(Dated: December 18, 2024)

Motivated by the time-reversal symmetry breaking signal in muon spin relaxation below a transition temperature without accompanying noticeable magnetic Bragg peaks in 5*d* ² Os double perovskites, a rare ferrooctupolar order was proposed to account for such hidden order. Here we study the phase transitions under a magnetic field in triangular and face-centered cubic lattices using classical Monte Carlo simulations. It is expected that higher-rank moments do not couple linearly to the magnetic field. Consequently, a field applied along the ferro-octupolar order is not anticipated to influence the ordering. However, we observe the emergence of antiferro-quadrupolar ordering mixed with the antiferro-octupolar order (AFQO) due to the field-induced bond-dependent exchange interaction. This field-linear interaction among non-Kramer doublets arises via the coupling to the excited triplet states enabled by the external field. In the triangular lattice, we uncover intriguing vortex states, which could inspire future research into 5*d* 2 triangular lattice systems.

I. INTRODUCTION

In transition-metal Mott insulators, orbital degeneracy is often lifted by Jahn-Teller effects, where the crystal lattice distorts, separating the degenerate orbitals. This splitting is commonly observed in e_g orbitals, where an octahedral crystal distorts into a tetragonal structure [\[1–](#page-6-0)[5\]](#page-7-0) leading to the lowenergy theory given by spin-only Hamiltonians [\[6\]](#page-7-1). However, when spin-orbit coupling (SOC) is strong and Jahn-Teller effects are weak, the spin and orbital degrees of freedom become intertwined and are described by the total angular momentum, known as pseudospin, J [\[7\]](#page-7-2). For a d^2 ion with strong SOC in an octahedral environment, it has been shown that the $J = 2$ ground state can be further split due to t_{2g} and e_g mixing, resulting in a new ground state that can host both quadrupolar and octupolar moments [\[8](#page-7-3)[–10\]](#page-7-4).

While multipolar ordered phases have been widely explored and observed in f -electron compounds, such as NpO_2 , PrX_2Al_{20} (X = Ti, V), and others [\[11–](#page-7-5)[20\]](#page-7-6), realizing a material with a *d*-orbital ion in an octahedral environment, requiring strong SOC and weak Jahn-Teller effects, has been challenging. This is because *d*-orbital systems typically exhibit weaker SOC and stronger Jahn-Teller distortions compared to their *f*-orbital counterparts [\[6,](#page-7-1) [21\]](#page-7-7). However, a recent class of osmium (Os) double perovskites, $Ba₂BOsO₆$ (B = Ca, Mg) with a single transition [\[8,](#page-7-3) [22,](#page-7-8) [23\]](#page-7-9) has been claimed to exhibit oc-tupolar moments [\[8–](#page-7-3)[10,](#page-7-4) [24\]](#page-7-10). In this structure, the Os^{5+} $(5d^2)$ ions form a face-centered cubic (FCC) lattice, with each ion confined in an octahedral crystal field.

To understand a microscopic route to possible octupolar orders, a microscopic Hamiltonian was developed that takes into account dominant intra- and inter-orbital exchange processes [\[25\]](#page-7-11). Through this model, bond-dependent interactions among quadrupolar moments via intra-orbital exchange were identified. The octupolar interaction was found to be antiferromagnetic, leading to frustration of the octupolar order on the FCC lattice, allowing quadrupolar order to emerge instead

[\[25\]](#page-7-11). However, when all intra- and inter-orbital hopping terms are included, it was suggested that this family of Os double perovskites lies at the boundary between a ferro-octupolar phase and a type-I antiferro-quadrupolar phase [\[26,](#page-7-12) [27\]](#page-7-13).

In a subsequent study expanding on the Hamiltonian including an external magnetic field, it was shown that an applied field induces an intriguing bond-dependent interaction between quadrupolar and octupolar moments, introducing a new form of frustration [\[28\]](#page-7-14). On the two-dimensional honeycomb lattice, this frustration enables the realization of a Kitaev spin liquid in multipolar systems [\[28\]](#page-7-14).

