 33%). Five PNe are located in the 'ND' region (three PG1159-PNe and two hybrid PG1159-PNe), which represents ∼33% of total. No PG1159 and its hybrid type PNe is seen in the 'N'-region where the He I emission at 1.083μ dominates [\[Whitelock](#page-20-5), [1985\]](#page-20-5). As there are only three hybrid PG1159-PNe, we discuss their distribution together with PG1159-PNe. To compare this result, ∼ 34% and ~ 43% of [WR]-PNe ([WRL] and [WRE]) are positioned in 'S & NS' and in 'ND' regions, respectively. The distributions of [WRE]- and [WRL]-PNe in the 'S' and 'NS' regions are quite similar (∼ 28% and ∼ 29% respectively). However, while no [WRL]-PNe is seen in the 'N' region, four [WRE]-PNe are located in this region. In the 'ND' region the distribution of [WRE]-PNe is more closer to the nebular box than the [WRL]-PNe. As the central star becomes hotter, the nebular atomic/ionic emission brightens making more number of [WRE]-PNe in the 'N' region. Otherwise, these two sub-groups of [WR]-PNe are quite similar in the 2*MAS S* CCDM. From this analysis, one can find that [WR]-PNe and PG1159-PNe show similar distributions in 2*MAS S* CCDMs in the 'S' and 'NS' regions, whereas *wels*-PNe differ from them: they are concentrated in or around the 'N' region. In the 'ND' region [WR]-PNe dominates and PG1159-PNe have their significant presence. It should be noted that A70 and A30 are classified as PNe in their transition phase from [WRE] to PG1159 [\[Weidmann et al.,](#page-19-21) [2020\]](#page-19-21). But their log(*S ^H*β) values derived by us are -5.09 and -4.91 respectively, which are well within the PG1159-PNe range shown in Table 3. These two PNe are located in the 'ND' region on the 2*MAS S* CCDM; ([*J* − *H*]0; [*H* − *K*]0) values respectively are (0.830; 0.618) for A78 and (0.789; 0.894) for A30. If they are confirmed candidates of

N=Nebula; S=Star; D=dust

Fig. 1: Extinction corrected near-IR CCDMs of PG1159- and hybrid PG1159-PNe plotted along with the near-IR colours of [WRE]-,[WRL],*wels*- and normal-PNe computed by MP20. [WRL]-PNe are shown as filled hexagons in black, [WRE]-PNe are as filled pentagons in green, *wels*-PNe are as filled triangles in blue, PG1159-PNe are as filled squares in red, hybrid PG1159-PNe are as filled stars in cyan and normal-PNe are shown as crosses in pink.

PG1159-PNe, then the fraction of PG1159-PNe in the 'ND' region becomes 41% which is quite similar to the fraction seen for the [WR]-PNe. As noted by MP20, a significant fraction (∼ 31%) of *wels*-PNe is also seen in the 'ND' region. The concentration of more number of PG1159-PNe and [WR]-PNe in the 'ND'-region shows the domination of emission from the hot dust component in these two groups of PNe. This hot dust component is a very small grain population with grain sizes varying from ∼ 10 to 50 Å, which may have formed from the winds of the [WR] CSPN $[G\acute{o}rny$ et al., [2001](#page-19-8)]. They have low heat capacity and hence, they thermally fluctuate in the harsh central star radiation field, transiently attaining very high temperatures (see [Muthumariappan et al.](#page-19-22) [\[2013\]](#page-19-22) and [Muthumariappan](#page-19-23) [\[2017](#page-19-23)] for a discussion on this grain population in a dusty PN IRAS18333-2357). PG1159-PNe are faint and have low electron densities due to nebular expansion, which shows that their nebular emissions have declined significantly over time. Hence, they are rarely seen near the 'N' box, whereas 17% [WR]-PNe are in or around the 'N' box. However, the emission from the hot dust components of PG1159-PNe do not seem to have declined significantly due to the nebular expansion as compared to the nebular line emission. This may be related to the heating of a statistical grain, which is independent of the radial distance from the central star, and the grain number density determines the net emission. Whereas for the gas, the ionizing radiation field is diluted with radial distance from the central star and both the ionization and recombination rates depend on the gas density. It is to be noted that the near-IR colours of normal-PNe are mostly seen near the stellar line, inside or closer to the nebular box and only a few of them (∼16%) are located in the 'ND' region, making a sharp difference with PNe having H-poor CSPNe.

