ABSTRACT

Context. Our current understanding is that intermediate- to high-mass stars form in a way similar to low-mass stars, that is, through disk accretion. The expected shorter formation timescales, higher accretion rates, and increasingly stronger radiation fields compared to their lower mass counterparts may lead to significantly different physical conditions that play a role in disk formation, evolution, and the possibility of (sub)stellar companion formation therein.

Aims. We search for the mm counterparts of four intermediate- to high-mass $(4 - 10 M_{\odot})$ young stellar objects (YSOs) in the giant H II region M17 at a distance of 1.7 kpc. These objects expose their photospheric spectrum such that their location on the pre-main-sequence (PMS) is well established. They have a circumstellar disk that is likely remnant of the formation process.

Methods. With the Atacama Large Millimeter/submillimeter Array (ALMA) we have detected, for the first time, these four YSOs in M17, in Band 6 and 7, as well as four other serendipitous objects. Besides the flux measurements, the source size and spectral index provide important constraints on the physical mechanism(s) producing the observed emission. We apply different models to estimate the dust and gas mass contained in the disks.

Results. All our detections are spatially unresolved, constraining the source size to < 120 au, and have a spectral index in the range 0.5-2.7. The derived (upper limits on the) disk dust masses are on the order of a few M_{\oplus} and estimations of the upper limits on the gas mass vary between 10^{-5} and $10^{-3} M_{\odot}$. Our modeling suggests that the inner disks of the target YSOs are dust depleted. In two objects (B331 and B268) free-free emission indicates the presence of ionized material around the star. The four serendipitous detections are likely (low-mass) YSOs. We compare the derived disk masses of our M17 targets to those obtained for YSOs in low-mass star-forming regions (SFRs) and Herbig stars, as a function of stellar mass, age, luminosity, and outer disk radius. The M17 sample, though small, is both the most massive and the youngest sample, yet has the lowest mean disk mass.

Conclusions. The studied intermediate- to high PMS stars are surrounded by low-mass, compact disks that likely do not offer a significant contribution anymore to either the final stellar mass or the formation of a planetary system. Along with the four serendipitous discoveries our findings showcase the capability of ALMA to probe disks in relatively distant, high-mass SFRs, and offer tentative evidence of the influence of the massive star formation environment on disk formation, lifetime, and evolution.

Key words. stars: massive - stars: pre-main-sequence - circumstellar material - remnant disks

1. Introduction

Recent developments in instrumentation, and more specifically, the advent of the *Atacama Large Millimeter/submillimeter Array* (ALMA), have made it possible to perform population studies of disks around low-mass young stellar objects (YSOs) and T Tauri stars. Studying such disk populations in a statistical manner and linking disk properties to age, exoplanet demographics and stellar parameters sheds light on the evolution of disks, including their dissipation timescales and mechanisms, as well as (sub)stellar companion formation within them (e.g. Pascucci et al. 2016; Ansdell et al. 2017; Andrews et al. 2013; Tripathi et al. 2017; Pinilla et al. 2020; Manara et al. 2023). Recently, this endeavor has been extended towards higher masses, that is, incorporating Herbig AeBe stars (mostly) in the lower

mass range around $2 M_{\odot}$, with a few higher mass objects up to $10 M_{\odot}$ (Stapper et al. 2022), who conclude that the disks of the studied Herbig stars are skewed towards higher mass and larger size than those of T Tauri stars.

It remains challenging to push this endeavor to higher masses, as the number of young objects becomes progressively smaller with increasing mass, and the birth environment of such objects is complicated by their large distance, crowding, and extinction. As a result, many of the questions regarding the life-time and dissipation mechanisms of disks, the mechanism of stellar and, possibly, planetary companion formation remain elusive in the higher mass ranges. A fair number of disks, outflows, and disk-like structures have been observed in mm- and cm-wavelengths around massive ($\geq 8 M_{\odot}$) young or proto-stellar

objects (e.g., Johnston et al. 2015, 2020; Beltrán & de Wit 2016; Ilee et al. 2016; Caratti o Garatti et al. 2017; Cesaroni et al. 2017; Ilee et al. 2018; Beuther et al. 2018; Maud et al. 2018; Sanna et al. 2019; Burns et al. 2023). However, the observed structures extend scales of hundreds to thousands au and, unlike in the quoted disk (population) studies, belong to embedded, early stages of formation when the photosphere of the central object is still obscured and its (final) mass is uncertain (see, however, McLeod et al. 2024).

We have searched for candidate massive YSOs in starforming regions (SFRs) associated with ultra-compact H II regions (e.g. Bik & Thi 2004; Hanson et al. 1996; Lumsden et al. 2013). In this context, a region of particular interest is the M17 Н п region (Figure 1) in the east side of the Omega (M17) giant molecular cloud complex, at a distance of ~ 1.7 kpc (Maíz Apellániz et al. 2022; Stoop et al. 2024). Its ionizing source, the young massive cluster NGC 6618, contains more than 100 B stars and at least 16 O stars. At least four of these stars have spectral types earlier than O6 V, the spectral type of θ^1 Ori C, the most luminous star in the Trapezium region of the Orion Nebula Cluster (ONC) (Hanson et al. 1997; Povich et al. 2007, 2009; Hoffmeister et al. 2008). With an estimated total stellar mass of ~8000 - 10,000 M_{\odot} , NGC 6618 is about five to six times as massive as the ONC (Povich et al. 2009; Kroupa et al. 2018). An important property of the candidate massive YSOs in this region is that they have visible photospheres, allowing to place them on the Hertzsprung-Russell diagram (HRD; Ochsendorf et al. 2011).

Ramírez-Tannus et al. (2017, hereafter RT17) characterized the young stellar population in NGC 6618 constraining its age to ≤ 1 Myr. Recently, the distance estimate to M17 was adjusted from 1.98 kpc (Xu et al. 2011) to ~ 1.7 kpc using Gaia DR3 data (Maíz Apellániz et al. 2022; Stoop et al. 2024). Also the age estimate has been refined by Stoop et al. (2024) who used the kinematic age of dynamically ejected massive runaway stars yielding an age of 0.65 ± 0.25 Myr. Within NGC 6618, RT17 identified a sample of pre-main-sequence (PMS) stars with masses $\sim 4 - 15 M_{\odot}$ that optically reveal their photospheres and, at the same time, show optical and near-infrared (NIR) signatures of a circumstellar disk extending close to the stellar surface (Backs et al. 2023; Poorta et al. 2023). Their stellar parameters were first determined by RT17 and later updated by Backs et al. (2024; in prep.), by fitting the normalized photospheric spectra using the non-LTE stellar atmosphere code FASTWIND (Santolaya-Rey et al. 1997; Puls et al. 2005) and a genetic algorithm based fitting approach KIWI-GA (Brands et al. 2022). In addition to the stellar properties, extensive modeling of the circumstellar disk features in the optical and NIR (Section 2.1) suggest that these objects are in the final stages of formation and have small scale gaseous and dusty disks. However, constraints on the existence of extended disk material and its mass are lacking so far.

The sample of PMS stars in M17 fits the common definition of Herbig Be stars in literature, but the objects have not been included in statistical studies and catalogues of Herbig stars (e.g. Vioque et al. 2018; Brittain et al. 2023), likely due to their distance, extinction, and the fact that they reside in the complicated environment of a massive SFR. Additionally, Stapper et al. (2022) study a volume-limited sample out to 450 pc, excluding any targets in M17.

In the context of the dearth of disk studies in the higher stellar mass regime, and in massive SFRs in general, this study aims to take the next step by constraining the extended disk properties of four intermediate to massive PMS stars in M17 with masses $\sim 4-10 M_{\odot}$. With ALMA we have detected, for the first time, the mm components of these YSOs, adding to the handful of similar objects for which ALMA observations have been obtained, such as: MWC 297 (B1.5 Ve, ~ 10 M_{\odot}) a rapidly rotating massive YSO at a distance of 418 pc (Sandell & Vacca 2023; Stapper et al. 2022) and IRS2 (early B) in NGC2024 at a distance of 450 pc (Lenorzer et al. 2004; van Terwisga et al. 2020). We adopt similar and refined techniques to constrain the disk mass, radius and structure of our targets. For the first time we apply a multiwavelength approach to this kind of object, including both photospheric optical to NIR spectra, as well as optical to MIR photometry and the newly obtained ALMA mm-wavelength data.

In the next section (section 2) we present the M17 targets and the ALMA observations. All four targets are detected, and in the covered fields we identify four additional sources, most likely (low-mass) YSOs. In section 3 we analyse the ALMA data and introduce the methods that we use to measure the disk masses. The mm emission is thermal in nature, that is, free-free radiation and/or thermal dust emission. Different estimates of the disk masses are presented in section 4. We discuss our results in section 5 and compare these with those obtained for T Tauri and Herbig stars. In the final section (section 6) we summarize our conclusions.

2. ALMA observations of M17 targets

2.1. M17 target sample

Four of the M17 PMS stars studied by RT17 were observed with ALMA. These four targets are listed in Table 1 along with their stellar parameters (Backs et al. 2024). Several recent studies have been performed to characterize the inner disks around (some of) these objects. Backs et al. (2023) have studied the double-peaked hydrogen emission lines in VLT/X-shooter spectra of B243 and B331 using the radiation thermo-chemical code ProDiMo (e.g., Woitke et al. 2016). They find that these lines form very close to the star, such that the disks likely continue (almost) up to the stellar surface, indicating the (expected, e.g., Alecian et al. 2013) lack of magnetic fields that are typical for low-mass stars. Based on the line forming region they estimate inner disk (< 20 au) masses on the order of $10^{-3} - 10^{-4} M_{\odot}$. They also find that line luminosity-accretion relations derived for lowto intermediate-mass stars (Fairlamb et al. 2017), imply accretion rates of 10^{-5} to $10^{-3} M_{\odot} \text{yr}^{-1}$. This would entail a substantial mass reservoir further out in the disk or in-falling onto the inner disk, that, given the evolutionary state of the stars, seems unlikely.