Here we investigate the field-induced phases of d^2 atoms with strong SOC in an FCC lattice, where each atom experiences octahedral crystal field splitting. Using classical Monte Carlo simulated annealing, we determine the classical ground states for various field directions. When the field is applied along the [111] body-centered direction, a ferrooctupolar (FO) moment is expected to be enhanced, as the magnetic field directly couples to the octupolar moment, similar to a Zeeman-like term. However, this natural expectation breaks down when the bond-dependent interaction induced by the field becomes dominant over the Zeeman-like coupling, leading to the emergence of an antiferro-quadrupolar ordering mixed with the antiferro-octupolar order (AFQO). Since the FCC lattice can be viewed as a stack of triangular lattices, we also examine the phase diagram in the triangular lattice, and find the emergence of intriguing vortex states that mix quadrupolar and octupolar configurations.

The paper is structured as follows: in Section 2, we provide an overview of the double perovskite structure and the FCC lattice of osmium atoms, along with a review of recent experimental and theoretical developments. In Section 3, we derive the field-induced Hamiltonian for the triangular and FCC lattices. Our phase diagrams for the triangular and FCC lattices are presented in Section 4. The discussion and summary are provided in the final section.

II. REVIEW ON DOUBLE PEROVSKITES AND PSEUDOSPIN MODEL

A. Double perovskites and the underlying FCC lattice

Double perovskite compounds, A_2 BB'O₆ are derived from simple perovskites, $ABO₆$, but with half of the B atoms replaced with B' atoms such that any two nearest neighbour (n.n.) B-sites exclusively contain only one B and B' atom. The end effect being the formation of two FCC lattices that intersect with each other, with one lattice being entirely composed of B and the other of B' atoms as shown in Fig. 1(a). The B and B' positions are filled by transition metal elements, with the oxygen atoms forming octahedral cages around them. For $Ba₂BO₅O₆$ with B = Ca, Cd, Mg, B atoms are nonmagnetic leading to a FCC lattice of d^2 multiplets [\[26\]](#page-7-12).

Two different coordinate systems are commonly used for describing spin exchange interactions in the literature, so we begin by reviewing these two bases and their relationship. Figures 1(b) and 1(c) depict the octahedral and crystallographic orthonormal bases used for constructing the FCC B' lattice. The relationship between the two bases is given by the following:

$$
\hat{\mathbf{a}} = \frac{1}{\sqrt{6}} (\hat{\mathbf{x}} + \hat{\mathbf{y}} - 2\hat{\mathbf{z}}), \ \hat{\mathbf{b}} = \frac{1}{\sqrt{2}} (\hat{\mathbf{y}} - \hat{\mathbf{x}}), \ \hat{\mathbf{c}} = \frac{1}{\sqrt{3}} (\hat{\mathbf{x}} + \hat{\mathbf{y}} + \hat{\mathbf{z}}), \tag{1}
$$

where the vectors \hat{x} , \hat{y} and \hat{z} are defined based on the positions of oxygen atoms, while \hat{a} and \hat{b} and \hat{c} are aligned with the crystallographic coordinates.

Throughout the paper, we will use the notation $[\alpha\beta\gamma]$ to de-
te a direction in the basis of the octahedral lattice vectors note a direction in the basis of the octahedral lattice vectors. For example, [111] denotes the same direction as $\hat{\mathbf{x}} + \hat{\mathbf{y}} + \hat{\mathbf{z}}$. A line over a number indicates the opposite direction. For example, $\begin{bmatrix} 110 \end{bmatrix}$ is the same direction as $\hat{\mathbf{y}} - \hat{\mathbf{x}}$. Note that the FCC lattice has a C_3 rotational symmetry about the [111] direction and can be considered as a stacked triangular lattice along the *c*-axis.

B. Osmium double perovskites

Various experimental and theoretical investigations have been conducted in Os-based double perovskites, $Ba₂BO₅O₆$ $(B = Ca, Mg)$, by various groups. Experimental investigations of this family of perovskites have found a peak in their heat capacity at $T^* \sim 50$ K, suggesting a phase transition [\[22,](#page-7-8) [23\]](#page-7-9). Measurement of magnetic susceptibility and fitting of inverse susceptibility to the Curie-Weiss law provide a negative Curie-Weiss temperature of Θ*CW* ∼ −130 K, commonly associated with type-I antiferromagnetic order [\[22,](#page-7-8) [23\]](#page-7-9). Similarly, inelastic neutron diffraction experiments observed strong, gapped, magnetic spectral weight at wavevectors [100] $(|Q|^{-1} \sim 0.78$ Å⁻¹) and [110] $(|Q|^{-1} \sim 1.1$ Å⁻¹), typical of the antiferromagnetic order [81]. However, further neutron powder antiferromagnetic order [\[8\]](#page-7-3). However, further neutron powder diffraction investigations revealed an absence of Bragg scattering at low temperatures at the [100] and [110] positions,