3.1.2. Mid- and Far-IR colour analysis

The warm, thermal equilibrium dust component of PN with a typical colour temperature of ∼ 150K - 300K was created in the cool and dense atmosphere of the AGB progenitor and is heated by the hard UV radiation of the CSPN [Stasińska and Szczerba, [1999b\]](#page-19-24). This dust component can be traced using the mid-IR bands of *W IS E* and *IRAS* . We use the 'N' and 'Q' band fluxes to trace this dust component in PG1159- and hybrid PG1159-PNe and compare them with the other groups of PNe with H-poor central stars to understand their evolution. The 'N' band is also, however, contaminated by the emission from Polycyclic Aromatic Hydrocarbons (PAH) and the atomic emission from forbidden transitions in the nebula (see MP20 for a discussion on this issue). The 22 μ m band of WISE and the 25 μ m band of *IRAS* are, however, least contaminated, and they trace the continuum dust better. The mid-IR colours of PG1159 and its hybrid type PNe at *W IS E* bands are shown along with that of [WRL]-, [WRE]-, *wels*- and normal-PNe in Fig. 2 (top panels). Similarly, their CCDMs in the *IRAS* bands were calculated and are shown in Fig. 2, along with the *IRAS* colours of the other three groups of PNe for a comparison (bottom panels). *IRAS* fluxes at its 60- and 100-µm bands are used to trace the cool AGB dust (cooler than 150K) in PNe. Errors in the photometric measurements at their respective wave bands of *W IS E* and *IRAS* are used to calculate the errors in the colours, which are shown at each point in the figure. As brought out from Fig. 2 the distribution of PG1159- and hybrid PG11159-PNe are in the cooler region which is different from that of [WRL]-,[WRE] and *wels*-PNe in the mid-IR and far-IR CCDMs. Only some normal-PNe are seen in the region which is occupied by PG1159-PNe.

The mean values of mid-IR colours for [WR]-PNe, *wels*-PNe and normal-PNe are shown with their standard deviations in Table 2 along with the values of PG1159-PNe (which includes hybrid PG1159-PNe) derived from this study. As seen in the table, the mean values of *W IS E* colours [3.4-4.2] and [4.2-12] for PG1159-PNe are smaller than the values reported for [WR]-, *wels*- and normal-PNe. *W IS E* [12-22] colour for PG1159-PNe is larger than the values obtained for other three groups; however, the *IRAS* [12-25] colour shows a significantly smaller value. The number of PG1159-PNe for which the photometric measurements are available at *W IS E* 12- and 22-µm bands are 13, whereas at 12- and 25-µm bands of *IRAS* , there are only 9 candidates have photometric

Fig. 2: Mid-IR CCDMs of PG1159- and hybrid PG1159-PNe derived using *W IS E* (top panels) and *IRAS* (bottom panels) photometry. They are plotted along with the mid-IR CCDMs of [WRL]-,[WRE]-*wels*- and normal-PNe. Data description as given in Fig. 1.

Colour	$[WR]$ -PNe	<i>wels-PNe</i>	PG1159-PNe	Normal-PNe
WIS E				
$[3.4 - 4.2]$	$0.88\pm0.58(63)$	0.81 ± 0.29 (47)	$0.463 \pm 0.52(11)$	$0.77 \pm 0.55(72)$
$[4.2 - 12]$	$5.17\pm1.20(63)$	5.29 ± 0.80 (47)	$3.57 \pm 1.1(10)$	$4.57 \pm 1.50(71)$
$[12 - 22]$	$3.37 \pm 0.90(73)$	$3.65 \pm 0.55(55)$	$4.30\pm0.95(15)$	$3.65 \pm 1.10(80)$
IRAS				
$[12 - 25]$	$3.45 \pm 0.63(55)$	$3.95 \pm 0.50(27)$	$2.06\pm0.97(7)$	$3.73 \pm 0.70(41)$
$[25 - 60]$	$2.41 \pm 0.74(78)$	$2.38\pm0.54(52)$	$3.45 \pm 1.10(11)$	$2.38 \pm 0.86(67)$
$[60 - 100]$	$0.21 \pm 0.50(29)$	$0.17\pm0.65(18)$	$1.12 \pm 1.81(8)$	$0.68 \pm 0.54(43)$

