ABSTRACT

We present a detailed study of a double-peaked Ly α emitter, named LAE-11, found in the proximity zone of quasar J0910-0414 at $z \sim 6.6$. We use a combination of deep photometric data from Subaru Telescope, *Hubble Space Telescope*, and *James Webb Space Telescope* with spectroscopic data from Keck/DEIMOS, *JWST*/NIRCam WFSS and *JWST*/NIRSpec MSA to characterise the ionising and general properties of the galaxy, as well as the quasar environment surrounding it. Apart from Ly α , we also detect H β , [OIII] $_{\lambda\lambda 4960,5008}$ doublet, and H α emission lines in the various spectral datasets. The presence of a double-peaked Ly α profile in the galaxy spectrum allows us to characterise the opening angle and lifetime of the central quasar as $\theta_Q > 49.62^\circ$ and $t_Q > 3.8 \times 10^5$ years, and probe the effect of the quasar's environment on the star formation of the galaxy. LAE-11 is a fairly bright ($M_{UV} = -19.84^{+0.14}_{-0.16}$), blue galaxy with a UV slope of $\beta = -2.61^{+0.06}_{-0.08}$ with moderate ongoing star formation rate ($SFR_{UV} = 5.25 \pm 0.69 M_\odot \text{ yr}^{-1}$ and $SFR_{H\alpha} = 12.93 \pm 1.20 M_\odot \text{ yr}^{-1}$). Since the galaxy is located in a quasar-ionised region, we have a unique opportunity to measure the escape fraction of Lyman Continuum photons using the un-attenuated double-peaked Ly α emission profile and its equivalent width at such high redshift. Moreover, we employ diagnostics which do not rely on the detection of Ly α for comparison, and find that all tracers of ionising photon leakage agree within 1σ uncertainty. We measure a moderate escape of Lyman Continuum photons from LAE-11 of $f_{\text{esc}}^{\text{LyC}} = (8 - 33)\%$. Detections of both H α and H β emission lines allow for separate measurements of the ionising photon production efficiency, resulting with $\log(\xi_{\text{ion}}/\text{Hz erg}^{-1}) = 25.59 \pm 0.08$ and 25.65 ± 0.09 , for H α and H β , respectively. The total ionising output of LAE-11, $\log(f_{\text{esc}}^{\text{LyC}} \xi_{\text{ion,H}\alpha}/\text{Hz erg}^{-1}) = 24.85^{+0.24}_{-0.34}$, is higher than the value of $24.3 - 24.8$ which is traditionally assumed as needed to drive Reionisation forward.

Key words. Early Universe, Reionisation, Galaxies, First Galaxies, Galaxy Formation

1. Introduction

The Epoch of Reionisation (EoR) marks the second and last major phase transition in the history of the Universe. During this era, the majority of neutral hydrogen gas in the intergalactic medium (IGM) became ionised. Observations of the Lyman- α (Ly α) forest in the spectra of high redshift quasars (QSOs) indicate that the EoR concludes at $z \sim 5.3$ (Bosman et al. 2018; Kulkarni et al. 2019; Bosman et al. 2022; Gaikwad et al. 2023; Spina et al. 2024). Though the end of EoR is tightly constrained, its onset and course are still uncertain due to the unknown nature and output of ionising radiation (Lyman Continuum; $E > 13.6$ eV) of the sources driving reionisation of the IGM. The current leading candidates for major drivers of the EoR are early star forming galaxies, whose young and massive stars produce a large amount of Lyman Continuum photons (LyC, $\lambda < 912\text{\AA}$)

(e.g. Robertson et al. 2013, 2015; Finkelstein et al. 2019; Dayal et al. 2020; Naidu et al. 2022).

With increasing redshift, the fraction of neutral hydrogen found in the IGM rises (e.g. Dijkstra et al. 2011; Inoue et al. 2014; Mason et al. 2018), making direct observations of LyC escape from early star forming galaxies nearly impossible. For this reason, the nature of the galaxies contributing the majority of the ionising budget is still uncertain. Some research points towards rare luminous galaxies as major sources of ionising radiation (Naidu et al. 2020; Nakane et al. 2024) as their late formation couples with the late onset of Reionisation. Others (e.g. Finkelstein et al. 2019; Mascia et al. 2024; Atek et al. 2024; Simmonds et al. 2024), on the other hand, prefer the contribution from the numerous faint ($M_{UV} > -18$) galaxies found at these times. Without measuring the amount of ionising photons these

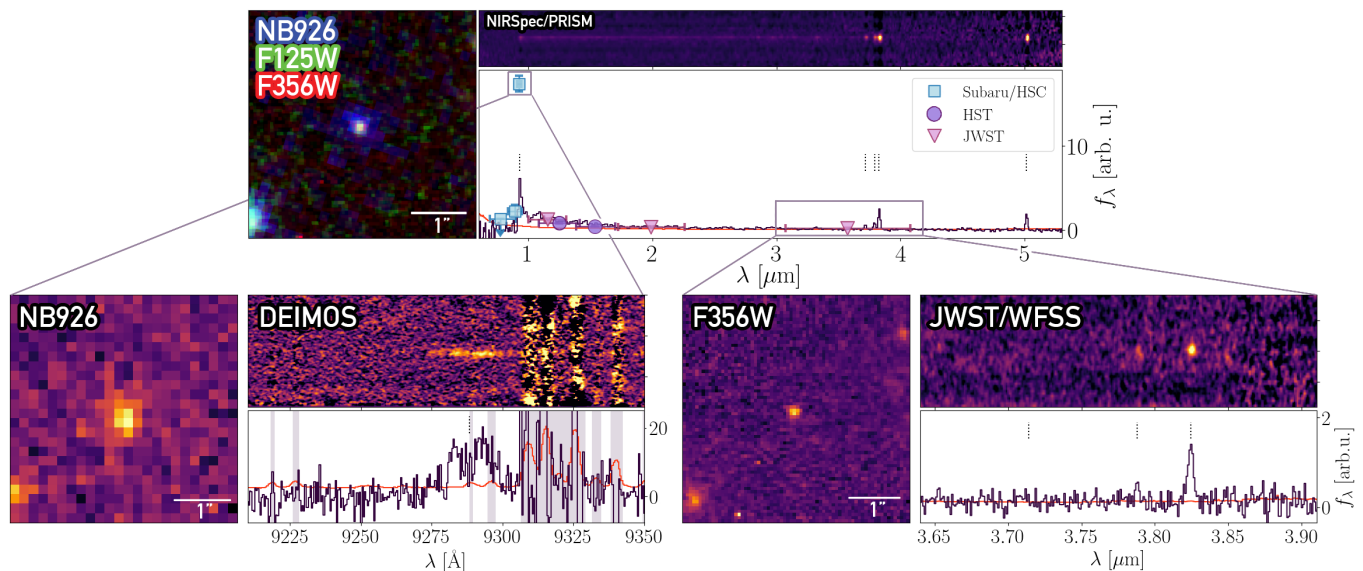

Fig. 1. The available photometric and spectroscopic dataset of LAE-11. (*upper*) A composite image of LAE-11 consisting of the *NB926*, *F125W* and *F356W* photometry, the 2D and 1D NIRSpect/PRISM spectrum of LAE-11 located at $z = 6.6405 \pm 0.0005$. The uncertainty on each pixel of the 1D spectrum is represented with a red line. The dotted vertical lines represent detected emission lines. From left to right: $\text{Ly}\alpha$, $\text{H}\beta$, [OIII] doublet, and $\text{H}\alpha$. The spectral energy distribution of LAE-11, encompassing photometric data from Subaru/HSC (blue squares), *HST*/WFC3 (purple circles), and *JWST*/NIRCam (pink triangles) is shown on top of the 1D NIRSpect spectrum. (*lower*) *NB926* image, 2D and 1D Keck/DEIMOS spectrum of LAE-11 on the left with *F356W* image, 2D and 1D *JWST*/NIRCam WFSS spectrum of LAE-11 on the right. The uncertainty on each pixel in both spectra are represented with a red line. The dashed vertical lines mark the position of the $\text{Ly}\alpha$ in the DEIMOS spectrum, $\text{H}\beta$ and [OIII] doublet emission lines in the NIRCam spectrum. The shaded vertical regions in the DEIMOS spectrum represent the skylines in the DEIMOS regions.

galaxy populations inject into the IGM, the character of the true drivers behind Reionisation cannot be easily resolved.

While direct measurements of the LyC escape cannot be performed for high- z sources, indirect diagnostics were inferred using low redshift ($z < 3$) analogues (see Zackrisson et al. 2013, 2017; Nakajima & Ouchi 2014; Izotov et al. 2018; Jaskot et al. 2019; Katz et al. 2022; Flury et al. 2022a,b; Choustikov et al. 2024, etc.). Some of these indirect tracers link LyC escape with $\text{Ly}\alpha$ emission due to the high sensitivity of its radiative transfer to neutral hydrogen column density. Whenever $\text{Ly}\alpha$ photons encounter dense neutral gas, they scatter and Doppler-shift until they emerge out of resonance through the red or blue wing of the line shape, creating a double-peaked line profile. The separation of the two peaks is directly linked to the neutral hydrogen column density that blocks LyC photons from escaping along the line of sight to the observer (e.g. Verhamme et al. 2015; Kakiichi & Gronke 2021), and is therefore a powerful indirect tracer of LyC leakage (e.g. Verhamme et al. 2015; Izotov et al. 2018; Flury et al. 2022b).

The double-peaked $\text{Ly}\alpha$ emission line profile is frequently observed in low- z $\text{Ly}\alpha$ emitters (LAEs), such as Green Peas galaxies (GPs; Orlitová et al. 2018) and $\text{Ly}\alpha$ blobs (LABs; Matsuda et al. 2006). However, the increased attenuation by the neutral IGM makes the detection of the blue peak rare at $z > 5$ (Matthee et al. 2017; Shibuya et al. 2018; Mason & Gronke 2020; Tang et al. 2024a), as even a small fraction of neutral gas ($x_{\text{HI}} \geq 10^{-4}$) leads to its suppression (Dijkstra 2014). Despite their apparent rarity, a small number of high- z LAEs residing in localised bubbles of ionised gas have been found, providing an excellent opportunity to measure the $f_{\text{esc}}^{\text{LyC}}$ of high- z galaxies. These galaxies reside either in large ionised bubbles (Hu et al. 2016; Matthee et al. 2018; Songaila et al. 2018; Meyer et al. 2021) or the proximity zones of high-redshift quasars (Bosman et al. 2020).

Quasar proximity zones trace small regions of highly ionised hydrogen around a luminous quasar, driven by the central AGN (Madau & Pozzetti 2000; Wyithe & Loeb 2004; Eilers et al. 2017; Satyavolu et al. 2023), allowing observations of flux blueward of $\text{Ly}\alpha$ at high- z . As seen in Zheng et al. (2006); Meyer et al. (2022); Wang et al. (2023) and others, high- z quasars, due to their implied large halo masses, are expected to trace overdense regions and protoclusters of star-forming galaxies, potentially increasing the chance of detecting LAEs in their vicinity, however observational results do not reach a consensus with some quasars lacking an overdense environment (e.g. Bañados et al. 2013; Mazzucchelli et al. 2017; Champagne et al. 2023; Rojas-Ruiz et al. 2024). As such, a high number of LAEs have been found in the proximity zone of the quasar J0910-0414, which was part of the *A Spectroscopic survey of biased halos in the Reionization Era* (ASPIRE) survey (Wang et al. 2023). One of these galaxies is located at a proper distance of $d_{\text{QSO}} \sim 0.3$ pMpc from the quasar, designated LAE-11, and displays a double-peaked $\text{Ly}\alpha$ emission line (Wang et al. 2024b), whose presence confirms the existence of an ionised region around J0910-0414. In this paper, we present a detail study of LAE-11 using data from Subaru Telescope, Keck Telescope, *Hubble Space Telescope* (*HST*), and *James Webb Space Telescope* (*JWST*).