Derkink et al. (2024) have looked at spectroscopic and photometric variability over days to years in multi-epoch data of B268, B275, and B243. They find intrinsic spectroscopic variability for all these objects in the atomic lines originating mostly close to the stellar surface, as well as evidence for asymmetric disk structures in the inner disk, such as spiral arms. They detect no strong photometric variations, (inverse) P Cygni line profiles, or high-velocity components in forbidden emission lines, making the presence of strong accretion (bursts) or jets unlikely.

Finally, Poorta et al. (2023) have modeled the first and second overtone CO bandhead emission in all four targets to constrain densities and temperatures in the inner disk. In line with previous studies, they find that this emission is typical for high (column) densities ($N_{\rm CO} \sim 10^{21} \,{\rm cm}^{-2}$) and temperatures (2000 – 5000 K), and originates close to the star (< 1 au), though not as close as the previously mentioned hydrogen emission lines. They also fit near- to mid-infrared photometry with a dust disk model and find that for a canonical dust-to-gas ratio the

^c Spectroscopic mass from modeling.

^{*d*} Number of hydrogen ionizing photons.

^e B331 is too embedded to allow for full modeling. Physical parameters were estimated by RT17, using spectroscopic classification and estimating T_{eff} and L from Kurucz calibration tables. The RT17 values were adjusted to the latest distance estimate of 1.7 kpc (see Section 2.1).

Fig. 1: The left panel shows a NIR color composite image of M17 based on 2MASS data: J (blue), H (green), and K (red), with large scale 1.3 mm continuum emission contours (archival ALMA Band 6 data, project code 2018.1.01091.S). Contour levels: 5, 15, 30, 70 × noise *rms* (resp. 0.018, 0.053, 0.11, 0.25 Jy). The middle panel shows only the ALMA mosaic, with the beam size in the bottom left corner. On both panels the rectangular region indicates the field in which all four targets in this study (indicated in red) are found. The rightmost panel is a zoom-in on this region with all targets and serendipitous discoveries marked in black. To give an impression of the scales, the radius of each object dot is 1", which corresponds to five times the image size of each panel in Figure 2.

derived column densities in the inner disk are inconsistent with those derived from the CO emission (see also Section 3.5.1). The inner disk structure, though critical for constraining the massaccretion rate, provides little information about global properties of the disk, such as total mass and size. To investigate these properties, longer wavelength data are needed.

In Figure 1 we present an overview of the M17 region in 2MASS colors and large scale mm emission in ALMA Band 6 from archival data (project code 2018.1.01091.S). The targets in this study are marked on each panel and the right panel shows a close-up of the region containing all four targets, as well as the new detections with ALMA that were made in the field of view around three of the four targets (see Section 2.3). Some new detections (B243 SW and B275 SE) clearly have 2MASS coun-

terparts. The figure illustrates the high source density as well as the large-scale emission in the region. This emission is largely resolved out in the high-resolution observations taken for this study (Table 2). Figure 2 shows a zoom in on all detected sources (see also Section 2.3).

2.2. ALMA observations and imaging

Under project ID 2019.1.00910.S we obtained ALMA 12 m array observations in Band 6 and Band 7 for our four targets in M17, resulting in eight fields to be imaged. The observational setups for the targets were close to identical; an overview of the observations per band is given in Table 2. Specific details per target are provided in Table A.1 in Appendix A. The observa-

Fig. 2: Zoom in on all detected sources. The target sources are labeled in red and the serendipitous detections in white; the latter named after the target in whose image they are detected (see Section 2.3). Note the slightly different flux scales of each image. Contour levels: 3, 5, 8, $10 \times \text{noise } rms$ (between 0.022 - 0.040 mJy in Band 6 and 0.056 - 0.083 mJy in Band 7). No radio continuum flux is detected for B268 in Band 7 and B331 NE in Band 6; they still are included as illustration.

tions were designed to detect the targets in the continuum, but also included the ¹²CO, ¹³CO, and C¹⁸O rotational 2-1 lines in Band 6 and ¹²CO rotational 3-2 line in Band 7. The respective spectral setups are summarized in Tables 3 and 4. The Band 7 data were manually calibrated by the ALMA staff using CASA

version 6.1.1 (CASA Team et al. 2022). The Band 6 data were calibrated with the ALMA pipeline version 2021.2.0.128 using CASA version 6.2.1.7. The signal-to-noise of the detected targets was too low for self-calibration. For all subsequent image deconvolution (imaging) and flux determination we used CASA version 6.2.1.7.

We imaged the continuum using natural weighting to maximize sensitivity, averaging over all spectral windows after including only line-free regions. Because the observed targets lie in a very young SFR, in some cases we had to exclude the data from shorter baselines that are sensitive to extended emission, in order to improve the signal to noise of the observed targets. In Band 6 we used *uv*-ranges of > 50 k λ , thereby excluding emission from scales larger than $\sim 4.13''$, which at the distance of M17 corresponds to \sim 7000 au. In Band 7 the *uv*-range was already limited to $> 50 \,\text{k}\lambda$ when all baselines were included, and we applied no further limit. An exception was made in both bands for the images surrounding B331. As can be seen in Figure 1, this target is located in a region with continuum emission on $\gtrsim 0.4''$ (700 au) scales, possibly associated with remnant cloud emission or a chance alignment, and we removed baselines $< 500 \text{ k}\lambda$ for images in both bands, thereby excluding emission from scales larger than \sim 700 au. A zoom-in of the images around each detected source (see Section 2.3) is shown in Figure 2. Larger field images showing the background and multiple sources at once are presented in Appendix C.

In an attempt to detect the targets in the selected CO lines we inspected image cubes averaged to $1 - 2 \text{ km s}^{-1}$. We found that all line emission was dominated by large scales, likely from the surrounding cloud. Removing shorter baselines did not yield detections of the continuum-detected sources in ¹²CO nor in ¹³CO. In order to estimate upper limits on the gas mass of possible disks (see Section 3.2) we determined the root-mean-square (*rms*) of the noise in the line images with *uv*-ranges of > 500 k λ (removing emission from scales larger than ~ 700 au). Assuming a FWHM line width of 10 km s⁻¹, we measure the noise *rms* in a cube with 10 km s⁻¹ wide channels to be ~ 0.8 mJy beam⁻¹, translating to a 3σ upper limit to the integrated line flux of

2.3. Detections and determination of fluxes in the continuum

The noise *rms* was determined from a large (radius $\sim 5''$) emission-free region in the images resulting from the procedure described in section 2.2. Different such regions were probed in each image and the variation of the rms between them was found to be negligible. A source is considered a detection if its flux is higher than five times the noise rms in one or both bands. Some sources minimally fulfilling this condition on the edge of the primary beam were considered noise peaks after visual inspection. Detections that are not among the original targets are named after the target in whose image they are detected; with upper-case letters appended indicating the position of the detection relative to the original target (e.g., SW for southwest etc.). Three of the four original targets are detected in both bands and four new sources are detected in the fields surrounding the original targets (fig. 2 and appendix C). B268 is only possibly detected in Band 6 (SNR 3), but is included in Figure 2 and further analysis because it is an original target. This object was imaged with a *uv*-taper of 0.08" to increase signal-to-noise, leading to the large beam size relative to the other images. B331 NE is detected in Band 7 (SNR 6) according to the set criteria; however, it is located in the high noise region on the edge of the primary beam, is not detected in Band 6, and has no infrared counterpart (see Figures C.4 and D.2). For completeness we therefore present it in Figure 2 and list in Tables 5 and 6, but otherwise exclude it from further analysis. All other detections are in both bands and have optical and/or NIR counterparts. Their exact positions and projected separations are listed in Table 5.

Fluxes were determined using the imfit task in CASA, which fits a two-dimensional Gaussian to the selected image component (full fit results are provided in Appendix B). All resulting major-axis FWHM were at most on the order of the beam size, so we concluded that none of the detected sources is resolved. As expected in that case, the resulting peak fluxes (given in Jy/beam) are all equal within errors to the integrated fluxes (given in Jy). Since the sources are contained in one beam we report only the peak fluxes in units Jy. The errors on the flux are taken to be the maximum of the standard flux calibration error of 10%, the noise *rms* and statistical errors from the fit. The resulting fluxes and their errors are listed in Table 6.

In addition to the ALMA fluxes, for all detected sources additional photometry and VLA radio fluxes were collected from catalogues and tables in literature. For the original targets the found photometric points are listed in Poorta et al. (2023). For the new detections the photometric flux points are listed in Table E.1. VLA fluxes were looked up from two extensive surveys in the M17 region with sensitivity down to 0.005 mJy at a beam size of about 0.04 arcsec² (Rodríguez et al. 2012; Yanza et al. 2022). The only detected source is B331, in both surveys. We list a 5σ upper limit for all other ALMA sources. The values are given in Table 6. Finally, all recovered flux points are plotted in Figure 4.

All the new sources are also detected in acquisition images in the K-band (central wavelength $\lambda_{\rm C} \sim 2.2 \ \mu m$ and FWHM $\sim 0.41 \ \mu m$) obtained with the LBT telescope on the 5th and 6th of July 2023 (A. Derkink, 2023, priv. comm.). On these images (Figures D.1 and D.2), the sources are clearly distinct from the original targets and have not moved in the almost two years time since the ALMA observations (Table 2).