FIG. 1: (a) Double perovskites with an interlocking FCC lattice formed by B and B' ions, represented as white and black spheres, respectively, with electrons depicted in gray. For clarity, only two octahedral oxygen structures are shown. (b) The octahedral coordinate system $\hat{\mathbf{x}}$, $\hat{\mathbf{y}}$, and $\hat{\mathbf{z}}$. (c) The crystallographic axis \hat{a} , \hat{b} , and \hat{c} .

contrary to the expectation [\[8\]](#page-7-3) making it a hidden order. Neutron powder diffraction experiments reveal a dipole ordered moment of $0.06\mu_B$ to $0.13\mu_B$, depending on the type of material substituted into the *B* atom [\[8\]](#page-7-3). Lastly, low temperature μ SR experiments show an oscillating asymmetry over time, indicating the presence of internal magnetic fields and thus time reversal symmetry breaking [\[22,](#page-7-8) [23\]](#page-7-9).

Furthermore, subsequent x-ray diffraction experiments have shown no changes in crystal symmetry [\[8\]](#page-7-3), indicating the absence of quadrupolar order, as it would lower the crystal symmetry from cubic to tetragonal [\[8](#page-7-3)[–10\]](#page-7-4). Thus, another proposal to explain the current data was developed. As briefly mentioned in the Introduction, treating the $t_{2g} - e_g$ mixing as a perturbation, the five-fold degenerate $J = 2$ state is broken into a lower non-Kramers doublet ground state and an excited triplet [\[8](#page-7-3)[–10\]](#page-7-4). In resemblance with the crystal field states e_g and t_{2g} , the lower non-Kramers doublet and excited triplet were referred to as E_g and T_{2g} , respectively [\[25,](#page-7-11) [26,](#page-7-12) [28,](#page-7-14) [29\]](#page-7-15). The lower E_g state does not carry dipole moment, but rather higher moments such as quadrupolar and octupolar [\[30](#page-7-16)[–32\]](#page-7-17). It was proposed that the ground state exhibits an FO order [\[10\]](#page-7-4), which leads to an internal orbital current and hence a magnetic field within the crystal, consistent with μ SR data. However, since the muon might impact the local crystal potential leading to a revival of dipole moment [\[33,](#page-7-18) [34\]](#page-7-19), further investigation of the hidden order needs to be explored. Furthermore, it has been challenging to experimentally detect a quadruoplar order [\[35](#page-7-20)[–37\]](#page-7-21), and thus a quadrupolar order has not been completely ruled out.

C. Local Hamiltonian and non-Kramer's doublet

Motivated by the above results, a microscopic model for the E_g non-kramer doublet was derived to understand the exchange processes leading to the octupolar order and its competition with the quadrupolar orders [\[25,](#page-7-11) [26\]](#page-7-12). Here we briefly review how to derive a microscopic Hamiltonian for the multipolar moments.

To construct an exchange model, one begins with a local atomic site *i* Hamiltonian, *Hⁱ* . After projecting out the high energy e_g states due to the large octahedra crystal field splitting, H_i is given by [\[26,](#page-7-12) [28\]](#page-7-14),

$$
H_{i} = U \sum_{m} n_{m+} n_{m-} + U' \sum_{m \neq m'} n_{m+} n_{m'-} + (U' - J_{H}) \sum_{m < m', \sigma} n_{m\sigma} n_{m'\sigma}
$$

$$
+ J_{H} \sum_{m \neq m'} (c_{m+}^{\dagger} c_{m'-}^{\dagger} c_{m-} c_{m'+} + c_{m+}^{\dagger} c_{m'-}^{\dagger} c_{m'-} c_{m'+}) + \lambda \mathbf{L}_{\text{eff}} \cdot \mathbf{S},
$$
\n(2)

where the summation is performed over orbitals exclusively in the t_{2g} basis and \mathbf{L}_{eff} = −1 due to the projecting out the e_g orbitals.