The structure of this paper is as follows: In Section 2 we describe the available dataset for LAE-11, and the reduction of each set of data. In Section 3, we detail the procedure used to calculate the systemic redshift of LAE-11, methods used to extract emission line measurements and the UV properties of the galaxy, and the SED-fitting of the spectro/photometric data available in this study. In Section 4, we present the measurements of the ionising properties of LAE-11, as well as the star formation rate (SFR) measurements. Moreover, we focus on the quasar itself and calculate its opening angle and lifetime. Finally, in Sec-

tion 5, we discuss the effects of the quasar ionising radiation on the galaxy, and discuss the impact that galaxies similar to LAE-11 had in the EoR. Throughout this work, we use the Λ CDM model Planck18 as presented in Planck Collaboration (2020) with the following parameters: $\Omega_{\Lambda} = 0.69$, $\Omega_{\text{m}} = 0.31$, and $H_0 = 67.7 \text{ km s}^{-1} \text{ Mpc}^{-1}$. All magnitudes quoted in this work are in the absolute bolometric (AB) system (Oke & Gunn 1983).

2. Data

The quasar J0910-0414 was discovered by Wang et al. (2019) using the data from the DESI Legacy imaging Surveys (Dey et al. 2019), the Pan-STARRS1 Survey (Chambers et al. 2016) and additional infrared imaging data. Candidate selection was followed by spectroscopic observations, where J0910-0414 was observed by Magellan/FIRE (Simcoe et al. 2013) and Gemini/GMOS (Hook et al. 2004). These spectra showcase a strong blueshifted CIV absorption feature, which categorises J0910-0414 as a Broad Absorption Line (BAL) quasar. The redshift of the host galaxy was measured with ALMA to be $z = 6.6363 \pm 0.0003$ using the [CII] line (Wang et al. 2024a). Due to its high supermassive black hole (SMBH) mass of $M_{\bullet} = (3.59 \pm 0.61) \times 10^9 M_{\odot}$ measured from its MgII line and UV brightness of $M_{\text{UV}} = -26.61$ (Yang et al. 2021), this quasar was selected as a likely candidate to trace an overdensity of galaxies. The quasar field and consequently LAE-11 were observed with a number of photometric and spectroscopic surveys which we use in this work, described in the following Section. The entire available dataset for LAE-11 is summarised in Fig. 1.

2.1. Photometry

2.1.1. Subaru/HSC

The first targeted photometric observations of the field surrounding quasar J0910-0414 were conducted from November 2019 to January 2020 with the Hyper Suprime-Cam (HSC) mounted on the 8.2 m Subaru Telescope (Miyazaki et al. 2018; Komiyama et al. 2018; Kawanomoto et al. 2018; Furusawa et al. 2018). The imaging covered a circular field of view with $r \sim 40'$ centred on the quasar (Wang et al. 2024b). The field was observed using two broad band filters, *i2* and *z*, and the narrow band filter *NB926* designed to capture the Ly α emission of J0910-0414's surrounding galaxies across the redshift range $6.494 < z_{\text{Ly}\alpha} < 6.739$. The exposure times were ~ 150 minutes, ~ 240 minutes, and ~ 313 minutes, respectively.

The detailed data reduction process using the hscPipe 6.7 pipeline (Jurić et al. 2017; Bosch et al. 2018) and LAE selection criteria are described in Wang et al. (2024b), though we provide a brief overview here. First, each individual observation was processed, calibrated, and then combined into a stacked mosaic. Afterwards, the pipeline implements photometric and astrometric calibrations to the stacked mosaics, resulting in a seeing in each mosaic of $0.79''$, $0.74''$, and $0.56''$ with 5σ limiting magnitudes measured in $1''.5$ diameter apertures of 27.31, 26.27, and 25.71

for filters *i2*, *z*, and *NB926*, respectively. To create a dataset of nearby LAE candidates, Wang et al. (2024b) imposed a colour selection requiring a substantially stronger detection in the narrow band filter compared to the broad band filter. The photometry was then extracted using the hscPipe pipeline. We use the measured magnitudes found in Wang et al. (2024b)

2.1.2. HST

To measure the rest-frame UV emission and spectral energy distribution (SED) of the galaxies clustered around the quasar J0910-0414, we use photometry with high spatial resolution which was obtained using the Wide Field Camera 3 (WFC3; Kimble et al. 2008) on board of the *HST* (Wang et al. 2020, PID 16187; P.I. Feige Wang) on March 10th, 2022. The observations utilised 4 primary orbits and were taken in the NIR *F125W* and *F160W* bands, centred on the position of the quasar, covering an area of $\sim 31 \text{ arcmin}^2$. The *HST* imaging was processed, calibrated and drizzled using the DrizzlePac package v3.2.1 (Fruchter & et al. 2010) with the reference calibration file `hst_0988.pmap`. The resulting drizzled and stacked mosaics result in exposure times of 9582.75 s and 10897.40 s with 5σ limiting magnitudes of 28.26 and 27.98 measured in a $0''.4$ diameter apertures for filters *F125W* and *F160W*, respectively. We extracted the photometry using source-extractor (Bertin & Arnouts 1996).

2.1.3. JWST

Additionally, we use complementary data obtained with the NIRCcam instrument (Rieke et al. 2003) on board of the *JWST*, which were taken as part of the medium-size *JWST* Cycle 1 program ASPIRE (PID 2078, P.I. Feige Wang). The survey focused on 25 quasar fields at $6.5 < z < 6.8$, including the quasar J0910-0414. The photometric observations were taken in August 2022 with the broad band filters *F115W*, *F200W*, and *F356W*, covering an area of $\sim 11 \text{ arcmin}^2$. This configuration covers the rest-frame optical emission from the quasar and its surrounding galaxies. The NIRCcam data were processed using the standard *JWST* pipeline (Bushouse et al. 2022) v1.8.3 in combination with a custom set of scripts which are detailed in Wang et al. (2023) and Yang et al. (2023). The reference calibration file `jwst_1015.pmap` was utilised. The resulting exposure times are 1417.254 s, 3779.344 s, and 1417.254 s and 5σ magnitudes of 29.24, 29.68, and 27.82 measured in $0''.32$ diameter apertures for filters *F115W*, *F200W*, and *F356W*, respectively. A source catalogue was extracted using SourceExtractor++ (Bertin et al. 2020) and the detailed procedure is described in Champagne et al. (2024a).

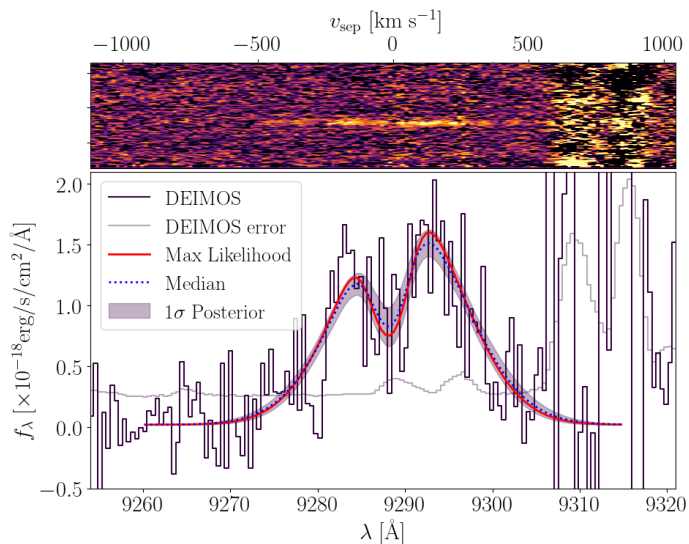

Fig. 2. (upper) 2D spectrum showcasing the double-peaked $\text{Ly}\alpha$ emission. (lower) The MCMC fit to the $\text{Ly}\alpha$ line profile. The dark and light purple lines mark the observed spectrum and its uncertainty. The red line indicates the maximum likelihood model. The dotted blue line shows the median model and the shaded region marks its 1σ posterior.

2.2. Spectroscopy

2.2.1. Keck/DEIMOS

We used optical spectroscopic data provided by the DEep Imaging Multi-Object Spectrograph (DEIMOS) (Faber et al. 2003) mounted on the 10 m Keck-II Telescope, which were obtained as a spectroscopic follow-up of the LAE candidates in the field of J0910-0414 by Wang et al. (2024b). LAE-11 was observed on the 25 Feb 2022, utilising a mask with a $\sim 1''$ slit width, the filter *OG550*, and the 830G grating (Wang et al. 2024b). The combination of these parameters allows for a spectral dispersion of $0.47 \text{ \AA}/\text{px}$ and a resolving power of $R \sim 4650$. The seeing on the night of the observation varied from $0.6''$ to $1.5''$. Overall, 18 exposures lasting 1200 s were taken.

We reduced the available spectroscopic data using the Python-based package for semi-automated reduction of astronomical spectra *Pypeit* v1.15.1 (Prochaska et al. 2020). We follow a standard spectroscopic reduction for Keck/DEIMOS, consisting of flat fielding, wavelength calibration, optimal extraction, and flux calibration for each observation. We carefully model the sky lines to correctly reconstruct the underlying spectrum. The normalised residuals of the sky model are presented in Fig. A.1. Afterwards, the 1D and 2D reduced spectral outputs were stacked, resulting in the total exposure time of 6 hours.

2.2.2. JWST/NIRCam WFSS

In addition to imaging survey, the ASPIRE collaboration obtained spectroscopic observations of the targeted 25 quasar fields using NIRCam *Wide Field Slitless Spectroscopy* (WFSS). These observations were targeting the [OIII] doublet of galaxies in the redshift range of $5.3 < z < 6.5$. The full description of the reduction steps is described in detail in Wang et al. (2023), but we provide a brief overview here. The WFSS observations employed grism-R paired with the *F356W* filter, providing a wavelength coverage spanning $3.1 - 3.9 \mu\text{m}$. The detection of LAE-11 fell onto module A of the detector. A primary dithering pattern was employed, using the three-point

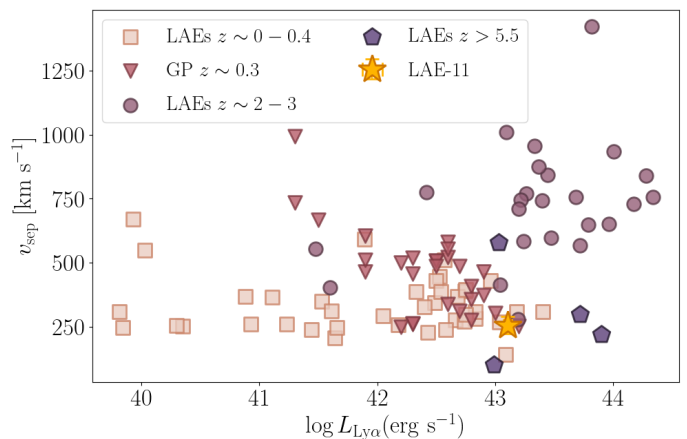

Fig. 3. The velocity separation of the $\text{Ly}\alpha$ emission profile in relation to its luminosity for $z \sim 0 - 0.4$ LAEs (Izotov et al. 2018, 2020, 2021, 2022, 2024), $z \sim 0.3$ GPs (Yang et al. 2017), $z \sim 2 - 3$ LAEs (Kulas et al. 2012; Hashimoto et al. 2015; Vanzella et al. 2016), and $z \geq 5.5$ LAEs (Hu et al. 2016; Songaila et al. 2018; Bosman et al. 2020; Meyer et al. 2021). LAE-11 is most consistent with local luminous GPs and LAEs.

INTRAMODULEX pattern, with a secondary subpixel dithering pattern 2-POINT-LARGE-WITH-NIRISS. The data were reduced using the same procedure as the NIRCam imaging data. Additionally, a tracing and dispersion model based on the work of Sun et al. (2022) was built to extract the 1D spectra from individual exposures with optimal extraction (Horne 1986). These 1D spectra were then stacked with inverse variance weighting as detailed in Wang et al. (2023). However, Wang et al. (2023) note that the offset between the spectral tracing model and the data along the dispersion axis cannot be estimated due to the lack of in-flight wavelength calibration data. As a conservative measure, they propose a constant velocity offset of $< 100 \text{ km s}^{-1}$, or $\Delta z < 0.003$ for the detected [OIII] emitters. The final spectra have exposure times of 3779.343 s, resolving power of $\sim 1300 - 1600$ and dispersion of $\sim 10 \text{ \AA}/\text{px}$.