3. Analysis

In order to draw conclusions on the measured fluxes and to constrain the source characteristics, we perform different analyses. First, to determine whether we can attribute the measured continuum fluxes to dust emission from a circumstellar disk or to free-free emission from ionized material we determine the spectral index in Section 3.1 and discuss its interpretation in Section 4.1. Second, under simplifying assumptions we calculate an upper limit on the gas mass from the non-detection of CO lines in Section 3.2. Thirdly, we estimate dust masses from the measured fluxes directly in Section 3.3. We then compare the measured fluxes with those obtained in a pre-calculated PRoDiMo model grid in Section 3.4. Lastly, in Section 3.5, we estimate disk masses using an adapted version of the disk model developed by Poorta et al. (2023) to fit CO bandhead emission from the same objects.

3.1. Spectral index and origin of detected fluxes

The slope between two or more different radio regimes is a widely used diagnostic toward characterizing the source of emission in the Rayleigh-Jeans limit. This slope is quantified as the spectral index which, following, e.g., Beckwith et al. (1990); Ty-choniec et al. (2020), is defined as:

$$\alpha = \frac{\log(F_{\nu_1}/F_{\nu_2})}{\log(\nu_1/\nu_2)} \tag{1}$$

with $F_{v_{1/2}}$ the flux at frequencies $v_{1/2}$, and $v_1 > v_2$ such that a positive spectral index indicates a descending slope toward longer wavelengths. For all detected sources we calculate the spectral index between ALMA Bands 7 and 6. For B331 we also determine the index between ALMA Band 6 and the VLA Xband at 10 GHz. The adopted frequencies for these bands are $v_7 = 341.4183$ GHz, $v_6 = 225.4311$ GHz, and $v_X = 10$ GHz for Band 7, Band 6, and VLA 10 GHz respectively. For B331 we additionally report a spectral index between the two VLA bands at 4.96 GHz and 8.46 GHz from Rodríguez et al. (2012). All the resulting indices are listed in table 6 and discussed in Section 4.1.

^{*f*} The spectral index between ALMA Band 6 and VLA 10 GHz is $\alpha = 0.53 \pm 0.06$. Rodríguez et al. (2012) report an index between VLA points 4.96 GHz and 8.46 GHz of $\alpha = 0.7 \pm 0.5$.

^{*g*} Only detected in Band 7, not subjected to further analysis.

^h This object was imaged with a UV-taper of 0.08" to increase signal-to-noise.

3.2. Upper limit on the gas mass

Based on the non-detection of the rotational ¹²CO (J = 2 - 1) line, we estimate an upper limit on the gas mass in the possible disks. Given that the beam sizes and rms values are very similar for the different object images we do this for one average limiting flux value ~ $24.0 \text{ mJy beam}^{-1} \text{ km s}^{-1}$ (Section 2.2). With a beam size of $0.07'' \times 0.04''$ this limit translates to an antenna temperature of ~ 220 K km s⁻¹. We used the non-LTE molecular radiative transfer code RADEX¹ (van der Tak et al. 2007) to estimate line radiation temperatures, using a kinetic temperature $T_{kin} = 100$ K, an H₂-density of 10^{10} cm⁻³ leading to LTE conditions, and a line width of 10 km s⁻¹ based on Keplerian velocities at ~ 30 to 50 au distance from our sources. Under these assumptions RADEX finds our limiting temperature with a CO column density $N_{\rm CO} \approx 4 \times 10^{17}$ cm⁻². The emission at this column density is optically thin ($\tau \approx 0.31$). Integrating over the beam size and assuming a CO abundance of $n(CO)/n(H_2) = 10^{-4}$, this column density results in an upper limit on the gas mass of $\sim 2 \times 10^{-5} M_{\odot}$.

If the disk is much smaller than the 120×70 au beam, the emission is likely optically thick, and, for an assumed kinetic temperature of 100 K, would have a brightness temperature of ~ 100 K. Such a disk would need to take up less than 20% of the beam area to remain undetected, corresponding to a disk radius of < 20-30 au, assuming an inclination in the range of 0-60°. Under the assumption of such a compact, optically thick disk, the CO column density could in principle be arbitrarily high. However, in the studied objects a constraint is provided by the CO bandhead emission, from which Poorta et al. (2023) derive a CO column density at the inner rim of the disk of $N_{\rm CO} \sim 1 - 8 \times 10^{21}$ cm⁻². This density is likely to decline further out in the disk with typical power law exponents between -1 (e.g., Woitke et al. 2016) and -1.5 (e.g., Poorta et al. 2023). Hence, to derive an upper limit on the gas mass under these conditions we adopt

a constant, average CO column density of $N_{\rm CO} \sim 5 \times 10^{20} {\rm cm}^{-2}$ and a CO abundance of $n({\rm CO})/n({\rm H_2}) = 10^{-4}$ throughout a disk of 30 au. In this case we derive an upper limit on the gas mass of $\sim 6 \times 10^{-3} M_{\odot}$.

3.3. Dust mass estimation: optically thin approach

Many studies use a simple approximation to estimate dust masses for populations of proto-planetary disks, assuming optically thin dust emission from an isothermal disk (e.g. Ansdell et al. 2016; Cazzoletti et al. 2019; Stapper et al. 2022). Under this approximation the dust mass in the disk is given by (Beckwith et al. 1990):

$$M_{\rm dust} = \frac{F_{\nu} d^2}{\kappa_{\nu} B_{\nu} (T_{\rm dust})},\tag{2}$$

with F_{ν} the measured flux at frequency ν , *d* the distance to the source, κ_{ν} the dust opacity at ν and $B_{\nu}(T_{dust})$ the Planck function at the assumed dust temperature T_{dust} . For the dust opacity we adopt the power law:

$$\kappa_{\nu} = \kappa_0 \left(\nu / \nu_0 \right)^{\beta},\tag{3}$$

with $\kappa_0 = 10 \text{ cm}^2/\text{g}$, $\nu_0 = 1000 \text{ GHz}$, and $\beta = 1$ from Beckwith et al. (1990). The commonly assumed dust temperature for disks around low mass stars is $T_{\text{dust}} = 20 \text{ K}$ (Andrews & Williams 2005). However, we anticipate higher temperatures due to the higher luminosities of our stars. Following Andrews et al. (2013) and Stapper et al. (2022) we use:

$$T_{\rm dust} = 25 \left(\frac{L_*}{L_{\odot}}\right)^{1/4}$$
 [K], (4)

resulting in dust temperatures between 110 K and 246 K for the objects in Table 1. For the serendipitous detections, for which we do not know the stellar luminosities, we adopt $T_{\text{dust}} = 150$ K.

¹ https://var.sron.nl/radex/radex.php

We list the resulting dust mass for all detected sources in Table 6 and emphasize that not for all of these objects dust emission is the most likely source of the measured flux (see Section 4.1). In Table 8 we list the dust masses under this approximation again only for the original targets with the purpose of comparing the results with the other estimates of disk gas and/or dust mass (see Section 4.2).

3.4. Disk mass estimation: ProDiMo model grid

To guide observations and serve as a reference for a first analysis, we computed a grid of models with an extended version of the radiation thermo-chemical code PRoDiMo (Woitke et al. 2009; Kamp et al. 2017) adapted for disks around hot stars (Backs et al. 2023). In these models we used the DIANA-standard model setup with a gas to dust mass ratio of 100 (Woitke et al. 2016). The grid consists of $10 \times 10 \times 5$ models with, respectively, total disk masses ranging from 5×10^{-4} to $5 \times 10^{-1} M_{\odot}$, outer radii from 20 au to 500 au, and inclinations from 15° to 75° . The central object for this grid was chosen to be B331 (see Table 1). The inner radius was set to 11.2 au, the dust sublimation radius for this object.

In our current analysis we use the resulting SEDs from these models solely as a reference point to compare with our other mass estimations (Table 8) and with the SEDs we calculate in Section 3.5. We fitted the model SEDs to the available photometry and ALMA points for each of the four targets in the sample. Before fitting we changed the underlying stellar continuum of each model to match the object in question. The best fit PRoDiMo models are all the same, with parameters $M_{\text{tot}} = 5 \times 10^{-4} M_{\odot}$ (lowest in grid), outer radius 233 au², and inclination 75° (highest in grid). Because the grid models are unable to fit the near- to mid-infrared photometry simultaneously with the ALMA points, and also provide little constraint on the disk mass, we use another disk model to acquire an improved fit of the data as described in the next section.

3.5. Dust and gas mass estimation: thin disk modeling

3.5.1. Model description

It is notoriously difficult to model the inner and outer regions of disks in one self-consistent model. As mentioned in Section 2.1, several previous studies have constrained the inner disk characteristics of the target sample based on infrared photometry and spectroscopy. In particular, Poorta et al. (2023, hereafter P23) constrain the column density and temperature of the gas in the inner parts of the disk ($\leq 1 - 2$ au) by fitting CO bandhead emission, and characterize the dust emission originating further out ($\leq 10 - 30$ au) by fitting the near- to mid-infrared SED. In this work, we aim to fit the SEDs including both the infrared photometry and the new ALMA-points, while taking into account the previously obtained constraints on the inner disk. For this we adopt the P23 model, which is a 1D Keplerian disk model that uses power laws for the radial density and temperature structure. It predicts the emission components from the CO gas and the dust assuming constant conversion factors for the H₂ to CO abundance and the dust-to-gas mass ratio. For this work we model only the dust emission, with a few adaptations with respect to the original model. For the inner disk column densities

Fig. 3: Illustration of the logistic function (Eq. 5) used for varying the dust to gas mass ratio M_d/M_g in the disk. The limiting values are fixed to the same values as in the models used for fitting: $(M_d/M_g)_{\text{base}} = 10^{-8}$ and $(M_d/M_g)_{\text{lim}} = 10^{-2}$. The value of the free parameter β is varied here to illustrate its effect.

we adopt the values resulting from fitting the first and second overtone CO bandheads.