Table 2: Mean values of colours between different IR bands and their standard deviations for PG 1159-PNe (which also includes hybrid type). They are compared with their respective values of [WR]-PNe, *wels*-PNe and normal-PNe. The number of PNe were given between two round brackets.

measurements. Hence, we considered the colours derived using the fluxes at *WIS E* 12- and 22-µm bands for this study. While the *IRAS* [25-60] colours are quite similar for [WR]-, *wels*- and normal-PNe, PG1159-PNe show a larger mean value, which indicates that the AGB dust in PG1159-PNe are relatively cooler than in other groups of PNe. Similarly in the far-IR, the mean value of *IRAS* [60-100] colour for PG1159-PNe from this work is significantly larger than the respective values for [WR]- and *wels*-PNe. We find that the mid-IR bands are increasingly brighter as one moves away from the 12μ m band, both below and above this wavelength. If we take that the contribution from the atomic/ionic lines relative to the dust continuum emission are similar for all PG1159-PNe, then the above finding shows that below 12μ m the continuum emission from the hot dust component dominates for PG1159-PNe and its hybrid type and the cool dust emission dominates above 12µm. This confirms the finding from 2*MAS S* CCDM (Section 3.1.1) that PG1159 and hybrid PG1159-PNe have a significant amount of hot dust component similar to [WR]-PNe. The mid-and far-IR CCDMs in Fig. 2 show that PG1159 and hybrid PG1159-PNe are concentrated in a region which is not occupied by the [WR]- and *wels*-PNe and only the faint normal-PNe are seen in this region. This clearly shows that PG1159-PNe are more evolved objects than [WR]- and *wels*-PNe, which is also expected from their smaller values of electron densities as compared to other PNe.

3.2. Gas and Dust properties

We derive the gas and dust properties of PG1159-PNe and hybrid PG1159-PNe as discussed in Section 2. As it can be seen from Table 1. the electron densities are not available for many of the sources in the literature for which we have taken a mean value of 500 cm^{−3}, which is a good approximation for PG1159-PNe. We list the values of different parameters, namely, $S_{H\beta}$, T_d , M_d , m_d/m_g , *LIR* and IRE derived for our sample of PG1159-PNe and hybrid PG1159-PNe along with their errors in Table 3. As there is only one hybrid PG1159-PN for which the gas and dust parameters are available, we discuss its properties together with PG1159-PNe. Table 4. shows the mean values of T_d , $\log(m_d)/m_g$, $\log(L_{IR})$ and $\log(IRE)$ and their standard deviations for [WR]-,*wels*and normal-PNe from MP20 and are compared with PG1159-PNe. The number of candidates used to obtain these values are in round brackets. Plots showing variation of different nebular and dust parameters against *S ^H*^β for [WR]-,*wels*- and normal-PNe are from MP20. However, we resolve [WRL]- and [WRE]-PNe in these plots to show the evolutionary connection. We discuss the nebular and dust properties of different groups of PNe below.

The mean *T^d* value for 11 PG1159-PNe is 75K which is significantly lower than the mean values obtained for other groups of

PNe (see Table 4). We plot the value of T_d against $S_{H\beta}$ for PG1159-PNe in Fig. 3 to find its variation as the PN ages. The figure also shows the variation of T_d against $S_{H\beta}$ for [WRL]-,[WRE]-, wels- and normal-PNe. Fig. 3 shows that all the PG1159-PNe are distributed in the lower end of S_{HB} values in the plot, where other PNe with H-poor central stars are not present. However, some of the normal-PNe are seen in this region. As can be seen from the plot, the T_d value decreases with S_{HB} for PG1159-PNe similar to the trend seen for the other groups of PNe (also see [Pottasch et al.](#page-19-25) [\[1988\]](#page-19-25), Górny et al. [\[2001\]](#page-19-8). However, a few PG1159-PNe (and some normal-PNe) show larger temperatures than the typical value of T_d expected at this region. The low S_{HB} values clearly show that PG1159-PNe are old objects and have expanded to larger sizes as compared to [WR]- and *wels*-PNe. This has resulted in lower gas density and smaller mean T_d for them.