2.2.3. JWST/NIRSpec MSA

Finally, we use data from a follow-up observation of J0910-0414 and its protocluster with JWST/NIRSpec *MultiObject Spectroscopy* (MSA) (Jakobsen et al. 2022), which was conducted in November 2023 (PID 2028; P.I. Feige Wang). The *PRISM/CLEAR* setup was employed in order to target the rest-frame UV and optical part of the spectrum of galaxies at $z \sim 6.6$ surrounding the quasar. The NIRSpec spectrum covers a wavelength range of $\lambda = (6000 - 53000) \text{ \AA}$, or the rest-frame wavelength range of $\lambda_{\text{rest}} = (785 - 6940) \text{ \AA}$. The data was reduced and processed using the standard JWST pipeline v1.13.3 and calibration reference file *jwst_1015.pmap* was used in the process. The exposure time of the final spectrum is 3939.0 s and has a resolution of $R \sim 100$ with an average dispersion of $\sim 100 \text{ \AA}/\text{px}$.

3. Methodology

In this section we first describe the methods used to constrain the redshift of LAE-11 and measure the properties of various spectral lines present in the available data. Next, we describe the model and process of SED fitting of the spectrophotometric data. Finally, we measure the UV slope β_{1550} and absolute UV magnitude M_{UV} of the galaxy, as well as its dust properties.

Table 2. The parameters, their priors, and fitted values of the line profile model using a combination of simple emission Gaussian and an absorption Voigt profile, which was employed in the MCMC fitting of the Ly α emission line profile.

Parameter	Prior	Value
$\log A_{\text{Gauss}} [\text{cgs}]$	$-17 > \log A_{\text{Gauss}} > -20$	-17.76 ± 0.07
$\sigma_{\text{Gauss}} [\text{\AA}]$	> 10	6.89 ± 0.74
$z_{\text{Ly}\alpha}$	$6.63 < z_{\text{Ly}\alpha} < 6.65$	6.6416 ± 0.0004
z_{trough}	$6.635 < z_{\text{trough}} < 6.647$	6.6405 ± 0.0005
$\log N [\text{cm}^{-2}]$	$12 < \log N < 15$	13.96 ± 0.24
$\log b [\text{cm/s}]$	$6.5 < \log b < 7.5$	6.93 ± 0.12

3.1. Redshift calibration

We estimate the systemic redshift of LAE-11 by determining the position of the trough of the double-peaked Ly α profile and by determining the redshift of the detected [OIII] doublet. We find a 1σ discrepancy between these two redshift estimates. We attempt to mitigate this tension by turning to the other available LAEs which are also [OIII] emitters in our sample of galaxies.

We start by calculating the systemic redshift of LAE-11 using the trough of the double-peaked Ly α profile in the DEIMOS spectra, as it has been found to be a reliable tracer of systemic redshift (e.g. Verhamme et al. 2006; Gronke et al. 2015; Verhamme et al. 2018). We use an MCMC analysis Python package `emcee` (Foreman-Mackey et al. 2013) to fit the Ly α profile with a combination of a simple emission Gaussian and an absorption Voigt profile parameterised by Tepper-García (2006). The free parameters describe the amplitude A_{Gauss} , redshift $z_{\text{Ly}\alpha}$ and variance σ_{Gauss} of the Gaussian component, and the redshift z_{trough} , neutral hydrogen column density N and the broadening parameter of the Voigt profile b . We initialise the fit with 500 Monte Carlo chains each undergoing 5000 iterations in order to sample the entire prior parameter space. To minimise the effect of the prior conditions on the best-fit parameters, we discard the first 1000 steps of each chain in the burn-in phase. The best-fit parameters and their errors are then calculated as the mean and 1σ of the combined MCMC chain steps. The priors, initial and best-fit values for each parameter can be found in Table 2, with the best-fit model presented in Fig. 2. We measure the redshift of the trough to be $z = 6.6405 \pm 0.0005$, in line with the measurement presented in Wang et al. (2024b).

We confirm the redshift calculation following the method of Verhamme et al. (2018). In this approach, the correlation between the velocity offset of the red peak v_{red} with respect to the systemic redshift, and half of the separation of the two peaks can be described with an almost one-to-one relation. We determined the peak separation by translating the fitted Ly α emission line model in velocity space and determining the local maxima. We find the velocity separation of the two peaks is $\Delta v_{\text{sep}} = 255.71 \pm 33.69 \text{ km s}^{-1}$. The velocity separation is comparable to local bright GPs and LAEs (see Fig. 3). Using the relation from Verhamme et al. (2018):

$$v_{\text{red}} = (1.05 \pm 0.11) \times \Delta v_{\text{sep},1/2} - (12 \pm 37) \text{ km s}^{-1}, \quad (1)$$

we find $v_{\text{red}} = 122.25 \pm 47.79 \text{ km s}^{-1}$, or $z = 6.640 \pm 0.001$, which is in agreement with our initial measurement. The offset of the red peak is comparable to Extreme Emission Line Galaxies

Fig. 4. The correlation between [OIII] + H β EW $_0$ and the velocity offset of the red Ly α peak as measured by Tang et al. (2024b) for 26 EELGs at $z \sim 2-3$ (circles). LAE-11 is depicted with a star. The colour of each data point corresponds to the Ly α EW $_0$ of each galaxy.

(EELGs) examined in Tang et al. (2024b), where galaxies with high equivalent widths of ([OIII] + H β) and Ly α show small peak offset (see Fig. 4).

Next we turn to the JWST spectra found in our data sample, specifically to the NIRCcam WFSS due to its high resolution. We identify a doublet in the 2D and 1D spectra which would correspond to the [OIII] doublet at $z \sim 6.6$. We fit each line with a simple Gaussian and tie the peak separation as dictated by atomic physics (Storey & Zeppen 2000). The [OIII] doublet suggests that LAE-11 is located at $z = 6.6372 \pm 0.0004$. This redshift estimation is in tension with our Ly α trough calculation even when adopting the conservative calibration redshift offset $\Delta z < 0.003$ quoted by Wang et al. (2023), resulting in 1σ tension. This redshift discrepancy cannot be resolved using the NIRSpect data, as the wavelength resolution is too low to differentiate between the two redshift solutions.

We attempt to correct this discrepancy by turning to the other LAEs reported by Wang et al. (2024b) which are present in the ASPIRE data. These galaxies are LAE-1 ($z_{[\text{OIII}]}$ = 6.537 ± 0.003) and LAE-12 ($z_{[\text{OIII}]}$ = 6.632 ± 0.003). Both galaxies showcase a Ly α profile with only one peak. We use the relation found by Verhamme et al. (2018), which ties the full width half maximum (FWHM) of the Ly α line and the offset of the red peak calibrated on a sample of low- z LAEs which are also CIII], H α or [OIII] emitters:

$$v_{\text{red}} = (0.9 \pm 0.14) \times \text{FWHM}(\text{Ly}\alpha) - (34 \pm 60) \text{ km s}^{-1}. \quad (2)$$

We fit the spectrum of LAE-1 with a spline due to the asymmetric shape of the Ly α line and a Gaussian to the Ly α line of LAE-12 to determine their FWHM. Using Eq. 2, we find that the velocity offset for LAE-1 and LAE-12 is $v_{\text{red}} = 143.30 \pm 66.04 \text{ km s}^{-1}$ and $v_{\text{red}} = 57.03 \pm 61.65 \text{ km s}^{-1}$, respectively. These offsets are then converted to redshifts as $z = 6.538 \pm 0.002$ and $z = 6.640 \pm 0.002$, for LAE-1 and LAE-12. We perform the same procedure using the right peak of LAE-11's Ly α profile and find $z = 6.640 \pm 0.002$. For LAE-1, we find that this redshift agrees with the value determined using its [OIII] doublet as $z_{\text{Ly}\alpha} - z_{[\text{OIII}]}$ = 0.001, however for LAE-12 the value is in 2.6σ tension with its [OIII] redshift with $z_{\text{Ly}\alpha} - z_{[\text{OIII}]}$ = 0.008. Meanwhile LAE-11 once again displays 1σ tension of $z_{\text{Ly}\alpha} - z_{[\text{OIII}]}$ = 0.003.

Torrallba-Torregrosa et al. (2024) showcase an offset in wavelength calibration present in spectra of the same object depending on the NIRCcam module used for the observation. We check

Table 3. The measured emission line properties in the spectra of LAE-11. EWs and their uncertainties are given in Å. Fluxes and flux errors are measured in $\times 10^{-18}$ erg/s/cm². Luminosities and luminosity uncertainties are given in $\times 10^{41}$ erg/s.

Line	DEIMOS & NIRCcam/WFSS			NIRSpec/PRISM		
	EW ₀	F_{λ}	L_{λ}	EW ₀	F_{λ}	L_{λ}
Ly α	140 \pm 10	25.34 \pm 1.57	127.72 \pm 9.48	41 \pm 11	3.72 \pm 1.45	19.57 \pm 7.64
H β	—	—	—	157 \pm 53	1.26 \pm 0.18	6.62 \pm 0.96
[OIII] ₄₉₆₀	426 \pm 121	1.75 \pm 0.24	9.18 \pm 1.24	462 \pm 73	1.95 \pm 0.17	10.26 \pm 0.89
[OIII] ₅₀₀₈	1172 \pm 157	5.07 \pm 0.51	26.68 \pm 2.27	1225 \pm 170	5.57 \pm 0.21	29.30 \pm 1.10
H α	—	—	—	1483 \pm 246	3.11 \pm 0.29	16.36 \pm 1.52

the modules of our galaxy sample and find that both galaxies with redshift discrepancies fall on module A of the NIRCcam detector, while LAE-1 is located on module B (see Fig. A.2). This would imply calibration issues with module A, however Torralba-Torregrosa et al. (2024) find the calibration issues on module B. For this reason, we adopt the redshift determined from the trough in the Ly α profile measured from its model as the systemic redshift. However, we discuss the implications on the ionising properties of LAE-11 when taking $z_{[\text{OIII}]}$ at face-value in Sec. 5.4.

3.2. Emission line measurements

Due to the high sensitivity of the NIRSpec detector, we are able to detect the continuum emission in the rest-frame UV, and marginally in the rest-frame optical region. To establish the continuum flux density in the UV region of the spectrum, we fit a simple power law from Ly α line to the Balmer break. Due to the $<2\sigma$ detection of the continuum from the Balmer break to the end of the spectrum, we use the continuum flux density calculated by the SED fitting (see Sec. 3.4).

Afterwards, we model and fit each detected line using a simple Gaussian model and the power-law continuum determined above. We model the high-resolution spectrum of the Ly α line with a Gaussian multiplied by a Voigt profile as described previously. We also fit each peak with a simple Gaussian to find the red-to-blue peak flux ratio (R/B), which results in $R/B \sim 1.2$. When fitting the [OIII] doublet, we fit two Gaussians simultaneously. We tie the peak separation of the two Gaussians, however we leave the redshift of the two peaks as a free parameter. Additionally we impose a uniform prior on the expected flux ratio of the lines from 2.48 to 3.48, centred on 2.98 as dictated by atomic physics (Storey & Zeippen 2000). The uncertainties in the measured properties are determined by perturbing the spectrum by a random draw from a Gaussian distribution whose standard deviation is set to the observed uncertainty of the spectrum. We repeat this process 1000 times, and calculate the 1σ standard deviation for each property. The detected lines, their fluxes, luminosities and equivalent widths (EWs) can be found in Table 3.

3.3. UV slope β_{1550} , rest-frame UV magnitude M_{UV} , and dust properties

Since we have access to the UV continuum emission in the NIRSpec data, we are able to directly measure the UV slope β_{1550} of LAE-11. The UV slope β_{1550} is parametrised as a slope of a power-law, following the relation $f_{\lambda} \propto \lambda^{\beta}$ at $\lambda_{\text{rest}} = 1550$ Å fol-

lowing Calzetti et al. (1994). We measure the UV slope β_{1550} by fitting a power-law to the observed spectrum in 10 wavelength windows, which are defined in Calzetti et al. (1994). To estimate the uncertainty on the measured β_{1550} , we perturb the observed spectrum 1000 times as before. Each perturbed spectrum is then fitted within the same region with a power-law. The final uncertainty is then calculated as the standard deviation of the distribution of measured β_{1550} of the 1000 values. The measured UV slope of the NIRSpec spectrum of LAE-11 is $\beta_{1550} = -2.61^{+0.06}_{-0.08}$.