Changes in the dust modeling pertain to the dust opacities and the dust-to-gas mass ratio. Where P23 use single grain-size astronomical silicate opacities from Laor & Draine (1993), we adopt the mass absorption coefficients calculated by Ossenkopf & Henning (1994) for dust in proto-stellar cores with the Mathis et al. (1977, i.e., MRN) size distribution. The tabulated dust opacities are for varying gas densities ($n_{\rm H} = 10^5$ to 10^8 cm⁻³) and for none, thin, or thick ice mantles on the grains. Due to the relatively hot and dense environments expected for the studied objects, we adopt $n_{\rm H} = 10^8$ cm⁻³ and grains without ice mantles.

The second change we introduce is that, instead of using a constant dust-to-gas mass ratio M_d/M_g throughout the disk, we vary this quantity using a logistic function as follows (see Figure 3 for an example):

$$M_{\rm d}/M_{\rm g} = (M_{\rm d}/M_{\rm g})_{\rm base} * \left[e^{\beta * (r-r_{\rm turn})}\right]^{-1} + (M_{\rm d}/M_{\rm g})_{\rm lim}.$$
 (5)

The function monotonically rises from the minimum limit $(M_d/M_g)_{\text{base}}$ to the maximum limit $(M_d/M_g)_{\text{lim}}$ as a function of disk radius *r* and free parameters β , the growth rate, and r_{turn} , the inflection point. As can be seen in Figure 3, the function approaches a step function for high values of β and a linear function for low values.

The motivation for introducing this function is that the P23 disk models with a constant dust-to-gas ratio cannot account for all the data points at the same time. This also holds for the previously described PRoDiMo models, which too have a constant dust-to-gas ratio. In both cases, models that fit the longer wavelength points strongly over-predict the infrared fluxes. This is likely connected to the fact that thermal dust emission in the near- to mid-infrared is not a good probe of the dust mass in the inner disk (e.g., P23, van der Marel 2023). This may be due to settling of the bulk of the dust to the mid-plane in the high-density inner regions of the disk, and only a small amount

² Because the density declines at higher disk radii, the disk's outer regions may easily fall below the detection limit, especially at low disk masses and high resolution observations. Thus, a large model outer radius can still be consistent with a 'smaller' observed source.

of grains in the disk surface layer contributing to the observable near- to mid-infrared thermal emission. This also leads to a sensitivity of the NIR emission to geometric effects such as the viewing angle. Since the P23 model lacks vertical structure, these effects would not be accounted for. Alternatively, the dustto-gas ratio could intrinsically vary, due to dust depletion in the inner disk in the presence of, for example, gaps, traps, pebble formation, or other disk structures and processes (e.g. van der Marel 2023). Of course, it is conceivable that a combination of these mechanisms is at play. Regardless of the physical situation, the approach described here is a way to allow the dust distribution in the disk to deviate from the gas column density structure. We briefly discuss interpretations and implications for the total disk mass in Section 5.1.1.

3.5.2. Extrapolation and fitting

With the P23 model and the previous modeling results we estimate the gas and the dust mass of the disk in two ways. Firstly, without fitting, and not taking into account the ALMA flux points, we directly extrapolate the column density in the inner disk derived from CO bandhead fitting by P23, $(\Sigma_i)_{CO}$, using the power law slope, q = -1.5, from the same fits. The gas mass is then given by

$$M_{\text{gas}} = \frac{n(\text{H}_2)}{n(\text{CO})} m_{\text{H}} \cdot (\Sigma_i)_{\text{CO}} \int_{(R_i)_{\text{gas}}}^{R_{\text{out}}} 2\pi r \left(\frac{(R_i)_{\text{gas}}}{r}\right)^q dr.$$
(6)

The inner radius for the gas, $(R_i)_{gas}$, is again taken from the CO bandhead fits (P23). The outer radius, R_{out} , is set to half the beam size of the image for each object (Tables 7, B.1, and B.2). Though B268 was imaged with a *uv*-taper to increase signal to noise (see Section 2.3 and Figure 2), for the purposes of this analysis we adopt a similar constraint on R_{out} as for the other sources. Similarly, the dust mass is given by

$$M_{\rm dust} = \frac{M_{\rm d}}{M_{\rm g}} \cdot \frac{n({\rm H}_2)}{n({\rm CO})} m_{\rm H} \cdot (\Sigma_i)_{\rm CO} \int_{(R_i)_{\rm dust}}^{R_{\rm out}} 2\pi r \left(\frac{(R_i)_{\rm gas}}{r}\right)^q dr.$$
(7)

The inner radius for the dust, $(R_i)_{dust}$, is defined as the point where the dust temperature reaches the dust sublimation temperature 1500 K and is estimated with a radiative equilibrium approach (following Lamers & Cassinelli 1999), using the dust opacities, the stellar temperature, and stellar radius (Table 1). Using the described logistic function (Equation 5) for the dustto-gas mass ratio has a negligible effect on the total disk mass. Therefore, for the purpose of this extrapolation we assume a constant dust-to-gas mass ratio $M_d/M_g = 10^{-2}$.

Secondly, we fit an SED to the photometry and ALMA flux points using the P23 model with the described adaptations. The SED has a stellar component that is represented by a Kurucz model matching the stellar parameters (Table 1). The dust emission from the disk is what we focus on. The fixed parameters going into the modeling are the inner and outer dust disk radius $(R_i)_{dust}$ and R_{out} (defined as before), the inclination *i* (taken from P23 CO fit results) and a temperature power law exponent which we fix to p = -1 based on exploratory fitting. We fit the initial column density Σ_i (at $(R_i)_{dust}$), power law exponent q, and the logistic function parameters r_{turn} and β (Eq. 5). The non-linear least-squares routine curve_fit from the SciPy module (version 1.9.3; Virtanen et al. 2020) is used to fit the data. The inverse of the errors on the flux are treated as weights and the errors on the fit parameters are calculated from the covariance matrix returned by the routine. The initial values and bounds of the fit parameters, as well as the fixed parameters and the results are listed in Table 7. The initial value of Σ_i and its bounds were determined by extrapolating $(\Sigma_i)_{CO}$ (P23) and its errors to $(R_i)_{dust}$, using q = -1.5 (P23). The resulting best fit SEDs are presented together with the data in Figure 4. In Figure 5 we show the temperature and dust-to-gas ratio of the best fit models along with their cumulative flux at two different wavelengths, all as a function of the disk radius.

The gas and disk masses resulting from the two approaches described in this section (extrapolation and fitting) are listed in Table 8. These figures and tables are discussed in Section 4.2.

4. Results

4.1. Spectral indices and nature of the sources

The most important diagnostics to distinguish the different physical origins of radio emission are source size and spectral index. We first briefly review the most common emission sources and their typical scales and spectral indices, and narrow down the possible mechanisms for the detected sources. We then consider the spectral indices for the sources separately.

4.1.1. Origin of radio emission and relation to spectral index

In general, the physical origin of radio emission can be thermal or non-thermal in nature (Yanza et al. 2022). Synchrotron emission by charged particles accelerated in a magnetic field is non-thermal. In a young massive SFR like M17 this could originate from the hot corona's of young low-mass stars (e.g. Feigelson & Montmerle 1999) or from colliding winds in massive binary systems (e.g Dougherty & Williams 2000). On much larger spacial scales than considered here, super-shells, for example due to collective stellar winds, may also produce nonthermal emission (e.g., Lozinskaya 1999). Non-thermal emission is most commonly, though not exclusively, associated with a negative spectral index, which we do not observe for any of the sources. For the original targets both mechanisms of compact non-thermal emission are very unlikely. On the one hand, the sources are too massive to harbor a magnetic field associated with a convective envelope. On the other hand, they show no signs of (near) equal mass binarity or strong stellar winds (Ramírez-Tannus et al. 2017, Backs et al. 2023, in prep.). Furthermore, the only object massive enough to generate a significant stellar wind would be B331 (~ 10 M_{\odot}), but an unresolved companion of similar mass also harboring such a wind would have resulted in a more luminous object. For the new detections a contribution from non-thermal emission cannot be excluded, as these sources could well be low-mass YSOs, but given their spectral indices (section 4.1.2), it would unlikely be the only contributing mechanism.

Thermal radio emission can either be due to free-free radiation or thermal dust emission. Since free-free radiation is caused by the (negative) acceleration of charged particles, it is always associated with ionized media. The most common of these that are relevant to the observed region are (remnants of) ultraor hyper-compact H II-regions surrounding young OB stars (e.g. Avalos et al. 2009; Sánchez-Monge et al. 2011), ionized winds of massive stars (e.g. Snell & Bally 1986), externally ionized protoplanetary disks (proplyds) (e.g. Stecklum et al. 1998; Zapata et al. 2004), jets from YSOs (e.g. Anglada et al. 2018), and photo-evaporating disk winds (e.g. Lugo et al. 2004). Thermal dust emission can originate either from a circumstellar disk

Notes. Disk mass estimates from (from left to right): Equation (2) (columns 1 and 2), PRoDIMo SED fitting (column 3), extrapolating the CO bandhead fitting results from P23 with disk sizes constrained by ALMA (column 4 and 5), and thin disk model SED fitting (column 5 and 6). The latter two approaches are explained in Section 3.5.2.

A discussion and comparison of the listed mass estimates is given in Section 4.2. For the comparison made to disk dust masses in other disk populations (Section 5.2.1) we relied on the dust mass estimates listed in column 2. Arrows up and down indicate lower and upper limits respectively.