Using Hund's rules and SOC, one finds a five-fold degenerate *J* = 2 as the lowest state. However, $e_g - t_{2g}$ mixing causes $J = 2$ to split, and such splitting of the $J = 2$ multiplet can be modeled by the cubic crystal field Hamiltonian given by [\[8](#page-7-3)[–10\]](#page-7-4),

$$
H' = \delta(O_4^0 + 5O_4^4),\tag{3}
$$

where O_4^0 and O_4^4 are Stevens operators given by [\[8,](#page-7-3) [9\]](#page-7-22)

$$
O_4^0 = 35J_z^4 - [30J(J+1) - 25]J_z^2 + 3J^2(J+1)^2 - 6J(J+1),
$$

\n
$$
O_4^4 = \frac{J_+^4 + J_-^4}{2}.
$$
\n(4)

Diagonalizing *H'* yields the E_g ground state, expressed in $|J^z\rangle$ states as

$$
|\uparrow\rangle = \frac{1}{\sqrt{2}} (|2\rangle + |-2\rangle), \quad |\downarrow\rangle = \frac{1}{\sqrt{6}} |0\rangle.
$$
 (5)

Using the E_g wavefunctions, the matrix representations of the two quadrupole and one octupole operators respectively are given as [\[26\]](#page-7-12)

$$
Q_{x^2-y^2} = J_x^2 - J_y^2, \quad Q_{3z^2-r^2} = \frac{3J_z^2 - J^2}{\sqrt{3}}, \quad T_{xyz} = \frac{\sqrt{15}}{6} \overline{J_x J_y J_z},
$$
(6)

where the overline symbol denotes symmetrization of the underlying operators. They can be expressed as Pauli matrices as follows [\[26,](#page-7-12) [28\]](#page-7-14):

$$
s^{1} \equiv \frac{1}{4\sqrt{3}} Q_{x^{2}-y^{2}}, \quad s^{2} \equiv \frac{1}{6\sqrt{5}} T_{xyz}, \quad s^{3} \equiv \frac{1}{4\sqrt{3}} Q_{3z^{2}-r^{2}}.
$$
 (7)

It is important to highlight that the quadrupole and a octupole operators are defined in the crystallographic basis shown in Fig. 1(c). As such, we will use the notation $(s^a, s^b, s^c) =$
 (s^3, s^1, s^2) as effective pseudospin-1/2 operators. Under such a (s^3, s^1, s^2) as effective pseudospin-1/2 operators. Under such a
system, the quadrupolar components, s^a and s^b are in a plane system, the quadrupolar components, s^a and s^b , are in a plane perpendicular to [111], while the octupolar component, s^c is parallel to the [111] line, i.e, *c*-axis.

FIG. 2: (a) Examples of exchange processes among t_{2g} orbitals on the FCC lattice: t_1 corresponds to hopping between *zy* and *zy* orbitals, *t*² to hopping between *yz* and *xz* orbitals, and *t*³ to hopping between two *xy* orbitals. (b) Dominant hopping within and between the planes perpendicular to [111] is illustrated. Solid red lines represent in-plane bonds (1–6), while dashed blue lines indicate out-of-plane bonds (7–12). Specifically, bonds 2, 5, 9, and 12 are *z*-bonds; bonds 3, 6, 8, and 11 are *x*-bonds, and bonds 1, 4, 7, and 10 are *y*-bonds.

D. Nearest neighbour exchange Hamiltonian

To construct the exchange Hamiltonian, we begin by considering the hopping processes between two sites, *i* and *j*, and then apply the lattice symmetry to generalize the exchange interactions for the remaining bonds. Let us consider a tightbinding model on the line spanned by \mathbf{b} (see Fig. 2(a)), which is referred to as a *z*-bond since the dominant hopping is of the form $xy \leftrightarrow xy$ and hence are perpendicular to the *z*-axis.

Denoting the n.n. sites as $\langle i j \rangle_z$ (the subscript indicates the bond type), the three types of orbital hopping integrals is given by

$$
H_{\langle ij\rangle_z}^{\rm TB} = c_i^{\dagger} T_{ij} c_j + c_j^{\dagger} T_{ij}^{\dagger} c_i,
$$
 (8)

where c_i^{\dagger} $i^{\dagger} = (c_i^{\dagger})$ *i*,*xy* , *c* † $\int_{i,xz}^{\dagger}$, $c_{i,yz}^{\dagger}$ [\[26\]](#page-7-12) and

$$
T_{ij}^{z} = \begin{pmatrix} t_3 & 0 & 0 \\ 0 & t_1 & t_2 \\ 0 & t_2 & t_1 \end{pmatrix} . \tag{9}
$$