In addition to UV slope, we are able to calculate the absolute rest-frame UV magnitude. We use the measured photometric flux from filter *F115W*, as it is centred on $\lambda_{\text{rest}} = 1500$ Å. We convert the photometric flux to absolute UV magnitude using the luminosity distance of the galaxy. Using this method, we find that the absolute UV magnitude is $M_{\text{UV,phot}} = -19.84^{+0.14}_{-0.16}$. We also measure the absolute UV magnitude using the fit to continuum emission performed in previous section, which results in $M_{\text{UV,cont}} = -19.90^{+0.13}_{-0.14}$. These two values agree within 1σ uncertainty. Throughout the paper, we will use the M_{UV} calculated from photometry. The resulting values can be found in Table 6.

Next, we look at the dust properties of LAE-11. First, we use the tight correlation determined by Chisholm et al. (2022):

$$E(B - V) = (0.47 \pm 0.01) + (0.171 \pm 0.007) \times \beta_{1550} \quad (3)$$

to convert the UV slope β_{1550} to colour excess $E(B - V)_{\text{UV}}$, resulting in $E(B - V)_{\text{UV}} = 0.02^{+0.03}_{-0.02}$. Following the relation between colour excess and extinction described in Domínguez et al. (2013):

$$A_V = (4.05 \pm 0.80) \times E(B - V), \quad (4)$$

we find $A_V = 0.08^{+0.14}_{-0.08}$, suggesting that LAE-11 is a dust-poor system. This is further supported by the dust attenuation obtained from SED fitting ($A_V < 0.01$) described in the following Section.

3.4. SED fitting with BAGPIPES

To constrain the properties of the stellar population of the galaxy we perform SED fitting with the BAGPIPES code (Carnall et al. 2019), using a combination of NIRSpec/PRISM spectroscopy and photometric data. BAGPIPES employs the stellar models introduced in Bruzual & Charlot (2003), which utilise the empirical spectral library MILES (Falcón-Barroso et al. 2011) and Kroupa & Boily (2002) initial mass function (IMF). Additionally, the models are complemented with additional nebular and continuum emission based on Cloudy models (Ferland et al. 1998; Byler et al. 2017).

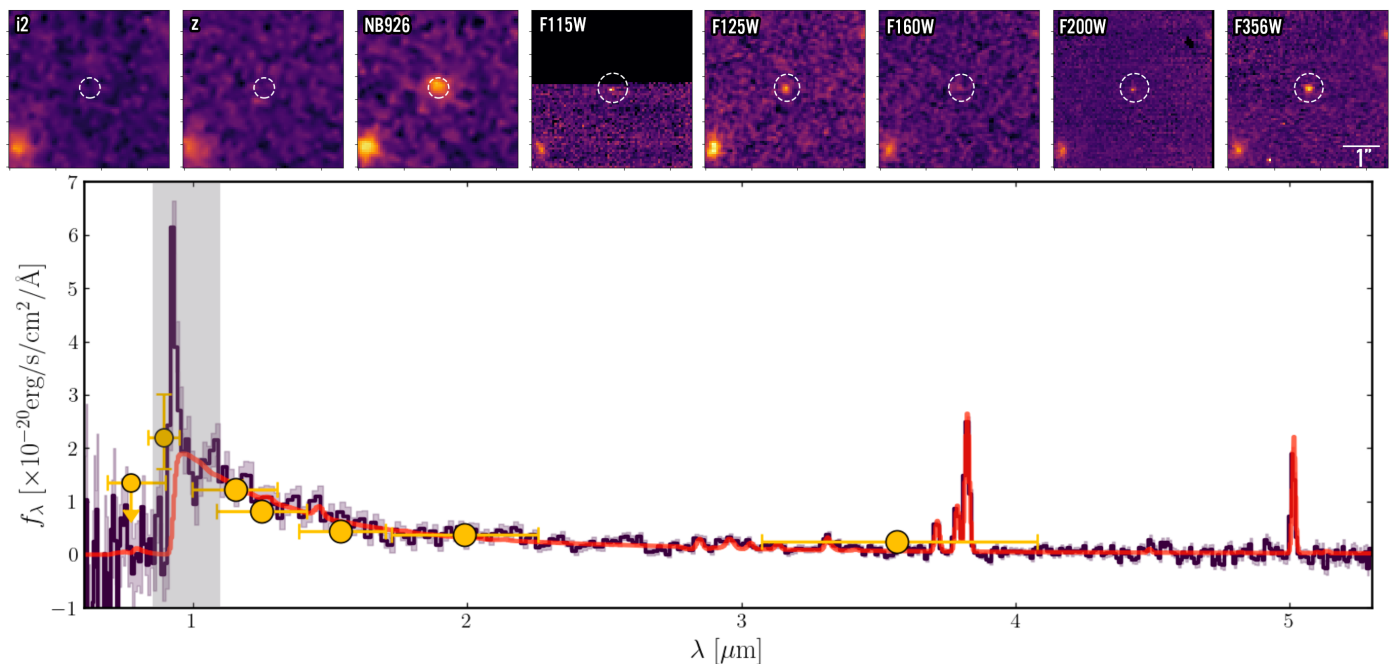

Fig. 5. (*upper*) Imaging of LAE-11 in all available bands across Subaru/HSC, *HST*/WFC3 and *JWST*/NIRCam, sorted by wavelength. The white dashed circle corresponds to the aperture used to measure the photometry in each filter. (*lower*) The observed NIRSpec PRISM spectrum and its 1σ uncertainty are depicted with a dark purple line and shaded region, the observed photometry with yellow points and the best-fitting SED with a red line. The shaded grey region marks the masked Ly α emission line, which was excluded from the fitting process due to the limitations of the model.

The redshift of LAE-11 is fixed to the systemic redshift determined by the trough of the double-peaked Ly α profile to $z = 6.6405$. We adopt the non-parametric star formation history (SFH) with $N_{\text{SFH bins}} = 7$ bins of [Leja et al. \(2019\)](#), with the first four spanning 0–2 Myr, 2–4 Myr, 4–8 Myr, and 8–16 Myr in lookback time to be sensitive to the variation in the recent SFH of the galaxy. The remaining bins are logarithmically spaced in the galaxy’s lookback time from 16 Myr to $z = 20$ (e.g. [Taccarella et al. 2022](#)). Finally, we apply dust attenuation following the dust model introduced in [Calzetti et al. \(1994\)](#) and allow A_V to uniformly vary as $0 < A_V < 4$. For the remaining parameters (stellar mass M_* , ionisation parameter U , metallicity Z) we use broad uniform priors, listed in Table 4. We mask the wavelength region spanning $1150 \text{ \AA} < \lambda_{\text{rest}} < 1450 \text{ \AA}$, due to the limitations of the model to reproduce the Ly α region. The resulting best-fit SED template, the predicted and observed photometry, and the NIRSpec spectrum are presented in Fig. 5. The best-fit SFH of LAE-11 is shown in Fig. 6. The best-fit values of the physical parameters are shown in Table 6. The posterior distributions for each parameter can be found in Fig. A.3.

4. Results

In this Section, we evaluate the properties of LAE-11. First, we calculate the escape fraction of Lyman Continuum photons using a set of proxies based on empirical relations and multivariate-empirical models. Next, we focus on the ionising photon production efficiency of the galaxy. Afterwards, we measure the star formation rate of LAE-11. Finally, we investigate the quasar-galaxy geometry and the quasar environment of J0910-0414.

4.1. Escape fraction of Lyman Continuum $f_{\text{esc}}^{\text{LyC}}$

To investigate the degree of LyC leakage undergoing in LAE-11, we must evaluate $f_{\text{esc}}^{\text{LyC}}$, the fraction of ionising photons which are able to escape into the IGM. Due to the low IGM attenuation of the Ly α line of high- z galaxies situated in quasar proximity zones, we have a unique opportunity to use the EW and peak separation of Ly α profile to estimate LyC leakage of LAE-11.

First, we measure the escape fraction of LyC photons using the peak separation of the Ly α profile ([Verhamme et al. 2017](#); [Izotov et al. 2018](#); [Flury et al. 2022b](#)). The empirical correlation between the velocity separation of the two peaks Δv_{sep} and the escape fraction of ionising photons $f_{\text{esc}}^{\text{LyC}}$ was estimated using a sample of 56 LyC leaking galaxies at $z < 0.4$. Using the peak separation determined in Section 3.1, and following the relation in [Izotov et al. \(2018\)](#):

$$f_{\text{esc}}^{\text{LyC}} = \frac{3.23 \times 10^4}{v_{\text{sep}}^2} - \frac{1.05 \times 10^2}{v_{\text{sep}}} + 0.095, \quad (5)$$

we find LyC leakage of $f_{\text{esc}}^{\text{LyC}} = 0.18 \pm 0.08$. The reliability of the double-peak Ly α velocity separation as a proxy of LyC leakage has, however, been called into question. [Naidu et al. \(2022\)](#) have shown, that some sources with high peak separation of $v_{\text{sep}} > 400 \text{ km s}^{-1}$, such as *Ion2*, *Ion3*, *Sunburst Arc* and others, leak $>20\%$ of their ionising photons. Additionally, numerical simulations by [Choustikov et al. \(2024\)](#) indicate that while it is unlikely to find strong leakers with wide peak separation, they find no real trend between the two quantities. Similar trend is observed in simulations by e.g. [Giovinazzo et al. \(2024\)](#), where multiple objects with low peak separation also showcase a low $f_{\text{esc}}^{\text{LyC}}$. However, it is still unclear whether these results are a product of a simulation bias. For this reason, we use additional estimators of LyC leakage to provide reliable measurements.

Table 4. The parameters and priors used for spectrophotometric SED fitting of LAE-11 with BAGPIPES.

Parameter	Prior
SFH	non-parametric (Leja et al. 2019)
$N_{\text{SFH bins}}$	7
dust type	Calzetti
A_V	(0, 4) uniform
$\log U$	(-4, -1) uniform
$\log M_\star/M_\odot$	(0, 15) uniform
$\log Z/Z_\odot$	(0.0001, 5) logarithmic

Begley et al. (2024) probed the correlation between the escape fraction of Ly α photons $f_{\text{esc}}^{\text{Ly}\alpha}$ and $f_{\text{esc}}^{\text{LyC}}$ with a sample of 152 star-forming galaxies (SFGs) at $4 < z < 5$. They first find a scaling relation between the $\text{EW}_0(\text{Ly}\alpha)$ and the Ly α escape fraction, which is then found to be in a linear correlation with $f_{\text{esc}}^{\text{LyC}}$. Following their method, we find that for LAE-11 the escape fraction of Ly α photons is $f_{\text{esc}}^{\text{Ly}\alpha} = 0.53 \pm 0.06$, and subsequently its LyC leakage is $f_{\text{esc}}^{\text{LyC}} \approx 0.08 \pm 0.03$.

Next, we employ the empirical relation between $f_{\text{esc}}^{\text{LyC}}$ and UV slope β_{1550} derived by Chisholm et al. (2022), using a selection of 89 SFGs and LyC emitters at $z \sim 0.3$:

$$f_{\text{esc}}^{\text{LyC}} = (1.3 \pm 0.6) \times 10^{-4} \times 10^{(-1.22 \pm 0.1)\beta_{1550}}. \quad (6)$$

Using this relation we calculate $f_{\text{esc}}^{\text{LyC}} = 0.20 \pm 0.18$. We note that the relation more robustly characterises a population-average escape fractions than an individual scenarios, resulting in the large uncertainty on the calculated $f_{\text{esc}}^{\text{LyC}}$.

Additionally, Naidu et al. (2020) examined the correlation between the star formation rate density Σ_{SFR} and LyC leakage. We use their empirical model:

$$f_{\text{esc}}^{\text{LyC}} = (1.6 \pm 0.3) \times \left(\frac{\Sigma_{\text{SFR}}}{1000 \text{ M}_\odot \text{ yr}^{-1} \text{ kpc}^{-2}} \right)^{(0.4 \pm 0.1)}. \quad (7)$$

We use both Σ_{SFR} calculated with L_{UV} and $L(\text{H}\alpha)$ described in Section 4.3. Since we only find the lower limits on $\Sigma_{\text{SFR}} > 3.59$ (9.44) $\text{M}_\odot \text{ yr}^{-1} \text{ kpc}^{-2}$ for L_{UV} ($L(\text{H}\alpha)$), we find the lower limits for $f_{\text{esc}}^{\text{LyC}} > 0.16$ (0.24) using L_{UV} ($L(\text{H}\alpha)$).