^a Sources dominated by free-free emission. Masses derived using ALMA data represent upper limits and are placed between brackets.

or from the surrounding molecular cloud. In the latter case, the emission is more diffuse.

The main question for the original target sample is whether the detected emission can be solely or partially attributed to thermal dust emission from a circumstellar disk, or whether free-free emission should be considered. Since all the detected sources are compact (≤ 150 au in diameter), a large-scale origin of the emission, such as diffuse free-free or dust emission from the surrounding H_{II}-region and molecular cloud, as well as large-scale jets and outflows can be readily excluded as sources of the measured fluxes. Possible contributors to free-free emission originating close to the star include a small scale HII-region³, the base of a radio-jet, or ionized gas in a stellar wind or a photoevaporative disk wind. The latter are commonly associated with a spectral index $\alpha \simeq 0.6$ (Panagia & Felli 1975; Wright & Barlow 1975; Lugo et al. 2004). If all the ionized gas close to the star is optically thin, the emission will have an index $\alpha \simeq -0.1$ in the observed ALMA frequencies.

Finally, the spectral index for optically thick thermal dust emission is that of a black body, that is $\alpha = 2$. For optically thin dust the spectral index will depend on the grain size distribution. Small-sized grains in the interstellar medium (ISM) result in $\alpha_{mm}^{ISM} = 3.7$, whereas lower indices, between 2 and 3, are interpreted as a sign of grain growth in proto-planetary disks around

low-mass stars (van der Marel 2023). If the index in such disks is higher, it may indicate a lack of larger grains.

4.1.2. Spectral indices for detected sources

The spectral index of each detected source is listed in Table 6. We discuss the targets and serendipitous detections separately.

For two of the original targets, B243 and B275, we measure a spectral index consistent with a flux dominated by thermal dust emission from a circumstellar disk. The slightly lower index for B275 ($\alpha = 1.7 \pm 0.48$), could signify that there is some contribution from free-free emission, though the upper limit on the VLA 10 GHz measurement suggests that this is minimal (see also Figure 4). For B243 we measure the highest index ($\alpha = 2.7 \pm 0.61$), making it the only target source for which we likely detect (partially) optically thin dust emission, with possibly a particle size distribution depleted in larger grains. The tentative detection of B268 in Band 6 is likely not related to a disk, since the source is undetected in Band 7, giving an upper limit to the spectral index ($\alpha < 1.2$). B331 is the only object also detected in the VLA studies by Rodríguez et al. (2012) and Yanza et al. (2022). The flux values in those studies show an offset relative to each other (see Figure 4), but the derived spectral index $\alpha = 0.7 \pm 0.5$ by Rodríguez et al. (2012) is consistent with our derived index between the two ALMA flux points (0.52 ± 0.48) and also with the index between ALMA Band 6 and VLA 10 GHz (0.53 \pm 0.06). These indices clearly indicate that in B331 free-free emission

³ Estimated sizes of hyper-compact H π -regions are between 10^{-3} and 10^{-2} pc (Tielens 2005; Sánchez-Monge et al. 2011), corresponding to ~ 200 - 2000 au.

Fig. 4: Best fit SEDs, NIR and MIR photometry points, ALMA and VLA flux points for our four original targets and four sources serendipitously detected in the covered fields. Each panel shows the flux data for the original target and the Kurucz model for its stellar continuum in blue. The best fit model SED from the thin disk modeling (described in Section 3.5) is plotted in orange. Each panel also shows the flux data for the serendipitous detection(s) made in the field of the respective original target (in green and red) - these data are not fitted. The downward arrows indicate the upper limit derived for non-detections (mostly VLA 10 GHz). Only B331 (upper right panel) is detected at VLA wavelengths. The dotted lines indicate the slopes between the radio flux points for this object, with a spectral index ~ 0.67 for the VLA points at 4.96 GHz and 8.46 GHz (Rodríguez et al. 2012), and ~ 0.52 between the ALMA and VLA 10 GHz flux points (Yanza et al. 2022). There is an offset between the data from Rodríguez et al. (2012) and (Yanza et al. 2022).

dominates the measured flux, though a thermal dust contribution from a disk cannot be excluded.

Based on these observations, we assume for our further analysis that the fluxes of B243 and B275 are dominated by thermal dust emission from a circumstellar disk, and those of B268 and B331 by free-free emission. For the latter two objects the (upper limit of) the Band 7 flux was used for fitting. Their fit results and mass estimates based on ALMA data are placed between brackets in Tables 7 and 8.

Of the serendipitous detections B331 NW and B331 SW have spectral indices well above 2, consistent with (partially) optically thin dust emission from a circumstellar disk. B275 SE ($\alpha = 1.4 \pm 0.55$) and B243 SW ($\alpha = 0.6 \pm 0.8$) have indices consistent with a large contribution from free-free emission, though, again, a contribution from dust in a disk cannot be excluded. We discuss the serendipitous detections in Section 5.3.

4.2. Fit results and disk mass estimates

The best fit values of the thin disk modeling (Section 3.5) are listed in Table 7 and the resulting models are shown in Figure 4. The results for B331 and B268 are placed between brackets, because the fitted ALMA Band 7 flux point is either likely dominated by free-free emission (B331) or an upper limit (B268). Fitting simultaneously the short- and long-wavelength data points required a relatively shallow column density decrease (q > -1.5, except for B243), and high inner-disk surface densities (all best fit Σ_i are on or close to their maximum bound). This reflects that models with a nominal density structure (q = -1.5) and a small disk size ($R_{out} \leq 50 - 70$ au) that fit the short-wavelength flux, underpredict the ALMA flux. We found the reverse of this effect in the ProDiMo models, which overpredict the short-wavelength fluxes while fitting the ALMA points.

Fig. 5: Dust temperature (blue) and dust-to-gas mass ratio (black) as a function of disk radius resulting from the thin disk model fit (described in Section 3.5) for each object. The dotted black vertical line indicates the fitted inflection point R_{turn} of the logistic function of the dust to gas mass ratio. In red is the normalized cumulative flux distribution to illustrate where in the disk the majority of the thermal dust emission originates for different wavelengths and how this relates to the local dust abundance and temperature. The red dashed line is for the flux at ~ 4 μ m, the red solid line for the flux at ~ 1.3 mm (ALMA Band 6).

The course of the dust-to-gas mass ratio in the disk as parameterized by R_{turn} and β (Equation (5) and fig. 3) differs per object. This is visualized in Figure 5, which shows the dust temperature and best fit dust-to-gas mass ratio in the disk as a function of disk radius. Only for B331 β is high, and the dust to gas ratio approaches a step function with R_{turn} indicating where in the disk the dust abundance rises significantly. In all other cases β is small, so that the dust abundance rises more or less linearly and R_{turn} indicates where it bends toward its limiting value at 10^{-2} . Figure 5 also shows the normalized cumulative flux in the NIR $(4 \,\mu\text{m})$ and in ALMA Band 6 (1.3 mm), illustrating where in the disk the emission originates at these wavelengths. From this we see that for B275, B243, and B268 the NIR flux is dominated by hot (~1000 K) dust in the inner parts of the disk ($\leq 5-10$ au). For B331 there are two contributions: one from very tenuous hot dust in the inner disk, and a second from a small dense ring of cooler dust (~ 300 K). The ALMA flux mostly originates from dust beyond R_{turn} , where the dust abundance is highest and the disk has more surface area. The emitting dust temperatures vary from object to object. For B275 and B331 the best fit models indicate a lack of extended cool ($\leq 50 - 100$ K) dust, that is, the ALMA flux is dominated by higher temperatures ($\sim 100 - 200$ K). Since the flux of B268 is an upper limit, these results suggest that only B243 can be said to have an extended disk containing cool dust.

Table 8 summarizes all disk mass estimates for the four intermediate- to high-mass PMS stars. Again, the estimates for B331 and B268 that are based on ALMA fluxes are placed between brackets, as the ALMA fluxes for these objects are likely dominated by free-free emission. The estimate based solely on the extrapolation of the inner disk (≤ 1 au) CO bandhead fitting result leads to the lowest gas and dust masses ($M_{gas} \sim 10^{-5} - 10^{-4} M_{\odot}$). The best fit PRoDiMo model leads to a mass estimate close to the values from the extrapolation ($M_{tot} = 5 \times 10^{-4} M_{\odot}$). As this is the lowest-mass model calculated in the grid and it overestimates the NIR emission, this can be considered an upper limit in the context of estimates based on PRoDiMo modeling.

The dust masses determined directly from the ALMA fluxes through Equation (2) and from modeling the SEDs with the thin disk model lead to similar dust masses, that are at most an order of magnitude higher than the previous two estimates. The slightly lower dust mass estimate in Band 7 simply reflects how the measured spectral index differs from that assumed for the dust opacity (Section 3.3). The fit results as illustrated in Figure 5 suggest that the inner disks are dust depleted, or, in the case of B331, that there is a dust gap.⁴ In general, gas and dust gaps do not have to coincide (e.g. van der Marel 2023). By varying the dust-to-gas ratio separately from the gas column density, the models allow for the gas to decouple from the dust. If, instead, a gas-dust coupling was enforced, or if the gas would be even more depleted than the dust, this would result in lower gas masses than those presented in column five of Table 8. Thus, the gas masses derived from using the adapted P23 model to fit the SEDs can be seen as upper limits. Of course, this does not change the fact that the estimation heavily relies on the adopted results from the CO bandhead fitting. Finally, we recall that the non-detection of CO lines with ALMA suggests an upper limit on the gas mass of ~ $2 \times 10^{-5} M_{\odot}$ in the optically thin case, or, when assuming an optically thick compact disk, ~ $6 \times 10^{-3} M_{\odot}$ (Section 3.2).