The dust mass m_d and the dust-to-gas mass ratios m_d/m_g for 11 PG1159-PNe are plotted against their $S_{H\beta}$ values, and are shown in Fig. 4 (top left and top right panels respectively). The figure also shows the plot for [WRL]-,[WRE]-, *wels*- and normal-PNe. As it can be seen from this plot, while the m_d/m_g shows no trend with $S_{H\beta}$ for PG1159 and other groups of PNe, the m_d plot versus S_{HB} is nearly flat down to a value of $S_{HB} \sim 3 \times 10^{-3}$ for all PNe and it shows a decreasing trend below this value. Most of the PG1159-PNe are located in this region, while the [WRL]-,[WRE]- and *wels*- PNe are predominantly seen in the flat region of the curve. The mean dust mass for PG1159-PNe is significantly lower than the mean values shown by the [WR]-,*wels*- and normal-PNe, as seen in Table 4. However, the mean *md*/*m^g* value is marginally larger for PG1159-PNe than the value obtained for the other groups (this is due to a large m_d/m_g value shown by Jacoby 1, otherwise they are all similar). The standard deviations associated with the mean values of the parameters and the number of candidates used to derive the mean values for different groups of PNe are shown in the table.

IR luminosity (*LIR*) of a PN we refer is the total continuum IR energy emitted from the thermal equilibrium dust (dust emission features are not included). They were estimated for 11 PG1159-PNe as shown in Table 3. The mean value of *LIR* for PG1159-PNe is significantly lower than the values seen for [WR]-,*wels*- and normal-PNe (see Table 4). A plot of L_{IR} against S_{HB} is shown in Fig. 4 (bottom left) for PG1159-PNe along with the other groups of PNe. As it can be seen in the plot, PG1159-PNe follow the same decreasing trend of *LIR* with *S ^H*^β shown by other PNe groups. However, PG1159-PNe are concentrated at the low *LIR* regions of the plot as compared to the other PNe with H-poor central stars. The excess amount of *LIR* in terms of additional IR energy observed from the nebula than what can be accounted by the absorption of Lyα radiation produced in the nebula, which is termed as IR excess (IRE) of a PN. Fig. 4 shows a plot of IRE against *S ^H*^β for PG1159-PNe and also for the other groups of PNe (bottom right). The plot does not show a relation between IRE and *S ^H*^β for all the groups of PNe considered here, implying that IRE does not change as the nebula evolves, as also noted by MP20. L_{IR} and H β flux decreases with the age of a PN, keeping the IRE unchanged. As seen from Table 4., PG1159-PNe show a mean IRE value which is lower than that of [WR]-PNe, but still higher than the value shown by the normal PNe. However, the mean value of *LIR* is significantly lower for PG1159-PNe when compared to the values shown by other groups of PNe.

3.3. S ^H^β *analysis of PNe*

There are 15 [WRL]-, 29 [WRE]- , 42 *wels*-, and 55 normal-PNe for which the values of *S ^H*^β were given by MP20 and we have derived the *S ^H*^β values for 18 PG1159-PNe and 3 hybrid PG1159-PNe in this work. From this data, we plot the number distribution of PNe against *S ^H*^β values for [WRL]-,[WRE]-, *wels*-, PG1159-, hybrid PG1159- and normal-PNe. We considered a bin size of 0.5 for log(*S ^H*β), and the histograms for all groups of PNe considered in this study are shown in Fig. 5. We perform a statistical analysis on the distributions of PNe against *S ^H*β, which can provide useful information on the origin and the evolutionary

Fig. 3: Variation of dust colour temperature with *S_{Hβ}* for PG1159-, and hybrid PG1159-PNe shown with the other groups of PNe derived by MP20. Data description as given in Fig. 1.

Fig. 4: Different nebular and dust parameters of PG1159- and hybrid PG1159-PNe derived from this study are plotted against *S ^H*β. Also shown in the plot are [WRL]-,[WRE]-,*wels*- and normal-PNe. Data description as in Fig. 1.

Fig. 5: Number distribution of PNe against log(*S ^H*β) (bin size 0.5). Top left: [WRL]- (dashed line), [WRE]- (solid line); top right: *wels*-; bottom left: PG1159- (solid line) and hybrid PG1159- (dashed line) and bottom right: normal-PNe.

connection between the different groups of PNe considered in this study.