To confirm our estimates of $f_{\text{esc}}^{\text{LyC}} \approx (10 - 20)\%$, we use the recent multivariate diagnostic Cox models developed by Jaskot et al. (2024a,b) to empirically predict $f_{\text{esc}}^{\text{LyC}}$ with a combination of observable properties. These models utilise a survival analysis technique to treat data with upper limits appropriately, and was developed using 50 LyC emitting galaxies at $z \sim 0.3$. For LAE-11 we use models and their input parameters:

- LAE with M_{1500} , $E(B - V)_{\text{UV}}$, and $\text{EW}_0(\text{Ly}\alpha)$;
- ELG-EW with M_{1500} , $\log M_\star$, $E(B - V)_{\text{UV}}$, and $\log \text{EW}_0([\text{OIII}] + \text{H}\beta)$;
- R50- β , which uses M_{1500} , $\log M_\star$, β_{1550} , and the UV half-light radius $R_{50,\text{UV}}$.

Using these models, we find $f_{\text{esc}}^{\text{LyC}} = (0.33^{+0.36}_{-0.21})$, $(0.18^{+0.38}_{-0.13})$, (> 0.18) for models LAE, ELG-EW, and R50- β , respectively.

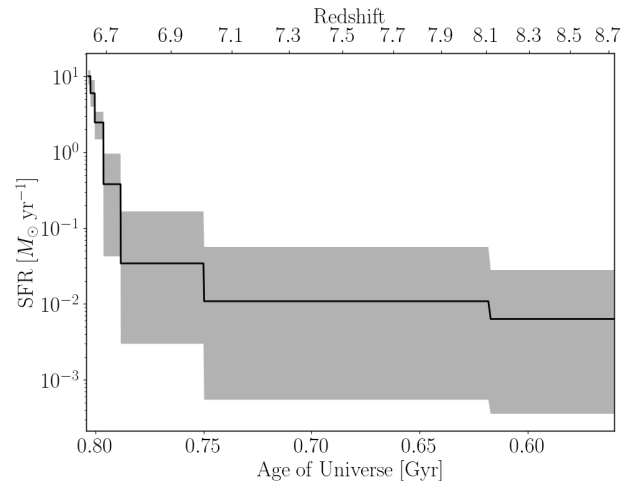

Fig. 6. The posterior non-parametric SFH of LAE-11 depicted with solid black line. The 1σ uncertainty is marked with a shaded grey region.

For R50- β model we only calculate the lower limit of the escape fraction, as the radius R_{UV} of the galaxy is smaller than the PSF. We note that the multivariate models point indicate higher uncertainties on the estimated values of the escape fraction. Jaskot et al. (2024b) caution that some galaxies at $z \gtrsim 6$ differ from the parameter space covered by the sample of low- z galaxies used to calibrate the model, increasing the uncertainties of the predictions. All the determined $f_{\text{esc}}^{\text{LyC}}$ values and the methods used to estimate them can be found in Table 5.

We compare the estimated values of $f_{\text{esc}}^{\text{LyC}}$ that were determined using the Ly α emission and those who used other galaxy properties. We find that both the peak separation and LAE model indicate a higher escape fraction of LyC ($\gtrsim 15\%$), while the relation by Begley et al. (2024) shows $f_{\text{esc}}^{\text{Ly}\alpha} < 10\%$. Models and relations focusing on galaxy properties not tied to the Ly α emission line do not show this dichotomy as the $f_{\text{esc}}^{\text{LyC}} - \beta_{1550}$ correlation by Chisholm et al. (2022), $f_{\text{esc}}^{\text{LyC}} - \Sigma_{\text{SFR}}$ relations, ELG-EW model and the R50- β model estimate a higher escape fraction of $\gtrsim 10\%$. We note, however, that these relations are either only lower limits on the escape fractions or show a high 1σ uncertainty. Comparing these two groups of $f_{\text{esc}}^{\text{LyC}}$ proxies, we find that they do not show a significant scatter among the calculated values, and all indicate that at least $\gtrsim 5\%$ of LAE-11's LyC photons are leaking into the surrounding IGM. The agreement between all available indirect tracers indicates that each is viable to determine LyC leakage of high- z galaxies, however multiple tracers are recommended to constrain its exact value. We discuss the implications of the measured $f_{\text{esc}}^{\text{LyC}}$ in Section 5.3.

4.2. Ionising photon production efficiency ξ_{ion}

We calculate the ionising photon production efficiency ξ_{ion} of LAE-11 using the H α and H β lines, respectively. We have access to both H α and H β lines, and therefore we check whether the assumption of Case B recombination scenario is warranted. We find that the ratio of $\text{H}\alpha/\text{H}\beta = 2.47 \pm 0.49$, which is in agreement with Case B scenario of $\text{H}\alpha/\text{H}\beta = 2.86$ (Osterbrock 1989).

In addition to $f_{\text{esc}}^{\text{LyC}}$, ionising photon production efficiency needs to be calculated to correctly estimate LAE-11's ionising

Table 5. Estimates of the escape fraction of ionising photons from LAE-11 using indirect empirical relations and multivariate models.

$f_{\text{esc}}^{\text{LyC}}$	Method	Reference
0.18 ± 0.08	Peak separation	Izotov et al. (2018)
0.08 ± 0.03	$f_{\text{esc}}^{\text{Ly}\alpha}$	Begley et al. (2024)
0.20 ± 0.18	UV slope β	Chisholm et al. (2022)
> 0.16	$\Sigma_{\text{SFR}(\text{UV})}$	Naidu et al. (2020)
> 0.24	$\Sigma_{\text{SFR}(\text{H}\alpha)}$	Naidu et al. (2020)
$0.33^{+0.36}_{-0.21}$	LAE model	Jaskot et al. (2024b)
$0.18^{+0.38}_{-0.13}$	ELG-EW model	Jaskot et al. (2024b)
> 0.18	R50- β model	Jaskot et al. (2024b)

output. ξ_{ion} is defined as:

$$\xi_{\text{ion}} = \frac{N(\text{H})}{L_{\text{UV,corr}}} \frac{1}{1 - f_{\text{esc}}^{\text{LyC}}} \text{Hz erg}^{-1}, \quad (8)$$

where $N(\text{H})$ is the production rate of ionising photons and $L_{\text{UV,corr}}$ is the intrinsic UV luminosity of the galaxy, calculated from M_{UV} . We calculate $N(\text{H})$ both with $\text{H}\alpha$ and $\text{H}\beta$ separately, assuming a Case B recombination with the $\text{H}\alpha$ ($\text{H}\beta$) line coefficient of $C_B = 1.36 \times 10^{-12}$ (4.79×10^{-13}) erg, electron density $n_e = 10^3 \text{ cm}^{-3}$, and electron temperature of $T_e = 10^4 \text{ K}$, as $N(\text{H}) = L_{\text{line}}/C_B$ (Leitherer & Heckman 1995). Using this method and $f_{\text{esc}}^{\text{LyC}} = 0.18 \pm 0.08$ estimated from the peak separation of $\text{Ly}\alpha$, we measure $\log(\xi_{\text{ion}}/\text{Hz erg}^{-1}) = 25.59 \pm 0.08$ and $\log(\xi_{\text{ion}}/\text{Hz erg}^{-1}) = 25.65 \pm 0.09$ for $\text{H}\alpha$ and $\text{H}\beta$, respectively. All the measured values and the methods used to calculate them can be found in Table 6. We discuss the implications of the measured ξ_{ion} in Section 5.3.

4.3. Star formation rate and star formation rate density Σ_{SFR}

We calculate the star formation rate (SFR) of LAE-11 using its UV and line properties. First, we use the standard relations found in Kennicutt (1998) which uses the Salpeter (1955) IMF and link the SFR of galaxies to their UV luminosity as:

$$\text{SFR}_{\text{UV}} = 1.4 \times 10^{-28} L_{\text{UV}} M_{\odot} \text{ yr}^{-1}, \quad (9)$$

and to the luminosity of the $\text{H}\alpha$ line following:

$$\text{SFR}_{\text{H}\alpha} = 7.9 \times 10^{-42} L(\text{H}\alpha) M_{\odot} \text{ yr}^{-1}. \quad (10)$$

We use the UV magnitude and the $\text{H}\alpha$ line from the NIRSpc data to calculate the SFR of LAE-11. Following these relations, we find $\text{SFR}_{\text{UV}} = 5.25 \pm 0.69 M_{\odot} \text{ yr}^{-1}$ and $\text{SFR}_{\text{H}\alpha} = 12.93 \pm 1.20 M_{\odot} \text{ yr}^{-1}$. All SFR values calculated in this work can be found in Table 6. The implications of the measured SFR for LAE-11 are further discussed in Sec. 5.2.

We also evaluate the SFR density of LAE-11 following the definition $\Sigma_{\text{SFR}} = \text{SFR}/2\pi R_{\text{UV}}^2$ (e.g. Shibuya et al. 2019; Naidu et al. 2020), where R_{UV} is the UV effective half-light radius. We measure the FWHM of LAE-11 using the value $\text{FWHM}_{\text{IMAGE}}$, which was calculated as a part of photometry extraction run with SourceExtractor, where FWHM is calculated assuming a Gaussian core. Next, we pick and stack fifteen bright visually-selected stars. We fit a 2D Gaussian to the stack in order to estimate the FWHM of the PSF, which results in $\text{FWHM}_{\text{PSF}} = 0.17''$.

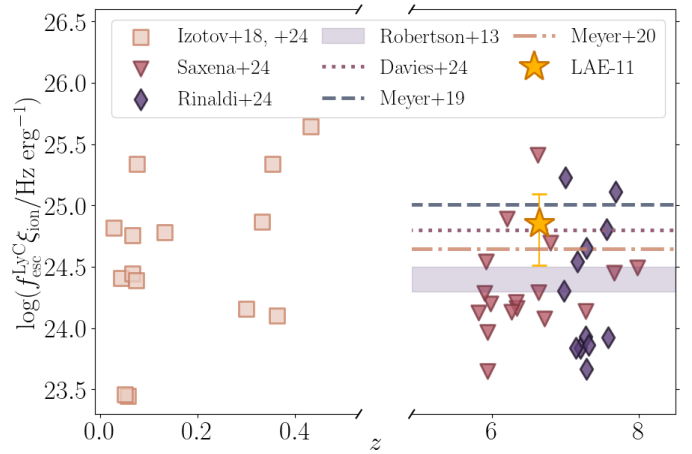

Fig. 7. The evolution of the ionising output of galaxies ($\xi_{\text{ion}} f_{\text{esc}}^{\text{LyC}}$) with redshift. The ionising output required to sustain Reionisation determined by Robertson et al. (2013) is depicted with shaded purple region, while the mean ionising output needed to maintain EoR adopted by Davies et al. (2024) is shown with a dotted pink line. The values determined by Meyer et al. (2019, 2020) are shown with a blue dashed and pink dashdotted lines. Low- z SFGs (Izotov et al. 2018, 2024) are shown with pale pink squares, high- z faint LAEs (Saxena et al. 2024) are shown with red triangles, high- z strong $\text{H}\alpha$ emitters (Rinaldi et al. 2024) are shown with purple diamonds, and LAE-11 is depicted with a yellow star. We have used the $f_{\text{esc}}^{\text{LyC}}$ estimated using the $\text{Ly}\alpha$ peak separation.

However, we find that the FWHM of LAE-11 is lower than this value, and therefore we can only estimate an upper limit on the UV radius. Following the approach of Torralba-Torregrosa et al. (2024), we calculate the UV radius in physical units as $\text{FWHM}/2$, resulting in $R_{\text{UV}} < 0.47 \text{ kpc}$. Additionally, we calculate the radius of the galaxy in the $\text{Ly}\alpha$ emission present in the NB926 filter, following the same method. LAE-11 is again unresolved and its FWHM is smaller than the PSF of the narrowband data ($\text{FWHM}_{\text{PSF}} = 0.34''$). We can therefore only obtain its upper limits on the $\text{Ly}\alpha$ radius of $R_{\text{Ly}\alpha} < 1.83 \text{ kpc}$.