Using the strong coupling expansion, the exchange Hamiltonian between the non-Kramer doublets along the *z*-bond takes on the following form [\[26\]](#page-7-12):

$$
H_{\langle ij\rangle_z} = J_\tau s_i^a s_j^a + J_Q \left(s_i^a s_j^a + s_i^b s_j^b \right) + J_O s_i^c s_j^c \tag{10}
$$

where to second order the exchange parameters are given as [\[26\]](#page-7-12)

$$
J_{\tau} = \frac{4}{9} \frac{(t_1 - t_3)^2}{U}, \quad J_Q = \frac{2}{3} \frac{t_1(t_1 + 2t_3) - t_2^2}{U},
$$

$$
J_Q = \frac{2}{3} \frac{t_1(t_1 + 2t_3) + t_2^2}{U}, \tag{11}
$$

where Hund's coupling has been ignored. Note that when $t_1 = 0$, $J_O(= -J_O) > 0$, leading to frustration of the octupolar moment on the FCC lattice, consistent with the Hamiltonian reported in Ref. $[25]$. However, when t_1 becomes finite, the octupolar interaction J_O can become negative, potentially leading to an octupolar order [\[26\]](#page-7-12).

The exchange interactions for the remaining bonds can be determined by applying the lattice symmetry. Below, we present the complete Hamiltonian for the triangular and FCC lattices, incorporating the effects of an external magnetic field.

III. HAMILTONIAN INCLUDING EXTERNAL MAGNETIC FIELD FOR MULTIPOLAR MOMENTS IN TRIANGLE AND FCC LATTICES

A. Triangular lattice

Now, let us consider the Zeeman term given by H_i^z = $\mu_B(L_i + 2S_i) \cdot \mathbf{h}$, where $\mathbf{h} = h_x \hat{\mathbf{x}} + h_y \hat{\mathbf{y}} + h_z \hat{\mathbf{z}}$. Based on symmetry considerations, multipolar moments do not couple to the field linearly. Instead we expect terms like $(2h_z^2 - h_x^2 - h_y^2)s^z$, $(h_x^2 - h_y^2)s^b$ and $(h_xh_yh_z)s^c$. However, what is overlooked in the symmetry analysis are the virtual processes involving the higher-energy triplet T_{2g} , separated by Δ . Since T_{2g} carries dipole moments, it is influenced by the Zeeman term. This splitting can induce additional exchange interactions between the quadrupolar and octupolar moments, and a linear Zeemanlike term may also emerge. We will now explore the full Hamiltonian, incorporating the external field in the triangular lattice.

Following the strong coupling approach used for the honeycomb lattice [\[28\]](#page-7-14), we derive the exchange terms for the triangular lattice, assuming *^h*/[∆] is a small parameter, alongside t_i/U . Let's first consider the *z*-bond. The additional quadratic terms take the following form:

$$
H_{\langle i j \rangle_{z}}^{B} = -\sqrt{2}J_{B}^{z}(s_{i}^{a}s_{j}^{c} + s_{i}^{c}s_{j}^{a}), \qquad (12)
$$

where

$$
J_B^z = \frac{8}{3\sqrt{6}} \frac{t_2(2t_1 + t_3)}{U} \frac{g_J \mu_B h^z}{\Delta}.
$$
 (13)

Since this term involves virtual hopping processes to the triplet T_{2g} , the coefficient J_{β}^z is proportional to h_z/Δ , where Δ
represents the energy splitting between T_{2g} and F_{γ} . Note that represents the energy splitting between T_{2g} and E_g . Note that $J_{B}^{\overline{z}}$ is only finite when the magnetic field has a *z*-component.

The remaining exchange interactions for $\langle i j \rangle$ ^{*y*} (n.n. *y*bonds) and $\langle i j \rangle_x$ (n.n. *x*-bonds) within the triangular lattice perpendicular to the [111]-axis as shown in Fig. 2(b) can be obtained by performing a C_3 rotation about the [111]-axis. Under this rotation, we note that the spin operators transform as follows:

$$
s^a \to -\frac{1}{2}s^a + \frac{\sqrt{3}}{2}s^b
$$
, $s^b \to -\frac{\sqrt{3}}{2}s^a - \frac{1}{2}s^b$, $s^c \to s^c$. (14)

Rotating once will give us the quadratic *x*-bond and once more after will give the *y*-bond.