Fig. 5 shows that the number distribution of PG1159-PNe and hybrid PG1159-PNe are distinctly different from the other groups: they are seen at very low $S_{H\beta}$ values while the other groups of PNe are seen at the higher values of $S_{H\beta}$. In addition, PG1159-PNe show good overlap with [WRE]-PNe in this plot. Similarly [WRL]-PNe are seen at lower values of *S ^H*^β than [WRE]-PNe and they also show a good overlap. This indicates an evolutionary sequence of [WRL]-PNe \rightarrow [WRE]-PNe \rightarrow PG1159-PNe. Hybrid PG1159-PNe are located within the *S* _{*HB*} range shown by other PG1159-PNe, indicating that hybrid PG1159-PNe do not form an evolutionary link between PG1159-PNe and other PNe with H-poor central stars. However, it is not apparent from the figure to say if the number distributions for [WR]-,*wels*- and normal-PNe are similar or different. To trace this, we invoke the Kolmogorov-Smirnov (KS) test statistics, which has been popularly used to check if the two given data sets (which are independent of their number distributions) are similar or differ significantly. The KS test is particularly useful for comparing cumulative distribution functions (CDFs) of two data sets.

The statistics is parameterized by two values: the 'D' value of KS statistics shows the maximum absolute difference between the CDFs of two data sets, and the 'P' value of the statistics indicates the probability of the null hypothesis that the distributions of the two data sets are the same [\[Peacock](#page-19-26), [1983,](#page-19-26) [Teegavarapu](#page-19-27), [2019\]](#page-19-27). A low 'D' value shows that the difference between the two data sets is very low ($D \ge 0.5$ infers significantly different data sets) and a high 'P' value shows that the hypothesis can not be rejected. We perform the KS test between the number distribution of [WR]-,*wels*- and normal-PNe with *S ^H*^β values to see if these data were derived from a similar sample. We find $D = 0.14$ and $P=0.99$ between the distributions of [WR]- and normal-PNe if one takes the entire data set or we take only the first peak (below $S_{HB} = 0.001$, which represents the younger group of PNe). KS test between [WRL]- and normal-PNe gives the values of $D = 0.2$ and $P = 1.0$. Between *wels*- and normal-PNe distributions, $D = 0.28$ and $P = 0.28$ 0.63 if one takes the full data set and $D = 0.14$ and $P = 0.99$ if we take the first peak. Our analysis shows that, particularly at higher values of *S ^H*^β (i.e., at the early stages of PNe), the number distribution functions of [WRL]-PNe and *wels*-PNe against *S ^H*^β are very similar to that of normal-PNe and hence they were derived from a similar sample.

Fig. 6 shows the difference between subsequent S_{HB} values for PNe plotted against their S_{HB} values, both in logarithmic scale, for [WRL]-, [WRE]-, *wels*-, PG1159- and hybrid PG1159-PNe. This plot clearly shows that there is a good overlap between [WRE]- and PG1159-PNe in S_{HB} indicating an evolutionary connection. A weak overlap is seen between [WRL]- and PG1159-PNe as [WRL]-PNe evolve to [WRE]-PNe. However, the *wels*-PNe have a significant gap in *S ^H*^β with the PG1159-PNe in this plot. In the logarithmic scale the gap in $\log(S_{H\beta})$ is 0.42, which is 3 times the mean of the differences in successive values of $\log(S_{H\beta})$ for *wels*-PNe (0.13) and 2.5 times that for PG1159-PNe (0.17). However, it should be noted that the number of PG1159-PNe known till date are not many and there is also a possibility that this gap in $log(S_{H\beta})$ could be due to the lack of observational points in this range.

4. Discussion

From the results we obtained above using IR data and *S ^H*^β analysis, we make a few suggestions on the evolution of [WR]-,*wels*-, PG1159-PNe and discuss them in the following sections.

Fig. 6: A plot of log(∆*S ^H*β) versus log *S ^H*^β for different group of PNe with H-poor CSPNe. See the text for details.