Using the upper limit of R_{UV} in turn gives the lower limit for Σ_{SFR} . Using the SFR estimated from UV and from $\text{H}\alpha$, we arrive at values $\Sigma_{\text{SFR}} > 3.59 M_{\odot} \text{ yr}^{-1} \text{ kpc}^{-2}$ and $> 9.44 M_{\odot} \text{ yr}^{-1} \text{ kpc}^{-2}$, respectively. Compared to the sample of galaxies at $z \sim 6$ (Shibuya et al. 2015), and [OIII] emitters found in the field of COLA1 (Torralba-Torregrosa et al. 2024), and strong LyC leakers such as COLA1 (Matthee et al. 2018), *Ion2* and *Ion3* (Vanzella et al. 2016, 2018) and others, LAE-11 belongs in the population with higher Σ_{SFR} based on the lower limits calculated in this work.

4.4. Inferred properties of quasar J0910-0414

Since we are able to observe the blue peak of the $\text{Ly}\alpha$ profile at such a high redshift, LAE-11 is certainly residing within the proximity zone of the quasar. Using the LAEs from Wang et al. (2024b) and [OIII] emitters found by the ASPIRE survey in the vicinity of the quasar whose positions in 3D space can be seen in Fig. 8, we are able to introduce some constraints on the proximity zone of J0910-0414.

Quasars are known as intrinsically variable sources. The changes in their brightness and thus production of ionising photons affect the surrounding IGM with a time delay, based on its properties and the distance from the quasar, creating a so-called “light-echo” imprint (e.g. Adelberger 2004; Visbal & Croft 2008; Schmidt et al. 2019; Kakiichi et al. 2022). By ob-

Table 6. Physical properties of LAE-11 calculated from line and continuum properties, and SED fitting.

Property	Value
β_{1550}	$-2.61^{+0.06}_{-0.08}$
$M_{\text{UV,phot}}^a$	$-19.84^{+0.14}_{-0.16}$
$M_{\text{UV,cont}}^b$	$-19.90^{+0.13}_{-0.14}$
$E(B - V)_{\text{UV}}$	$0.02^{+0.03}_{-0.02}$
A_V	$0.08^{+0.14}_{-0.08}$
A_V (BAGPIPES)	< 0.01
$\log M_\star / M_\odot^c$	$7.93^{+0.14}_{-0.08}$
$\log U$	$-1.33^{+0.21}_{-0.27}$
$\log Z/Z_\odot$	$-0.86^{+0.03}_{-0.03}$
R_{UV}	< 0.47 kpc
$R_{\text{Ly}\alpha}$	< 1.83 kpc
SFR_{UV}	$5.25 \pm 0.69 M_\odot \text{yr}^{-1}$
$\text{SFR}_{\text{H}\alpha}$	$12.93 \pm 1.20 M_\odot \text{yr}^{-1}$
$\log \text{sSFR}_{\text{UV}} / \text{yr}^{-1}$	-7.04 ± 0.43
$\Sigma_{\text{SFR}(\text{UV})}$	$> 3.59 M_\odot \text{yr}^{-1} \text{kpc}^{-2}$
$\Sigma_{\text{SFR}(\text{H}\alpha)}$	$> 9.44 M_\odot \text{yr}^{-1} \text{kpc}^{-2}$
$\log \xi_{\text{ion}} / \text{Hz erg}^{-1}(\text{H}\alpha)$	25.59 ± 0.08
$\log \xi_{\text{ion}} / \text{Hz erg}^{-1}(\text{H}\beta)$	25.65 ± 0.09

Notes. ^a M_{UV} was calculated using the *F115W* flux. ^b M_{UV} was calculated using the fit to continuum flux. ^c Stellar mass M_\star was converted from Kroupa to Salpeter IMF according to [Madau & Dickinson \(2014\)](#).

servicing the changes in the IGM located further from the quasar, we are able to determine its lifetime t_Q . The quasar lifetime is defined such that if the light from the recent activity was observed at time $t = 0$, the quasar actually turned on at a time $-t_Q$ in the past ([Eilers et al. 2017](#)). Since LAE-11, located ~ 0.3 pMpc from the quasar and is residing in the ionised region, it is carrying a imprint of the quasar’s past activity. This allows us to determine the lower limit of the quasar’s lifetime as defined in [Bosman et al. \(2020\)](#):

$$t_Q > \frac{\sqrt{d_\parallel^2 + d_\perp^2} - d_\parallel}{c} \text{ s.} \quad (11)$$

We measure the line-of-sight proper distance d_\parallel and the perpendicular distance along the plane of the sky d_\perp of LAE-11 from J0910-0414 as $d_\parallel = 0.21 \pm 0.01$ pMpc and $d_\perp = 0.25$ pMpc, respectively. Using Eq. 11, we find the lower limit of J0910-0414’s lifetime to be $t_Q > 3.8 \times 10^5$ yr. In Fig. 10, we compare the lifetime of J0910-0414 to other quasars. On the basis of short observed proximity zones along the line-of-sight, some quasars at $z \gtrsim 6$ have been identified as being “young” with bright lifetimes $t_Q < 10^4$ yr ([Eilers et al. 2018, 2021](#)). Even though the proximity zone of J0910-0414 is not visible due to its nature as

a BAL quasar, the fact that its ionisation field reaches the location of LAE-11 independently demonstrates that it is not a young quasar. Its bright-phase lifetime is more consistent with the mean lifetime of quasars at $z < 5$ measured from their He II proximity zones ([Khrykin et al. 2021; Worseck et al. 2021](#)) and from clustering arguments (e.g. [Laurent et al. 2017](#)).

Next, we analyse J0910-0414’s possible opening angles. We assume that the quasar is radiating in a bipolar cone with an opening angle θ_Q with an ionising photon production rate $\dot{N}_{\text{ion}}^{\text{QSO}}$. By using the available photometry in the y_{ps1} band and the UV slope β for J0910-0414 from [Yang et al. \(2021\)](#), we integrate over the luminosity density L_ν of the quasar as $\dot{N}_{\text{ion}}^{\text{QSO}} = \int_{\nu_{\text{HeII}}}^{\nu_{\text{H}\alpha}} L_\nu / h\nu \, d\nu$. We find that the ionising photon production rate in the observed frame of the quasar is $\dot{N}_{\text{ion}}^{\text{QSO}} = (3.43 \pm 0.02) \times 10^{57} \text{ s}^{-1}$. The quasar’s surroundings are unaffected by the photoionisation rate outside of the bipolar cones, while on the inside they are affected by a ionisation field given by photoionisation rate $\Gamma_{\text{HI}}^{\text{QSO}}$:

$$\Gamma_{\text{HI}}^{\text{QSO}}(d_\perp, d_\parallel) = \frac{-\sigma_{\lambda 912} \beta \dot{N}_{\text{ion}}^{\text{QSO}} [-\Delta t(d_\perp, d_\parallel)]}{3 - \beta \, 4\pi(d_\perp^2 + d_\parallel^2)} \text{ s}^{-1}, \quad (12)$$

where $\sigma_{\lambda 912}$ is the photoionisation cross section at the Lyman Limit ($\lambda = 912 \text{ \AA}$), $\Delta t(d_\perp, d_\parallel)$ is the time delay at a distance $d_{\text{QSO}}^2 = d_\perp^2 + d_\parallel^2$ from the quasar, d_\perp is the perpendicular separation along the plane of the sky and d_\parallel is the line-of-sight distance from the quasar with a negative sign towards the observer. Due to the tight constraints on the redshifts of both the quasar and LAE-11, we locate the galaxy behind the quasar at $230.93^{+1.31}_{-1.36}$ away from the observer in counter-clockwise direction. This position allows us to constrain the minimal opening angle of the quasar θ_Q , since both the observer and LAE-11 are within the cone. More specifically, the BAL nature of J0910-0414 suggests that we are viewing it at an angle very close to the edge of the ionisation cone (e.g. [DiPompeo et al. 2012; Nair & Vivek 2022](#)).

We note that the other two LAEs observed in close proximity to J0910-0414 (red and dark orange in Fig. 9) do not show double-peaked Ly α morphologies, but this is not necessarily an indication that they are located *outside* of the ionisation cone; at $z < 3$, only roughly $\sim 1/3 - 1/2$ of LAE are double-peaked ([Kulas et al. 2012; Trainor et al. 2015](#)). LAE-11, therefore, needs to be situated in either of the two cones (“clockwise” or “counter-clockwise” from the observer). Using the 1σ value of LAE-11’s positional angle, the opening angle of the quasar θ_Q is then constrained to

$$\theta_Q > \arctan\left(\frac{r_{\perp, \text{LAE-11}}}{r_{\parallel, \text{LAE-11}}}\right) > 49.62^\circ \quad \vee \quad \theta_Q > 130.38^\circ, \quad (13)$$

for “counter-clockwise” and “clockwise” direction as shown in Fig. 9. The only other quasar for which this measurement could be performed, J0836+0054 ([Bosman et al. 2020](#)), requires an ionisation opening angle $\theta_Q > 21^\circ$ to illuminate its proximate double-peaked LAE (see also [Borisova et al. 2016](#)). For both of these quasars, the ionisation opening angle is therefore much larger than the measured width of quasar radio jets, $\theta_{\text{Q,radio}} < 2^\circ$ ([Pushkarev et al. 2017](#)).

5. Discussion

5.1. Quasar contribution to LAE-11’s Ly α emission

The ionisation field of QSOs can influence the Ly α emission of its nearby LAEs, contributing with a *fluorescence-triggered*

emission. Fluorescence results from the reprocessing of ionised photons from the QSO by the neutral hydrogen gas clouds in the proximate galaxies (e.g. Hogan & Weymann 1987; Cantalupo et al. 2007; Hennawi & Prochaska 2013). This effect is observable either if the LAE is in the foreground, or $d \lesssim 3.2$ pMpc in the background of the quasar (Trainor & Steidel 2013). Since LAE-11 is only ~ 0.3 pMpc behind J0910-0414, we calculate the quasar’s contribution to its Ly α luminosity.

Following the method of Bosman et al. (2020), we define the fluorescent Ly α luminosity contributed to a system with a cross section σ_{LAE} and distance d_{QSO} from the quasar as:

$$L_{\text{fluor.}}(\text{Ly}\alpha) \simeq \frac{2}{3} h\nu_{\alpha} f_{\phi} \frac{\sigma_{\text{LAE}}}{4\pi d_{\text{QSO}}^2} \dot{N}_{\text{ion}}^{\text{QSO}} \text{ erg s}^{-1}, \quad (14)$$

where f_{ϕ} is the illuminating fraction. Assuming that all fluorescent emission is scattered into the line-of-sight, the illuminating fraction takes on the value $f_{\phi} = 1$. For the cross section of LAE-11, we assume a simplified spherical geometry of $\sigma_{\text{LAE-11}} = 4\pi R_{\text{Ly}\alpha}^2$. Finally, we use $\dot{N}_{\text{ion}}^{\text{QSO}}$ calculated in the previous section and find that J0910-0414 contributes $< 3\%$ within 3σ uncertainty to the Ly α luminosity of LAE-11.

5.2. Star formation in the quasar environment

Quasars and active galactic nuclei (AGNs) have been proposed as a likely driver behind quenching of star formation in host and proximate galaxies, as their outflows can prevent gas from cooling and delay the onset of star formation (e.g. Silk & Rees 1998; Kashikawa et al. 2007; Fabian 2012) or even completely expel gas reservoirs in small haloes ($M_h \leq 10^7 M_{\odot}$) located at a distance of 1 pMpc in $\lesssim 10^8$ years (Shapiro et al. 2004). Due to LAE-11’s close proximity to J0910-0414, we wish to examine the impact of the quasar’s ionisation field on the star formation of the galaxy.