Lastly, $\mathbf{h}_{\text{eff}} = h_{\text{eff}}^a \hat{\mathbf{a}} + h_{\text{eff}}^b \hat{\mathbf{b}} + h_{\text{eff}}^c \hat{\mathbf{c}}$ is expressed in crystallographic basis and is given by

$$
h_{\text{eff}}^{a} = 6(g_{J}\mu_{B})^{2} \frac{2h_{z}^{2} - h_{x}^{2} - h_{y}^{2}}{\Delta}
$$

\n
$$
h_{\text{eff}}^{b} = 6(g_{J}\mu_{B})^{2} \frac{h_{x}^{2} - h_{y}^{2}}{\Delta}
$$

\n
$$
h_{\text{eff}}^{c} = \frac{4}{3\sqrt{3}} \frac{t_{2}(t_{1} - t_{3})g_{J}\mu_{B}}{U} \frac{(h_{x} + h_{y} + h_{z})}{\Delta} - 36\sqrt{3}(g_{J}\mu_{B})^{3} \frac{h_{x}h_{y}h_{z}}{\Delta^{2}}.
$$
\n(15)

The above forms of h_{eff} are expected based on the symmetry. The resulting Hamiltonian is same as the one obtained for the honeycomb lattice [\[28\]](#page-7-14), except that there are six n.n. bonds with two x-, two y-, and two z-bonds in the triangular lattice.

B. FCC lattice

For the FCC lattice, there are 12 bonds connecting to a site. 6 bonds denoted by the number 1 to 6 (denoted by red line) as shown in Fig. 2(b) are within the triangular plane discussed in the above subsection, while the remaining 6 bonds denoted by the number 7 to 12 (denoted by blue line), connect sites between the n.n. belong to different triangles, i.e., out-of-plane bonds. For the bonds within the plane (red bonds), the tight binding parameter is the same as Eq. (9). However, the 6 bonds connecting outside the triangular plane (blue bonds) have different tight binding parameters. For example the *z*bond along [110]-direction takes the form of

$$
T_{\langle ij\rangle\text{eout-of-plane}}^{z} = \begin{pmatrix} t_{3} & 0 & 0\\ 0 & t_{1} & -t_{2} \\ 0 & -t_{2} & t_{1} \end{pmatrix},
$$
 (16)

where the sign of t_2 changes due to the bond direction. This leads to J_B interactions gaining a negative sign, while the other terms are not altered as summarized below.

Combining all the exchange contributions, the full effective Hamiltonian for the FCC lattice can then be expressed as:

$$
H = \sum_{\langle ij \rangle_{\gamma}} J_{\tau} \tau_i^{\gamma} \tau_j^{\gamma} + J_Q \left(s_i^a s_j^a + s_i^b s_j^b \right) + J_O s_i^c s_j^c + H_{\langle ij \rangle_{\gamma}}^B - \sum_i \mathbf{h}_{\text{eff}} \cdot \mathbf{s}_i,
$$
\n(17)

where

$$
H_{\langle i j \rangle_{\gamma}}^{B} = \begin{cases} -\sqrt{2}J_{B}^{\gamma}(\tau_{i}^{\gamma} s_{j}^{c} + s_{i}^{c} \tau_{j}^{\gamma}) & \langle i j \rangle_{\gamma} \in \text{in-plane} \\ +\sqrt{2}J_{B}^{\gamma}(\tau_{i}^{\gamma} s_{j}^{c} + s_{i}^{c} \tau_{j}^{\gamma}) & \langle i j \rangle_{\gamma} \in \text{out-of-plane} \end{cases} (18)
$$

where γ can take on values of *z*, *x*, or *y* and is determined by the type of bond $\langle i j \rangle$ (see Fig. 2(b)), $\tau_i^{\gamma} \equiv s^a \cos \theta_{\gamma} + s^b \sin \theta_{\gamma}$,
where $\theta_i = 0$, 2^{π} , 4π when $\gamma_i = 5$, γ_i . Note the sign difference where $\theta_{\gamma} = 0$, $\frac{2\pi}{3}$, $\frac{4\pi}{3}$ when $\gamma = z$, *x*, *y*. Note the sign difference
in front of the *L*_p term between the in-plane ys out-of-plane in front of the J_B term between the in-plane vs. out-of-plane bonds.