5. Discussion

We present the first ALMA detections of disks around well studied, intermediate- to high-mass PMS stars at distances well beyond 1 kpc. Analysis of their properties reveals that they are mainly low-mass, compact disks, possibly dust-depleted in the inner regions, that likely do not contribute significantly anymore to the final stellar mass, nor to the formation of any significant planetary system (Section 5.1.1). Two of our target sources are dominated by free-free emission, indicating the presence of ionized material close to the star (Section 5.1.2). We place these findings in the context of trends observed in low mass SFRs and among Herbig stars, and find tentative evidence for an influence of the massive star formation environment on disk formation and evolution (Section 5.2). We also report four serendipitous detections, showcasing the capabilities of ALMA to probe disks in high mass SFRs (Section 5.3).

5.1. Detection of compact mm-emission towards intermediate- to high-mass PMS stars: what have we found?

5.1.1. Detection of disks

Of the four intermediate- to high-mass PMS stars in M17 presented in Section 2.1, three were unambiguously detected with ALMA in Bands 6 and 7. B268 was marginally detected in Band 6, providing an upper limit on the Band 7 flux and spectral index. The spectral indices presented in Section 4.1.2 suggest that of the four detections, two (B275 and B243) are likely related to cool dust emission from a disk, while the other two (B331 and B268) have a significant contribution from free-free emission, limiting constraints on possible outer disk masses to upper limits. Different approaches were used to estimate (upper limits to) the dust and gas masses in the disks. For the gas mass, these estimates were partially based on earlier results from fitting CO overtone bandhead emission from the inner disks of the targets.

The results detailed in Section 4.2 and Figure 5, obtained by fitting the SEDs with the adapted P23 model, suggest that the inner disks are dust depleted. In Section 3.5.1 it was mentioned

that the variation of the dust-to-gas ratio could also reflect a scenario in which the hot surface layers of the inner disk and the geometrical orientation determine the level of NIR flux, rather than the amount of dust itself. The P23 1D (geometrically thin) disk model cannot distinguish between these scenarios (or a combination of them) and if the inner disks are not as dust depleted as the best-fit models suggest, this could increase the dust mass. However, this increase will be minor since the issues only affect the inner part of the disk, while the bulk of the dust still resides in the outer parts. Moreover, the gas masses reported in Table 8 (and the remarks made on the results in Section 4.2) would remain unaffected.

The overall picture emerging from the reported results is that the studied objects are surrounded, if at all, by small ($R_{out} \leq 50 - 70$ au) circumstellar disks with low dust masses (at most a few M_{\oplus}). Estimations of the gas mass in the disks range from ~ 10⁻⁵ up to about ~ 10⁻³ M_{\odot} . It is possible, even likely, that the disks are more compact than assumed in the modeling and optically thick in the CO lines as discussed in Section 3.2. If that is the case, the gas mass might be as high as ~ 6×10⁻³ M_{\odot} . In any case, the low disk masses imply that all stars in the sample have essentially finished their main accretion phase, that is, have stopped accreting amounts of mass that still could contribute significantly to the final mass of the central star. This is in line with the well-detected photospheres of these objects and the previously reported lack of jets, outflows, or other signs of strong accretion bursts (Derkink et al. 2024).

In this context the presence of CO overtone bandhead emission in the spectra, which is often associated with accretion and earlier stages of formation (see Poorta et al. 2023, and references therein), may be surprising. Also, the hydrogen emission lines in the spectra of these targets are often linked to accretion and used to estimate accretion rates in Herbig stars (e.g., Wichittanakom et al. 2020). Accretion rates reported for objects with CO bandhead emission are very diverse, ranging from 10^{-3} to $10^{-8} M_{\odot} \text{yr}^{-1}$ (Poorta et al. 2023). Accretion rates of the order $\sim 10^{-7} - 10^{-8} M_{\odot} \text{yr}^{-1}$ are consistent with the mass (upper limit) estimates.

Our modeling suggests that the inner disks are dust depleted, reminiscent of gap- or ring-like structures in transition disks (TDs) among lower mass PMS stars (van der Marel 2023). Herbig stars are traditionally classified into Group I and Group II disks, originally based on their SED appearance (Meeus et al. 2001). The basic characteristics of these groups are summarized in Table 9⁵. Group I disks can be understood to be the high mass equivalent of T-Tauri TDs, with a large inner cavity, and a mmbright, extended, massive outer disk component. Classification in terms of Group I/II for our objects is ambiguous. Based on their near- to mid-infrared colors, and their inner dust gap B275 and B331 qualify as Group I. However, in terms of their low mm-brightness and their limited size all objects in our sample qualify as Group II.

We discuss the lack of extended, massive disks in mmemission further when comparing our results to previously studied disk populations in Section 5.2.

5.1.2. Free-free emission

While some contribution of cold dust to the mm-emission of B331 (and possibly B268) cannot be excluded, the spectral in-

 $^{^{4}}$ An alternative interpretation of the logistic function that was introduced in Section 3.5.1 will be discussed in Section 5.1.1.

⁵ For extensive discussion of the Meeus groups and their properties under different observations see e.g., Garufi et al. (2017); Brittain et al. (2023); van der Marel (2023)

Table 9: Herbig AeBe Group I and II source characteristics.

dices indicate a dominant role for free-free emission. The spectral indices found for B331 (0.5-0.7) are consistent with a stellar wind or disk wind. However, (a contribution of) other mechanisms such as optically thin free-free emission from ionized gas close to the star or the base of a radio jet cannot be excluded (see Section 4.1). With a mass of ~ $10 M_{\odot}$, B331 is the most massive source in the sample. There are no indications of a strong stellar wind in the X-shooter spectra (Ramírez-Tannus et al. 2017). As can be seen in the SED of B331 (top right panel of Figure 4) it lacks the NIR excess seen in the other sources, the infrared excess only starts at ~ $4-5 \,\mu$ m. This translates into the gap-like feature modeled in the dust abundance (Figure 5), that is, the dust is absent up to ~ 45 au, after which the dust-to-gas ratio steeply rises to 10^{-2} . Backs et al. (2023) also model this gap and, in the absence of long wavelength data, classify the object as a Group I source. All in all, the spectral index and the derived disk morphology combined could suggest a photo-evaporative disk wind. This is consistent with photo-evaporation mechanisms where the disk is being sublimated further away from the star and a middisk gap works its way both out- and inwards (Alexander et al. 2006; Hollenbach et al. 1994). Similar inner gaps have been observed for massive YSOs by Frost et al. (2021) who also attribute this, at least in part, to photo-evaporation.

The fact that B268 is only marginally detected indicates that the dust disk of this object is more dissipated than that of the other objects. It is noteworthy that both its stellar characteristics and its infrared SED are very similar to that of B243, for which a mm-disk is most clearly detected (Table 1 and fig. 4). It is also interesting that the CO bandhead emission for this source is very pronounced (Poorta et al. 2023), but that the estimated mass of its disk based on this emission is the lowest of all objects in the sample (columns five and six in Table 8). This underlines that the (near-)infrared view of a disk does not necessarily predict its properties probed at longer wavelengths. The most likely explanation of the observations of this source remains that its disk is more compact than that of the other, detected sources.

5.2. Disk masses and sizes compared to other disk populations

5.2.1. Low-mass star forming regions and Herbig stars

In Figures 6 and 7 we compare our objects with samples from the low-mass SFRs Lupus (Ansdell et al. 2016) and Upper Sco (Barenfeld et al. 2016), and with a sample of Herbig AeBe stars within a distance of ~ 450 pc studied by Stapper et al. (2022). Dust masses for all the objects in the quoted studies were determined from ALMA Band 6 and/or 7 continuum flux using Equation (2), be it sometimes with different assumptions on the dust temperature than in this study. For the purpose of comparison we therefore use the dust mass derived from Equation (2), and because of the (possible) free-free contamination discussed earlier we use the (upper limits on the) dust masses based on the Band 7 flux.

^c From Table 1.

 $^{d}\,$ For the serendipitous detections the M17 age from Stoop et al. (2024) is used.

In the four panels of Figure 6 we show the dust mass in the disk versus stellar mass (upper left), age (upper right), stellar luminosity (lower left), and outer dust radius (lower right). The parameters used for this comparison are summarized in Table 10. Compared to the other samples, our sample is small. The purpose of this comparison is therefore to see to what extent the higher mass objects in M17 follow previously identified trends.

In low mass SFRs two main trends have been observed with respect to dust masses among Class II disk populations (Lada 1987). The first is an increase with stellar mass, and the second is a decrease with stellar or region age (e.g., Pascucci et al. 2016; Ansdell et al. 2017; Barenfeld et al. 2016). The stellar mass trend can be seen in the Lupus and Upper Sco data points in the upper left panel of Figure 6, the age trend is seen when comparing between those regions globally (upper right panel). The Herbig sample of Stapper et al. (2022) follows the positive correlation with stellar mass, but not the negative correlation with older age. The authors explain this by suggesting that the effects of mass and age can be degenerate. As also found in previous studies (e.g., van der Marel & Mulders 2021), stars with higher mass do not only start out with a more massive disk, but also appear to retain this mass for a longer time. van der Marel & Mulders (2021) find that the existence of dust traps, caused by structures such as an inner gap or ring-shaped clearing, is necessary to retain an observable mm-dust reservoir for a longer time. Both Stapper et al. (2022) and van der Marel (2023) propose that such structures may form more readily in disks with higher mass.

There is a large spread in dust mass in the shown samples and as such the dust masses of the M17 objects are not outliers. However, the M17 sample studied here is both the most massive and the youngest sample in question, yet of all the samples has the lowest mean disk mass, contrary to the described trends above. The mean values are listed in Table 11 and shown in Figure 6. Also, the models suggest a mm-dust gap, yet for the M17 objects this does not come with an extended, high-mass mm-dust disk. On the other hand, in the intermediate- to high-mass range the evolutionary timescale of the star may approach or become small with respect to disk evolution timescales of low mass stars.