We begin by calculating the UV intensity of the QSO radiation at the location of LAE-11 in the units of J_{21} , where $J_{21} = 1$ corresponds to an intensity of $10^{-21} \text{ erg s}^{-1} \text{ cm}^{-2} \text{ Hz}^{-1} \text{ sr}^{-1}$ at the Lyman limit (LL; $\lambda = 912 \text{ \AA}$):

$$\frac{L_{\text{LL}}^{\text{QSO}}}{(4\pi d)^2} = J_{21}(d) \times 10^{-21} \text{ erg s}^{-1} \text{ cm}^{-2} \text{ Hz}^{-1} \text{ sr}^{-1}, \quad (15)$$

where $L_{\text{LL}}^{\text{QSO}}$ is the quasar’s luminosity at the Lyman limit and d is the physical distance from the quasar to LAE-11. We again utilise the available photometry in the y_{ps1} band and the UV slope β from Yang et al. (2021) to calculate $L_{\text{LL}}^{\text{QSO}}$. Following this method, we find that the UV intensity at LAE-11’s location is $J_{21} = 18.63 \pm 2.04$. Kashikawa et al. (2007) show that star formation is completely suppressed in haloes with $M_h \leq 3 \times 10^9 M_{\odot}$ at intensity $J_{21} \geq 3$. At intensities of $J_{21} \sim 20$, star formation is delayed by ~ 50 Myr in halos with $M_h \leq 10^{10} M_{\odot}$. The absence of a Balmer break in the spectrum of LAE-11 points towards an absence of older stellar population. This trend can also be observed in the recovered SFH from the spectrophotometric SED fit (see Fig. 6). We note, however, that Witten et al. (2024) found that a young stellar population of 1/3 of the total stellar mass can effectively suppress the Balmer break in the observed spectra of high- z galaxies. The fact that LAE-11 appears to have formed recently is consistent with a delay in the star formation due to the quasar’s influence, but it is also possible that the galaxy’s recent growth would have occurred even in the quasar’s absence. Indeed, studies of larger samples of galaxies around $z > 6$ quasars

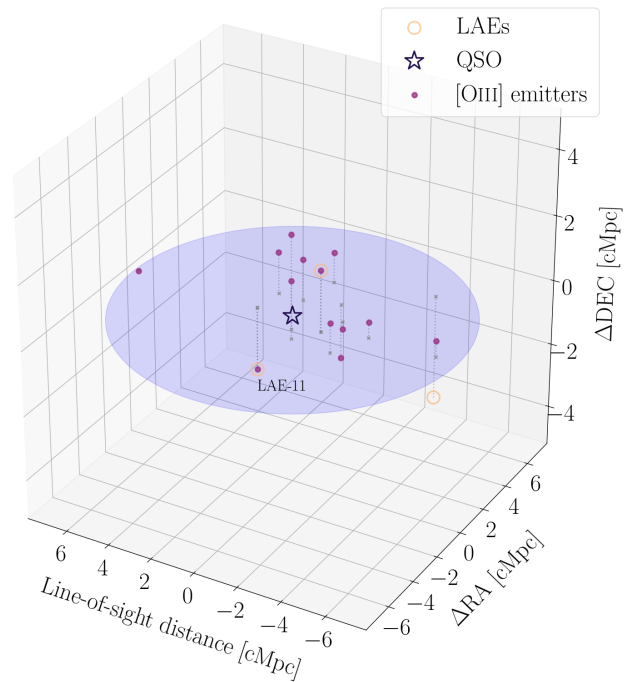

Fig. 8. The positions of the LAEs (orange circles) and [OIII] emitters (purple dots) in 3D comoving coordinates with respect to the position of J0910-0414 (blue star). The line-of-sight distance is defined to be negative towards the observer with the quasar positioned at 0 cMpc. RA (DEC) is defined to be negative when the RA (DEC) of the galaxy is smaller than the RA (DEC) of the QSO. The purple plane depicts the declination plane of the quasar. Each galaxy has its position projected onto this plane with a gray dashed line.

find that the quasar has a negligible impact on their properties (Champagne et al. 2024a,b). Therefore, we can only infer the lower limit on the halo mass following the Kashikawa et al. (2007) model as $3 \times 10^9 M_{\odot} \lesssim M_h$.

5.3. LAE-11 as a bursty Reionisation-driving galaxy

LAE-11 is a galaxy with a blue UV slope β_{1550} ($\beta_{1550} = -2.61^{+0.06}_{-0.08}$). Topping et al. (2024) have investigated the UV slope of galaxies at high redshift and found the median value of $\beta \sim -2.3$ for $5 < z < 7.3$. However, they also find 44 objects with extremely blue UV slopes ($\beta \leq -2.8$), which are best described by density bounds HII regions with $f_{\text{esc}}^{\text{LyC}} \sim 0.5$. LAE-11 is comparable to these outliers rather than the average galaxy at these redshifts, indicating a high LyC escape fraction. This is further confirmed by our calculation using the $f_{\text{esc}}^{\text{LyC}} - \beta$ relation found by Chisholm et al. (2022). The significant escape fraction of LyC photons is further confirmed with a selection of indirect tracers (see Table 5), which all point towards an $f_{\text{esc}}^{\text{LyC}}$ of at least $> 5\%$.

The effective production of ionising photons of LAE-11 (Table 6) is comparable to other blue star-forming galaxies at high- z (e.g. Bouwens et al. 2016; Nakajima et al. 2018; Saxena et al. 2024; Simmonds et al. 2023, 2024; Torralba-Torregrosa et al. 2024) as well as H α emitters (HAEs) at $z \sim 7 - 8$ (Rinaldi et al. 2024). Additionally, this value is in line with the ionising photon production efficiency of low- z LyC leakers (e.g. Izotov et al. 2018, 2024). However, $\log(\xi_{\text{ion}}/\text{Hz erg}^{-1})$ of LAE-11 is higher than the average value found for faint galaxies at $z < 4$ (Bouwens et al. 2016), or HAEs at $z \sim 2 - 3$ (Chen et al. 2024).

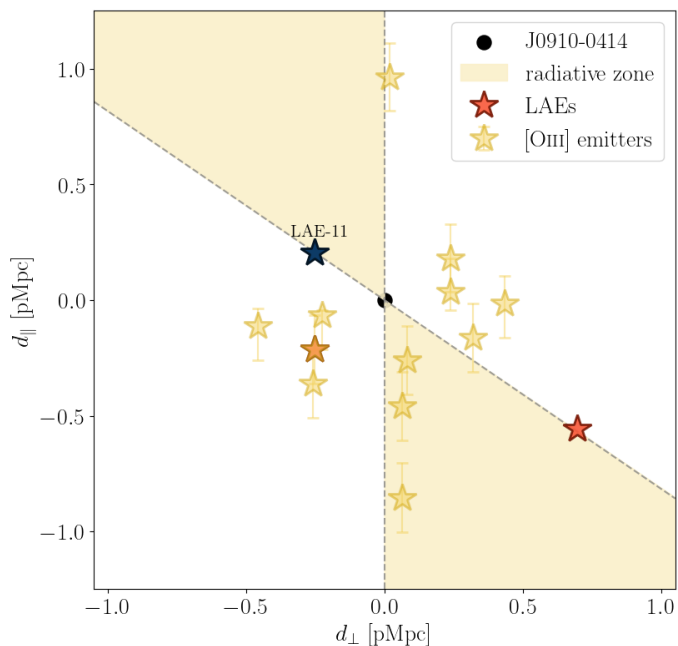

Fig. 9. The physical neighbourhood of Q0910 (black circle) surrounded by proximate [OIII] emitters from the ASPIRE survey (yellow stars) and LAEs from Wang et al. (2024b, red stars), and LAE-11 (dark blue star). The parallel distance d_{\parallel} is defined as negative towards the observer. The perpendicular distance d_{\perp} is defined negative if $RA_{\text{gal}} < RA_{\text{QSO}}$. We note that LAE-12 is also an [OIII] emitter, and showed with an orange colour. J0910-0414’s ionisation field (yellow shaded region) is depicted “counter-clockwise” from the observer and depicts the lower limit on its opening angle θ_Q , assuming a bipolar cone geometry. Since both the observer and the double-peaked LAE must be within this region, we can infer that the lower limit of $\theta_Q > 49.62^\circ$.

By measuring both the $f_{\text{esc}}^{\text{LyC}}$ and ξ_{ion} of LAE-11, we can investigate its total ionising output, which results in $\log(f_{\text{esc}}^{\text{LyC}} \xi_{\text{ion, H}\alpha} / \text{Hz erg}^{-1}) = 24.85^{+0.24}_{-0.34}$. Compared to low- z SFGs, high- z faint LAEs and high- z H α emitters, LAE-11 is compatible with the galaxies with effective ionising output (see Fig. 7). Additionally, the usually assumed ionising output of galaxies required to maintain the reionisation of the Universe is $\log(f_{\text{esc}}^{\text{LyC}} \xi_{\text{ion}} / \text{Hz erg}^{-1}) = 24.3 - 24.6$ (Robertson et al. 2013), 25.01 (Meyer et al. 2019), 24.64 (Meyer et al. 2020) or 24.8 (Davies et al. 2024), which are lower or comparable to LAE-11’s value. LAE-11 could therefore be a prototypical galaxy with a significant contribution to the ionising budget near the end of the EoR.

The blue UV slope, and an absence of a Balmer break possibly point towards a very young stellar population of the galaxy. The SFR of LAE-11 estimated using the UV emission is lower compared to the one diagnosed via the H α line with $\text{SFR}_{\text{H}\alpha} / \text{SFR}_{\text{UV}} = 2.46 \pm 0.40$. While the nebular emission of H α traces the formation of the most massive O and B stars with lifetimes of a few million years, the UV emission arises from a wider mass range of the same stellar population measuring timescales of 100 Myr (e.g. Lee et al. 2009). Therefore, the difference in these two tracers might indicate that the galaxy is undergoing a burst of star formation at the time of the observation (e.g. Glazebrook et al. 1999; Sullivan et al. 2000; Domínguez et al. 2015; Emami et al. 2019; Asada et al. 2024). This is further supported by the SFH extracted by SED fitting (Fig. 6).

Reionisation-era galaxies are characterised by extreme [OIII] and H β emission, with equivalent widths ranging from 300 Å to

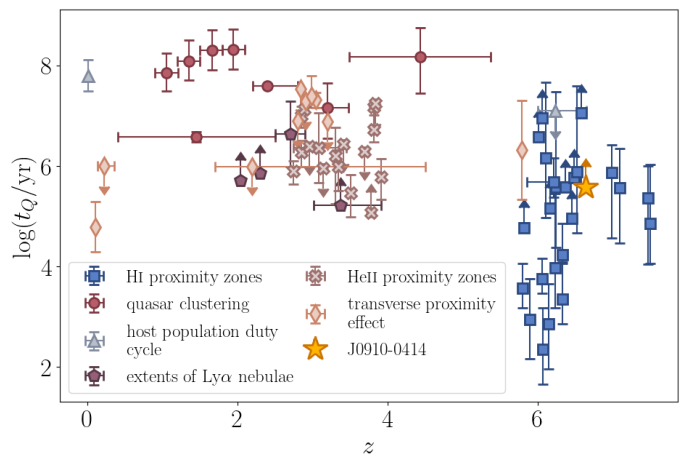

Fig. 10. Quasar lifetimes from literature as a function of redshift. Measurements using HI proximity zones along the line of sight are shown with blue squares (Eilers et al. 2018, 2021; Davies et al. 2019, 2020; Andika et al. 2020; Morey et al. 2021), studies using quasar clustering are depicted with red circles (Shen et al. 2007; Shankar et al. 2010; White et al. 2012; Laurent et al. 2017). Measurements inferred from the duty cycle of the quasar host population are shown with grey triangles (Yu & Tremaine 2002; Chen & Gnedin 2018), while those using extends of Ly α nebulae are depicted with purple pentagons (Trainor & Steidel 2013; Cantalupo et al. 2014; Hennawi et al. 2015; Borisova et al. 2016). Furthermore, quasar lifetime estimates calculated from the HeII proximity zones are shown as light brown crosses (Khrykin et al. 2019, 2021; Worseck et al. 2021), and studies using the transverse proximity effect are marked with a pink diamond (Kirkman & Tytler 2008; Keel et al. 2012; Schmidt et al. 2017, 2018; Oppenheimer et al. 2018; Bosman et al. 2020). Our estimation of t_Q for J0910-0414 is depicted with a yellow star. Adapted from Eilers et al. (2021).

3000 Å (e.g. Endsley et al. 2021, 2023), as expected in galaxies with young stellar populations and low metallicity (e.g. Labbé et al. 2013; De Barros et al. 2019). LAE-11 meets all of these conditions, with $\text{EW}_0([\text{OIII}] + \text{H}\beta) = 1843.94 \pm 192.83$ Å and $\log Z/Z_{\odot} = -0.86 \pm 0.03$. Furthermore, the high equivalent widths of Ly α , [OIII] and H β in the spectra of LAE-11 are comparable to the most extreme EELGs at $z \sim 2 - 3$ identified by Tang et al. (2024b) (see Fig. 4).