Parameter	$[WR]$ -PNe	<i>wels-PNe</i>	PG-1159	Normal PNe
(mean value)	(No. of PNe)	(No. of PNe)	(No. of PNe)	(No. of PNe)
$T_d(K)$	$96 \pm 25(78)$	$95 \pm 14(52)$	$75 \pm 17(11)$	$93 \pm 31(67)$

log[IRE]	0.64 ± 0.60 (54)	0.47 ± 0.22 (42)	0.50 ± 0.22 (11)	0.43 ± 0.40 (52)

Table 4: Mean values of nebular and dust parameters and their standard deviations for PG1159-PNe obtained from this study are shown along with their respective values for [WR]-,*wels*- and normal-PNe. See the text for more details. .

4.1. Dust-to-gas mass ratios of PNe

Does the grain population in PN undergo substantial evolution during its evolution and does the m_d/m_g ratio of PN decrease before the envelope is dispersed into the ISM were key questions which were debated for a long time. [Natta and Panagia](#page-19-28) [\[1981\]](#page-19-28), [Lenzuni et al.](#page-19-29) [\[1989\]](#page-19-29) have discussed this elaborately in their analytical study made on 243 PNe using *IRAS* data and have suggested that the mean grain size and m_d/m_g show significant changes during the evolution of PNe. [Neugebauer et al.](#page-19-14) [\[1984\]](#page-19-14) also arrived at the same conclusion using *IRAS* photometry of 46 PNe. Stasinska and Szczerba [\[1999a\]](#page-19-16) used extensive photo-ionization models for 500 PNe, constrained by *IRAS* fluxes, and found no evidence for the decrease of m_d/m_g with the age of the nebula. They also found that the decrease in the mean grain size found by [Lenzuni et al.](#page-19-29) [\[1989\]](#page-19-29) is an artefact associated with their analysis and that the timescale of grain destruction is larger than the lifetime of a PN. Fig. 4 (top left panel) shows that the dust mass is not correlated with $S_{H\beta}$ down to a value of $S_{H\beta} \sim 3 \times 10^{-3}$ for all PNe and the graph shows a decreasing trend below this value. Most of the PG1159-PNe and some normal-PNe are located in this region. This is, however, not a real picture as found in the models of Stasińska and Szczerba [\[1999a\]](#page-19-16). They brought out that the atomic emission lines of [OIII] at 25.9μ m and 51.8μ m can contaminate significantly the fluxes at 25- and 60μ m bands of *IRAS*. Hence, the dust colour temperature derived from the fluxes at these two bands could be overestimated, leading to a smaller dust mass. As also seen from Fig. 3, larger dust colour temperatures are seen at low *S ^H*^β values, supporting this argument. We find a wide range in the values of *md*/*m^g* for all PNe up to a factor of ∼50; most PNe have values in Fig.4 (top right panel) from 0.0002 to 0.01. However, partly this could be caused by two reasons: 1) we have assumed an emissivity exponent of grains $\alpha = -1$ uniformly for all PNe. While this value suits for carbonaceous grains, for silicates a value of $\alpha = -2$ will be more appropriate. This overestimates the dust colour temperature and in turn underestimates m_d/m_g . Our analysis shows that taking carbonaceous grains in the place of silicates will lead to a maximum difference of 40% in the estimated value of m_d/m_g . Also, one can note that most of [WR]- and *wels*-PNe and about 50% of normal-PNe have carbonaceous grains, as discussed by MP20. 2) some PNe are radiation-bounded (about 20%;Stasińska and Szczerba [\[1999a\]](#page-19-16)) and have significant amount of neutral mass around ionized region, and the gas mass estimated from $H\beta$ flux refers to only the ionized gas component. This leads to an underestimation of the total nebular mass (ionized and neutral gas), in turn overestimating *md*/*mg*. We arrive at the same conclusion of Stasin ska and Szczerba [\[1999a\]](#page-19-16) that PNe are formed with a range of m_d/m_g and in addition we also do see that this is irrespective of if their CSPNe are H-rich or H-poor.