Fig. 6: Disk dust mass as a function of stellar mass (upper left), age (upper right), stellar luminosity (lower left), and outer dust radius (lower right), based on ALMA continuum data for different samples. The low-mass PMS populations of the Lupus (Ansdell et al. 2016) and Upper Sco (Barenfeld et al. 2016) SFRs are shown in orange and green, respectively. For these populations the age range of the SFR is indicated by plotting each object as a horizontal line in the age-plot. The Herbig Ae/Be sample from Stapper et al. (2022) is shown in blue and grey. The grey points are special cases in their sample that are both higher mass and younger - the labeled objects are discussed in the text. In black we show the PMS stars in M17 studied in this work. In the upper panels the mean dust mass, and the mean stellar mass (left) and age (right) of each sample is indicated with horizontal and vertical dashed lines. Upper limits on the dust mass are indicated by downward triangles. Upper limits on the outer dust radius (lower right) are indicated by triangles pointing left.

Higher mass stars may sooner deplete their disks due to short formation timescales, high accretion rates, strong UV illumination, and outflows from the star and/or disk. To allow for these effects in the age comparison across the stellar mass ranges, in Figure 7 we plot the age of the objects "normalized" by the PMS lifetime corresponding to their stellar mass. The dust mass in this plot is "normalized" by the stellar mass to better isolate the effects of age. (Almost) all plotted objects appear indeed on their PMS (age/ZAMS-age< 1). As may be expected, the M17 objects are further in their PMS evolution than the low mass star populations, where the PMS lifetime is (very) long (10^7 to almost) 10⁹ Myrs) compared to disk evolution timescales. Compared to the Herbig sample from Stapper et al. (2022) the M17 objects are similar, or slightly earlier in their evolution. Though there are some Herbig stars that fall in the same range, with respect to all the samples the stellar-mass-normalized dust masses of the M17 sample are very low.

The age-plot in Figure 6 includes the serendipitous discoveries which, as discussed in Section 5.3, are likely lower mass YSOs with disks comparable in mass to the original targets. As argued in that section, considering the density of YSOs in the region, the lack of higher-mass disk discoveries may hint at a disk population with relatively low masses, especially for a SFR as young as M17.

One possible explanation for the findings above is that the formation environment plays a crucial role in the initial disk mass distribution as well as disk evolution and lifetime. This explanation is supported by studies in other massive SFRs. Eisner et al. (2018), for example, study the disk population (92 disks) in the Orion Nebula Cluster and find compact disks (< 60 au), with low masses and with only a weak correlation between stellar mass and disk mass compared to low-density SFRs (see Table 11 for mean disk and stellar masses of their sample). They suggest that the disks are affected by photo-ionization and, pos-

Fig. 7: "Normalized" disk dust mass versus "normalized" age for the same samples as in Figure 6. The dust mass is normalized to the stellar mass of each object. The age is divided by the PMS lifetime of a star of the respective mass, set by the ZAMS-age from the MIST PMS tracks (Dotter 2016). For the objects in Lupus (orange) and Upper Sco (green), for which no individual age is known, the age range is indicated by plotting each object as a horizontal line. The dashed lines indicate the mean values of both quantities for the different populations.

Table 11: Mean disk dust masses and mean stellar masses for the samples from five star-forming regions plotted in Figure 6 and discussed in the text.

Region/Sample	< M _{dust} >	σ^{a}	$< M_{*} >$	σ^{a}	age
	(M_{\oplus})	(M_\oplus)	(M_{\odot})	(M_{\odot})	(Myr)
M17	1.7	0.82	6.5	2.3	0.6±0.3
Upper Sco	3.9	15	0.33	0.29	5-11
ONC^b	8.2	14	0.78	2.3	~1
Lupus	17	28	0.45	0.50	1-3
Herbig sample ^c	40	48	2.0	0.38	7±3

^a Standard deviation of the averaged values.

^b Orion Nebula Cluster sample from Eisner et al. (2018), not plotted in Figure 6.

^c The main sample from Stapper et al. (2022) (blue marks in Figure 6), excluding the (higher mass) exceptions (gray marks in Figure 6; see also Section 5.2.2).

sibly, stellar encounters. Similar population studies in Orion suggest that even intermediate far-UV radiation fields from A0 and B stars have a significant impact on the evolution of protoplanetary disks (van Terwisga et al. 2020; van Terwisga & Hacar 2023). Investigating mass and accretion in the disk population of the Lagoon Nebula (M8), Venuti et al. (2024) also find evidence for faster disk evolution in the central regions with respect to the outskirts of this massive SFR.

Finally, the upper limits on the disk radii are consistent with the observed trend between disk mass and radius in Stap-

Table 12: Parameters for high mass Herbig stars from Stapper et al. (2022).

Object	M _{dust}	R _{dust}	$\log L/L_{\odot}$	M_*	age
	(M _⊕)	au		$\left(M_{\odot}\right)$	(Myr)
HD58647	1.0±0.1	<126	$2.44_{-0.09}^{0.11}$	$3.9^{0.3}_{-0.2}$	$0.84_{-0.18}^{0.12}$
MWC297	65.7±9.6	<253	$4.41^{0.39}_{-0.50}$	14^{6}_{-5}	$0.04_{-0.02}^{0.07}$
ZCMa	7.6±6.4	<41	$2.25_{-0.29}^{0.51}$	$3.8\substack{+0.8\\-0.8}$	$0.80_{-0.59}^{0.83}$

per et al. (2022). Given the discussion above it would appear likely that the detections comprise optically thick, compact disks (≤ 30 au), that are able to shield themselves to survive the high UV-radiation environment. The mass estimate even in this case remains rather low. Next to external evaporation and encounters in the dense environment after disk formation, this might also be due to processes like competitive accretion limiting the amount of mass the disks could assemble during disk formation (e.g., Bate 2018).

5.2.2. Herbig stars of higher mass

In addition to the influence of the SFR environment on the disks, another (not mutually exclusive) explanation for the low disk masses of the M17 targets could be a faster disk evolution and dissipation in the higher stellar mass ranges. So far, in our comparison we have taken into account the bulk of the Herbig stars in Stapper et al. (2022), which have a mean mass of $\sim 2 M_{\odot}$ (the blue marks in Figure 6, see also Table 11), significantly lower than the masses of the M17 targets. Stapper et al. (2022) marked a few objects in their sample as exceptions (grey marks on the plots) because their Herbig nature was ambiguous - three of these due to their high-mass or very young nature. These three "exceptions" (MWC297, ZCMa, and HD58647) are labeled in the plots, because they are similar to the M17 objects in age, mass, and luminosity (lower left panel in Figure 6 and Table 12).

The low number of objects of this nature stresses the dearth of YSOs in the higher mass ranges ($\geq 4 M_{\odot}$) that have been subject to multi-wavelength studies. Because of this, it is not possible at the moment to derive statistical properties, and the comparison remains on an object-to-object basis. The difference between the labeled sources and the M17 targets is that the former are relatively isolated objects while the latter are located in a dense cluster environment. We now discuss each labeled source separately.

The two objects ZCMa and HD58647 are similar in mass (~ 3.8 M_{\odot}) and both have outflows associated with accretion. ZCMa has a FU Orionis variable companion and an asymmetric outflow (Baines et al. 2006). HD58647 is observed to have a disk wind from an accretion disk (Kurosawa et al. 2016) and its dust mass is similar to the M17 objects. This serves as an example that low (observable) dust mass and ongoing accretion can both be present.

MWC297 is a high mass star (~ 14.5 M_{\odot}) in the Herbig catalogue of Vioque et al. (2018), but was earlier classified as a zeroage-main-sequence star of ~ 10 M_{\odot} by Drew et al. (1997). Manoj et al. (2007) detect a remnant formation disk (< 80 au) with dust mass similar to that reported by Stapper et al. (2022) (~ 100 M_{\oplus}). They note the possibility of a disk wind or stellar wind based on a VLA spectral index of ~ 0.6. Interestingly, while a hot (~ 1500 K) gas component from the inner disk (~ 12 au) was detected in CO ro-vibrational fundamental and overtone emission, no cold gas was detected in CO lines at mm-wavelengths (Sandell & Vacca 2023; Manoj et al. 2007).

MWC297 is very similar to B331 in stellar mass, age, and luminosity. Moreover both have CO overtone bandhead emission in the NIR, both lack cold CO gas, and they have a similar VLA spectral index. The only significant difference is that the dust disk of MWC297 is almost two orders of magnitude higher in mass. Perhaps this points to a role for the environment in the disk evolution of high-mass YSOs.

5.3. Serendipitous discovery of sources

In the four fields surrounding the original targets four serendipitous detections were made in both ALMA Bands. All these radio sources have NIR counterparts. We collected NIR and MIR photometry from VizieR Catalogues ⁶. The flux points are listed in Table E.1and plotted in Figure 4. The source positions and projected distances from the closest original target are listed in Table 5.

We estimated the expected number of extra-galactic background sources as a function of field-size by adopting Equation A10 from Anglada et al. (1998) with the ALMA 12m primary beam $\theta_A \approx 20.6'' \times (300/\nu)$ GHz. This yields (similar to Equation A11 from Anglada et al. (1998))

$$< N > = 0.00196 \left\{ 1 - \exp\left[-0.00123 \left(\frac{\theta_{\rm F}}{\rm arcsec} \right)^2 \left(\frac{\nu}{300 \,\rm GHz} \right)^2 \right] \right\} \\ \left(\frac{\nu}{300 \,\rm GHz} \right)^{-2} \left(\frac{S_0}{\rm mJy} \right)^{-0.75} \left(\frac{\nu}{5 \,\rm GHz} \right)^{-0.525} ,$$

with $S_0 = 0.165$ mJy the minimum detectable flux density at the field center, taken to be five times the sensitivity in Band 6; $\nu = 225$ GHz the Band 6 frequency; and $\theta_F = 14''$ the field diameter. We find the expected number of extra-galactic sources in each field to be negligible, $\langle N \rangle \approx 2 \times 10^{-4}$.