5.4. Alternative interpretations of LAE-11 at $z_{[\text{OIII}]}$

In this subsection we interpret the ionising properties of LAE-11 when the $z_{[\text{OIII}]}$ is taken at face-values. At this redshift, the expected Ly α emission line falls on the left peak of LAE-11’s Ly α profile. The velocity offset the left peak from the systemic redshift in this scenario falls to $v_{\text{left}} = 4.80 \pm 24.27$ km s $^{-1}$ and the velocity offset of the right peak is $v_{\text{right}} = 260.75 \pm 24.44$ km s $^{-1}$. A small sample of galaxies with a similar profile (red-dominated with blue peak situated at systemic redshift) were found at lower redshift by Kulas et al. (2012), Trainor et al. (2015) and Vitte et al. (2024). These works suggest that the origin of the double peak in this case arises from processes other than radiative transfer of Ly α photons. Since LAE-11 is a compact source and neither of the peaks is spatially offset from the other in the 2D spectra, we discard the possibility of a satellite source or merger contaminating our data.

Barring this scenario, the most likely interpretation of the profile would then position the apparent left peak into the centre position of a triple-peaked intrinsic line profile. In this case, the central peak corresponds to Ly α emission which escapes with-

out scattering through holes in the neutral interstellar medium (ISM), while the other two peaks arise due to Ly α photon scattering. In order to see this peak, the IGM around LAE-11 must still be ionised to a high degree. This interpretation is supported by the weak detection of transmission in the spectrum at $v_{\text{sep}} \sim -400 \text{ km s}^{-1}$ at $\lesssim 2\sigma$, which could be interpreted as the third Ly α line peak (see Fig. 2). Since the left peak would act as the central peak of the line, and is observed, there is an ionised channel in the ISM allowing a 100% leakage of LyC photons from the galaxy (e.g. Zackrisson et al. 2013). However, this result of $f_{\text{esc}}^{\text{LyC}} = 100\%$, would indicate that the ionising photon production efficiency ξ_{ion} approaches infinity as indicated by Eq. 8, since no Balmer emission lines are expected in this scenario. We also remind the reader of the discussion in Section 3.1, where discrepancies are identified between the Ly α and [O III] redshifts not only for LAE-11 but also for another galaxy which similarly falls on module A of the NIRCcam observations.

A final alternative interpretation of the line shape, if the $z_{[\text{OIII}]}$ is taken at face value, could be the presence of a neutral hydrogen gas clump in the vicinity of the galaxy. This clump would be responsible for the trough feature in the line profile, which in this scenario has a velocity offset of $v_{\text{trough}} = 125.25 \pm 22.06 \text{ km s}^{-1}$. This gas with neutral hydrogen column density of $\log N_{\text{HI}} = 13.96 \pm 0.24$ would therefore be falling into the galaxy. Since the double-peak in this scenario would not result from Ly α radiative transfer, the peak separation could not be used for LyC leakage calculation and only other proxies would have to be utilised. However, even in this scenario, LAE-11 would still be required to reside in an ionised IGM as the Ly α emission line would still be highly transmissive at the systemic velocity.

6. Summary

We present an analysis of a double-peaked Ly α emitter in the proximity of quasar J0910-0414 at $z = 6.6405 \pm 0.0005$ discovered in a search for a protocluster anchored by a high- z quasar by Wang et al. (2024b). The detection of the blue peak implies that the galaxy is located within the ionising radiation of the quasar's proximity zone. We utilise a combination of ground based high-resolution Keck/DEIMOS spectroscopy, JWST WFSS spectroscopy, low-resolution NIRSspec MSA spectroscopy, as well as photometric data spanning the UV to optical wavelengths to characterise the physical parameters and ionising output of the galaxy. Moreover, we use our findings to introduce constraints on the properties of the central quasar. Our key findings are summarised as follows:

1. LAE-11 displays a narrow double-peaked Ly α emission profile with a velocity separation of $\Delta v_{\text{sep}} = 255.71 \pm 33.69 \text{ km/s}$. The peak separation is comparable to luminous low redshift LAEs and GPs, while high- z double-peaked LAEs (Hu et al. 2016; Songaila et al. 2018; Bosman et al. 2020; Meyer et al. 2021) tend to represent the brightest sources with wider peak separation.
2. LAE-11 is a fairly bright UV galaxy ($M_{\text{UV}} = -19.84^{+0.14}_{-0.16}$) with a moderately steep UV slope ($\beta_{1550} = -2.61^{+0.06}_{-0.08}$). Analysing the direct imaging of LAE-11 reveals a very compact structure of $R_{\text{UV}} < 0.47 \text{ kpc}$. Using the Balmer decrement, indirect tracers, and SED fitting, we find that LAE-11 is a very dust-poor system. The spectrophotometric fit furthermore characterises the galaxy as low mass ($\log(M_{\star}/M_{\odot}) = 7.93^{+0.14}_{-0.08}$) with low metallicity ($\log(Z/Z_{\odot}) = -0.86 \pm 0.03$). We are also able to report on the SFR of the galaxy determined both by UV continuum and H α line to

be $\text{SFR}_{\text{UV}} = 5.25 \pm 0.69 M_{\odot} \text{ yr}^{-1}$ and $\text{SFR}_{\text{H}\alpha} = 12.93 \pm 1.20 M_{\odot} \text{ yr}^{-1}$.

3. Utilising a number of indirect tracers and multivariate models, we evaluate the escape fraction of ionising photons $f_{\text{esc}}^{\text{LyC}}$. We find that all tracers point towards an escape fraction of at least $\geq 5\%$, with all diagnostics pointing towards an escape fraction of $f_{\text{esc}}^{\text{LyC}} = (0.08 - 0.33)$. Furthermore, we calculate the ionising photon production efficiency to be $\log(\xi_{\text{ion}}/\text{Hz erg}^{-1}) = 25.59 \pm 0.08$ (25.63 ± 0.08) using the H α (H β) emission line detected in the NIRSspec spectrum. The total ionising output of the galaxy is therefore $\log(f_{\text{esc}}^{\text{LyC}} \xi_{\text{ion,H}\alpha}/\text{Hz erg}^{-1}) = 24.85^{+0.24}_{-0.34}$. This is higher or comparable to the canonical value commonly used for galaxies in order to maintain the EoR (Robertson et al. 2013; Meyer et al. 2019, 2020; Davies et al. 2024). LAE-11 therefore belongs to the population of galaxies which inject a significant amount of ionising radiation into the IGM in the early Universe.
4. The star formation in LAE-11 has not been extinguished despite the quasar induced ionising intensity of $J_{21} = 18.63 \pm 2.04$, conversely it is undergoing an active star burst at the time of the observation. Therefore, the burst in SFR and the possible lack of older stellar population points towards a recent formation of the galaxy. This is consistent with a delayed SFR due to QSO influence, however studies of larger samples of galaxies around $z > 6$ quasars indicate that their impact on surrounding galaxies is insignificant (Champagne et al. 2024a,b). Following the model presented in Kashikawa et al. (2007) implies that mass of its dark matter halo is $3 \times 10^9 M_{\odot} \lesssim M_h$.
5. Finally, we constrain the opening angle and lifetime of the central quasar J0910-0414. By constraining the location of LAE-11, we found the lower limit on the quasar's opening angle to be $\theta_Q > 49.62^\circ$ and the lower limit on the quasar lifetime to be $t_Q > 3.8 \times 10^5$ years.

Acknowledgements. KP and SEIB are supported by the Deutsche Forschungsgemeinschaft (DFG) under Emmy Noether grant number BO 5771/1-1. Data presented herein were obtained at Keck Observatory, which is a private 501(c)3 non-profit organization operated as a scientific partnership among the California Institute of Technology, the University of California, and the National Aeronautics and Space Administration. The Observatory was made possible by the generous financial support of the W. M. Keck Foundation. This research is furthermore based in part on data collected at the Subaru Telescope, which is operated by the National Astronomical Observatory of Japan. The authors wish to recognize and acknowledge the very significant cultural role and reverence that the summit of Maunakea has always had within the Native Hawaiian community. We are most fortunate to have the opportunity to conduct observations from this mountain. Moreover, this research is based on observations made with the NASA/ESA Hubble Space Telescope obtained from the Space Telescope Science Institute, which is operated by the Association of Universities for Research in Astronomy, Inc., under NASA contract NAS 5-26555. These observations are associated with program #16187. This work is also based in part on observations made with the NASA/ESA/CSA James Webb Space Telescope. The data were obtained from the Mikulski Archive for Space Telescopes at the Space Telescope Science Institute, which is operated by the Association of Universities for Research in Astronomy, Inc., under NASA contract NAS 5-03127 for JWST. These observations are associated with program #2078.

Appendix A: Additional figures

Fig. A.1. (*upper*) The raw coadded 2D spectrum generated by the PyPeit pipeline. (*middle*) The sky subtraction residuals resulting from the subtraction of the sky model from the raw coadded 2D spectrum. (*lower*) The final residuals after subtracting both the sky model and the object model, which is used to extract the 1D science spectrum.

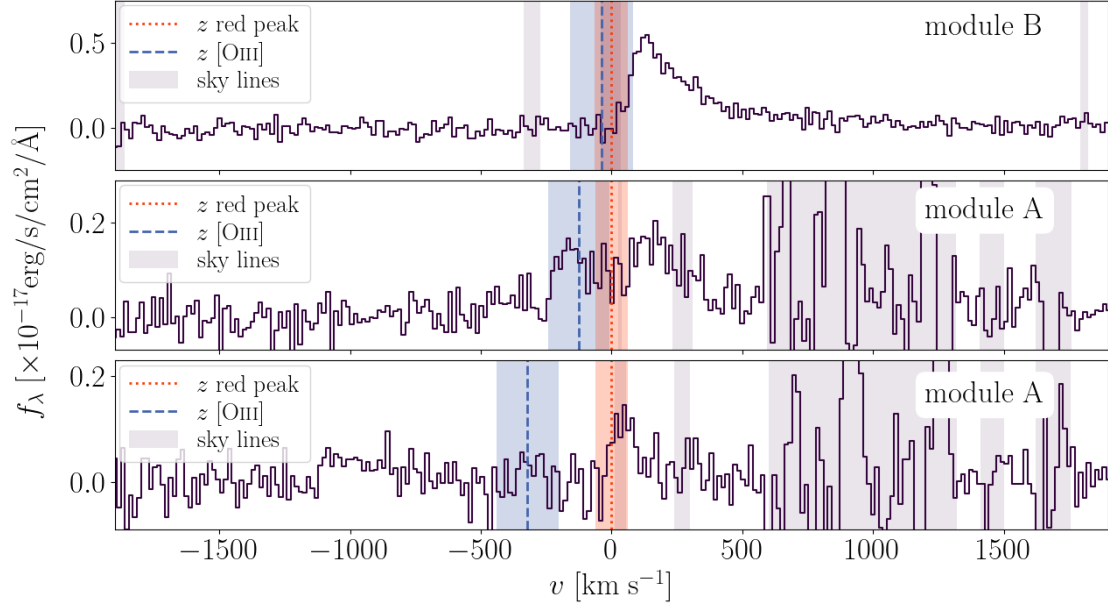

Fig. A.2. DEIMOS spectra of the LAEs in our sample with [OIII] spectra from *JWST*/NIRCam WFSS. LAE-1 (*upper*), LAE-11 (*middle*) and LAE-12 (*lower*) are shown with a purple line, and the skyline regions are marked with a shaded purple region. The dashed blue line represents the redshift of the galaxy as measured from the [OIII] doublet with the shaded blue region representing the conservative calibration redshift offset adopted by Wang et al. (2023), while the dotted orange line corresponds to the redshift calculated using $\text{FWHM}(\text{Ly}\alpha)$ as seen in Eq. 2 with the shaded orange region representing its measured uncertainty.

Fig. A.3. Corner plots showing the posterior distributions of the free parameters of the SED fit of LAE-11 using BAGPIPES. The contours indicate the 1σ , 2σ , and 3σ posterior of each parameter. The histogram of each parameter is shown on top of the corner plots, with the median shown with a dashed lines indicating the median and 1σ distribution.