4.2. Origin of PNe with H-rich and H-poor central stars

It was believed that the H-poor atmosphere of [WR] star was formed due to thermal pulse occurring at the final-AGB phase, or late (while the star evolves in the constant luminosity track after ejection of PN) or very late (when the CSPNe evolve through the WD cooling track) AGB phases (born-again PNe; [Iben](#page-19-30) [\[1993\]](#page-19-30), Löbling et al. [\[2019](#page-19-31)]. PNe, which have gone through late- or very late-thermal pulse phases show resolved envelopes in their optical images which were ejected at two different epochs of the progenitor star's evolution. For example, the born-again PNe A30 and A78 [\[Borkowski et al.](#page-19-32), [1994,](#page-19-32) [Todt et al.](#page-19-33), [2015\]](#page-19-33). However, most of the [WR]- or *wels*-PNe do not show such morphologies in their resolved optical images. Our finding that the young PNe with [WR] and *wels* central stars have the number distribution functions against $S_{H\beta}$ which are very similar to that of the normal-PNe implies that PNe of these three groups originated in a quite similar way. This indicates that [WR]- and *wels*- PNe were formed directly from AGB evolution as how the normal-PNe were born without facing late or very late thermal pulses. There are, however, a very few exceptions: there are five born-again PNe known till date, and among them, a few show [WR] type central star like the CSPNe of A58 and IRAS 15154-5258 [\[Zijlstra](#page-20-7), [2002\]](#page-20-7) which have seen the late thermal pulse. The overlap of $S_{H\beta}$ values in Fig. 6 between [WRE]- and PG1159-PNe shows a continuity in *S ^H*^β and hence an evolutionary connection between them and [WRE]

and [WRL] are evolutionarily connected. Such a continuity is not seen between *wels*- and PG1159-PNe. This may indicate that *wels*-PNe and PG1159-PNe may not form an evolutionary sequence, though this may require more observations for confirmation. While none of the [WR] stars show hydrogen in their spectra, hybrid-PG1159 stars do show hydrogen in absorption. This may indicate that some PG1159 stars can also be formed through other rout(s) which are different from [WR] phenomena.

5. Conclusions

We studied the properties of PNe around 26 PG1159 stars known till date, which includes four hybrid PG1159 type, and compared them with the properties of [WR]-, *wels*- and normal-PNe reported earlier to understand their evolutionary status. We used archival IR photometry of PNe in addition to their $H\beta$ fluxes, sizes and distances obtained from the literature, as available, to make this study. We make the following conclusions:

- 1. The near-IR CCDMs of PG1159 and hybrid PG1159-PNe show a tendency of their distribution near the stellar line (66%). Next to this they tend to populate in the 'ND' region which is dominated by the [WR]-PNe. This may indicate the presence of significant amount of hot dust (statistically fluctuating small grains) within the nebula. The AGB dust traced by the mid-IR bands are relatively cooler for PG1159-PNe when compared to [WR]-, *wels*- and normal-PNe.
- 2. PG1159 and its hybrid type PNe are found at the lower end of *S ^H*^β where [WR]-PNe and *wels*-PNe are not seen and only some normal-PNe are present. smaller IR luminosities and similar IRE when compared to other groups. While their dust-togas mass ratio is somewhat larger than that of the other groups of PNe, their mean dust mass is smaller. The dust-to gas mass ratio is not correlated with S_{HB} for all groups of PNe.
- 3. There is a good overlap between [WRE]- and PG1159-PNe in their *S_{HB}* values which indicates an evolutionary connection between them. However, the *wels*-PNe show significant gap in *S_{Hβ}* with PG1159-PNe. The number distributions of [WRL]and *wels*-PNe against *S ^H*^β are very similar with that of PNe with H-rich central stars. This may indicate that [WR]-,*wels*and normal PNe have evolved in a similar way, i.e. direct evolution from the AGB.

6. Acknowledgements

This research has made use of the SIMBAD database, operated at CDS, Strasbourg, France. This publication makes use of data products from the Two Micron All Sky Survey, which is a joint project of the University of Massachusetts and the Infrared Processing and Analysis Centre, funded by the National Aeronautics and Space Administration and the National Science Foundation. This work is based in part on observations made with *W IS E*, obtained from the NASA/IPAC Infrared Science Archive, operated by the Jet Propulsion Laboratory, California Institute of Technology, under contract with the National Aeronautics and Space Administration. The authors thank the anonymous referee for his/her useful comments which have improved the manuscript. The research work was supported by the DST-SERB grant of Govt. of India (Grant No: CRG/2020/000755) received by the author C. Muthumariappan.