We now discuss known characteristics per source.

The two sources B275 SE and B243 SW are listed in the Massive Young star-forming Complex Study in Infrared and X-rays (MYStIX; Broos et al. 2013) catalog as an X-ray (Chandra) source with NIR counterpart, and classified as "young star in a massive SFR". Both objects also feature in a study by Yang et al. (2022), who use machine learning techniques to assign probabilities (P) to the classification of X-ray sources based on multi-wavelength features (X-ray, NIR-MIR photometry and colors). They classify B275 SE as low-mass X-ray binary (LMBX) with P = 0.4 or as YSO with P = 0.3. Considering the evolved nature of LMBX's and the young age of M17, the first classification seems rather unlikely. B243 SW is classified as YSO with P = 0.75. This object is also labeled as a variable source in *Gaia* DR3 Gaia Collaboration et al. (2023).

Based on these findings, both B275 SE and B243 SW are likely (low mass) YSOs. The spectral indices ($\alpha = 1.4 \pm 0.55$ and $\alpha = 0.6 \pm 0.8$ respectively) indicate a contribution from free-free emission, for B275 SE probably next to dust emission from a circumstellar disk. In the case of B243 SW, the presence of both variability and X-rays may indicate that the free-free emission is related to an outflow driven by ongoing accretion (see, e.g., Rota et al. 2024). However, even without correcting for the contribution of free-free flux, the derived dust mass for this detection is rather low (see Table 6). B331 NW and B331 SW have spectral indices well above 2, consistent with (partially) optically thin dust emission from a circumstellar disk. B331 NW ($\alpha = 2.3 \pm 0.6$) has a relatively low projected separation from B331 (1.4", ~2300 au) and is therefore not resolved in most photometric surveys. In the reported data from Pan-STARRS1 (Chambers et al. 2016) and MYStIX crowded fields (King et al. 2013) it is barely resolved, and the measured fluxes are likely contaminated by B331. It is clearly observed as a distinct source in the previously mentioned acquisition images from LBT (Figure D.2). B331 SW ($\alpha = 2.4 \pm 0.5$) is the faintest detection in the NIR with only one survey (King et al. 2013) reporting fluxes, yet it is the second (after B331) brightest detection with ALMA. Perhaps this object is of lower mass, partly obscured by its disk, or simply more embedded.

All in all, it is likely that all four serendipitous detections relate to (lower-mass?) YSOs and that at least two have a dust disk. None of these objects is resolved, and the measured fluxes are similar to those of the original targets, leading to again similar values for (upper limits on) the dust mass and radius. For the reported masses in Table 6 a temperature of T = 150 K was used. Assuming lower dust temperatures for these sources, e.g., $T_{dust} = 20$ K, would result in dust mass estimates about one order of magnitude higher (i.e., a few tens of M_⊕), closer to the averages found in low-mass SFRs (Figure 6). Yet for the two objects with free-free emission this would still represent an upper limit.

The overall picture from these detections, under the assumption that they are YSOs, is that their disks are small and on the lower mass end for an age of ~ 0.6 Myrs (see upper right panel Figure 6). While the discoveries testify to the source density in the region, it is remarkable that brighter disks that would have been detected if present in these fields, are lacking. The number of sources is too small to be conclusive, but it is not unlikely that we are "catching" the brightest (i.e., most massive) disks and that deeper observations would yield a yet fainter population. As suggested before for the original targets it is possible that the disks are compact, optically thick, and more massive than derived under an optically thin assumption. That would support the notion that in a dense, high-UV environment like M17 perhaps this is the kind of disk that survives, when disks survive at all.

6. Summary and conclusions

In this paper, we present ALMA mm-continuum detections of four intermediate- to high-mass PMS stars in the massive star forming H $\scriptstyle\rm II$ region M17 (distance 1.7 kpc) and report on the serendipitous discovery of four additional sources, likely lowmass YSOs. All detected sources are unresolved at a resolution of $\sim 0.07''$, constraining the outer radius of the emission to maximally ~ 60 au. We use the spectral index between ALMA Bands 6 and 7, and (upper limits on) the VLA cm-flux to determine the origin of the mm-emission, that is, free-free radiation or thermal dust emission. We derive (upper limits on the) dust masses from the ALMA continuum flux and an upper limit on the gas mass from the non-detection of the rotational ¹²CO (J = 2 - 1) line. We combine the ALMA data with near- to mid-infrared photometry and spectroscopy and apply different models to estimate the total disk masses of the target sources. In the following we summarize our results:

- The disks around the four target sources as well as the four serendipitous discoveries contain a dust mass of (at most) a few M_{\oplus} .
- Estimates of (the upper limit on) the total gas mass in the disks around the intermediate- to high-mass PMS stars vary

⁶ https://vizier.cds.unistra.fr/viz-bin/VizieR

between ~ $2 \times 10^{-5} M_{\odot}$, and, when assuming an optically thick compact disk, ~ $6 \times 10^{-3} M_{\odot}$.

- Spectral indices suggest that the fluxes from two target sources and two serendipitous sources have a significant contribution from free-free emission from ionized material. In the higher-mass sources (B331 and B268) this may indicate a small-scale H II-region, the base of a radio jet, or a photo-evaporative disk wind. In the (likely) low mass sources (B275 SE and B243 SW) the combination with X-ray emission may indicate an accretion driven outflow.
- Our modeling suggests that the inner disks of (some of) the targets are dust depleted, reminiscent of gap- or ring-like structures, despite the presence of hot and dense gaseous disks, as evidenced by CO bandhead emission from these objects.
- Comparison to disk population studies in low-mass SFRs and among Herbig stars indicates that our sample is both the most massive and the youngest. However, contrary to commonly observed trends, it has the lowest mean disk dust mass.

All in all, we conclude that the studied targets are surrounded by low-mass, compact disks that likely do not offer a significant contribution anymore to either the final stellar mass or the formation of a planetary system. Along with the four serendipitous discoveries, our findings offer tentative evidence of the influence of the massive star formation environment on disk formation, lifetime, and evolution. The detections presented hint at a rich YSO population in M17, with disks detectable by ALMA. This, along with the thousands of known IR excess sources in M17 (Lada et al. 1991; Jiang et al. 2002), offers the perspective of disk population studies that not only include a significant number of intermediate- to high-mass targets, but also allows the study of them along side low-mass YSOs in a massive SFR.

Appendix B: Full fitting results

In Tables B.1 and B.2 we provide the detailed results of the 2D Gaussian fitting procedure described in Section 2.3. Where the values for the deconvolved major/minor axes are missing, the CASA fitting task could not deconvolve the source from the beam, due to insufficient resolution. The cases where the deconvolved axes are provided, the resulting values are significantly smaller than the corresponding beam axis and likely not representative of true source sizes.

Appendix C: Field images

In Figures C.1 to C.8 we show fields from the images created to determine source detections (described in Section 2.2). Fields from these images were already presented in Figure 2 zooming in on each detected source. To clarify the significance of the detections we present a larger field for each target source, in Band 6 and Band 7. Each field shows the area around the detections (or, in case of Figure C.8, the lack thereof) with the sources labeled in white, as well as the 5, 7, and $8 \times rms$ contours which are drawn in white, orange-red, and yellow respectively. Only on figure Figure C.7 the white contours indicate $3 \times rms$. The beam is indicated in the bottom left corner, and a scale bar is shown in the bottom right corner, both in red. The images are scaled such that only emission from $\geq 2 \times rms$ is non-zero.

Parameter	B275	B275 SE	B331	B331 NW	B331 SW	B243	B243 SW	B268

B275 BAND 6

Fig. C.1: Image around target source B275 in ALMA Band 6, showing detections of B275 and B275 SE.

B275 BAND 7

Fig. C.2: Image around target source B275 in ALMA Band 7, showing detections of B275 and B275 SE.

B331 BAND 6

Fig. C.3: Image around target source B331 in ALMA Band 6, showing detections B331, B331 NW and B331 SW simultaneously.

B331 BAND 7

Fig. C.4: Image around target source B331 in ALMA Band 7, showing detections B331, B331 NW and B331 SW as well as B331 NE, which could also be a noise peak.

B243 BAND 6

Fig. C.5: Image around target source B243 in ALMA Band 6. B243 and B243 SW are detected on this image.

Fig. C.6: Image around target source B243 in ALMA Band 7. B243 and B243 SW are detected on this image.

A&A proofs: manuscript no. ALMA_paper

Fig. C.7: Image around target source B268 in ALMA Band 6. B268 is only possibly detected in this image (SNR 3), as the central contour that could otherwise be a noise peak coincides precisely with the coordinates of the NIR source (marked by the white circle).

Article number, page 28 of 31

Fig. C.8: Image around target source B268 in ALMA Band 7. Though the location of B268 is marked for reference, there are no detections in this image.

Appendix D: Acquisition images LBT

All serendipitous detections have NIR counterparts. Apart from catalogued fluxes, these sources were also detected in the K-band on acquisition images made with the LBT telescope (see Section 2.3, and Derkink et al. 2024, in prep.).

Fig. D.2: Serendipitous detections near B331.

Appendix E: Photometry

Table E.1: Photometry for the serendipitous detections.