Furthermore, $\mathbf{h}_{\text{eff}} = h_{\text{eff}}^a \hat{\mathbf{a}} + h_{\text{eff}}^b \hat{\mathbf{b}} + h_{\text{eff}}^c \hat{\mathbf{c}}$ is expressed in crys-

tallographic basis and is given by

$$
h_{\text{eff}}^{a} = 6(g_{J}\mu_{B})^{2} \frac{2h_{z}^{2} - h_{x}^{2} - h_{y}^{2}}{\Delta}
$$

\n
$$
h_{\text{eff}}^{b} = 6(g_{J}\mu_{B})^{2} \frac{h_{x}^{2} - h_{y}^{2}}{\Delta}
$$

\n
$$
h_{\text{eff}}^{c} = -36 \sqrt{3} (g_{J}\mu_{B})^{3} \frac{h_{x}h_{y}h_{z}}{\Delta^{2}}.
$$
\n(19)

The linear *h* term observed in the honeycomb and triangular lattices with the form of $h_{\text{eff}}^c = \frac{4}{3}$ $rac{4}{3\sqrt{3}}$ $rac{t_2(t_1-t_3)g_J\mu_B}{U}$ $(h_x+h_y+h_z)$ $\frac{n_y + n_z j}{\Delta}$ does not occur in the FCC lattice, because there are positive contributions from the n.n. in-plane (1-6) and negative contributions from the n.n. out-of-plane (7-12). They cancel out.

The FCC lattice Hamiltonian does not follow the form as the one derived for the honeycomb and triangular lattices. In the FCC lattice, there are 12 bonds, and J_B^{γ} alternates it sign, and the linear *h* term in h_{eff}^c does not occur in the FCC lattice.

IV. PHASE DIAGRAM AND FIELD-INDUCED PHASES

Exchange parameters J_{τ} , J_Q and J_Q for Os double perovskites, $Ba₂BO₅O₆$ (B = Ca, Cd, Mg) are reported using the combination of density functional theory and strong coupling expansion [\[26\]](#page-7-12). As reported in Ref. [\[26\]](#page-7-12), the exchange parameters, in the absence of an applied field, result in a FO ground state for $Ba₂MgOsO₆$, whereas $Ba₂CaOsO₆$ and $Ba₂CdOsO₆$ exhibit antiferro-quadrupole (AFQ) ground states. In all three cases, slight modifications to the exchange parameters can shift the ground state from FO to AFQ or vice versa. In light of this, our starting point is finding where this transition occurs. This is done classically by minimizing the Hamiltonian via Monte Carlo simulated annealing [\[38–](#page-7-23)[41\]](#page-8-0).

For fixed $J_{\tau} = 2.8$ and $J_O = -1.5$, close to the exchange parameters for Os double perovskites (all exchange parameters are in unit of meV), we find that the phase transition from FO and AFQ occurs at approximately $J_O = -0.85$. To explore the effects of the magnetic field through J_B and h_{eff} on FO and AFQ orders, we choose two different values of $J_O = -0.9$ and $J_O = -0.7$, as these values are near the phase transition and yield FO and AFQ phases, respectively.

Applying a field in the [111]-direction, where $\mathbf{h}_{\text{eff}} = h_{\text{eff}}^c \hat{\mathbf{c}}$, we observe that $J_B^x = J_B^y$ $J_B^y = J_B^z$. For clarity, let us define $J_B^{\gamma} \equiv$ J_B and $h_{\text{eff}}^c \equiv h_{\text{eff}}$. For Os double perovskites the exchange parameters produce J_B < 0 [\[26\]](#page-7-12). In order to explore the phase space, we will treat J_B and h_{eff} as independent parameters, and present the phase diagram as a function of J_B and h_{eff} . Before we present the classical phase diagram for the FCC lattice for Os double perovskites, we present the result on a triangular lattice first.

A. Triangular lattice

Using J_{τ} = 2.8, and J_Q = -1.5, we present the classical phase diagram obtained through Monte Carlo simulated annealing for the FO (J_O = −0.9) and AFQ (J_O = −0.7) cases

FIG. 3: Classical phase diagrams computed by Monte Carlo simulation on the triangular lattice when a field is applied in the [111]-direction and (a) $J_Q = -0.9$, and (b) $J_Q = -0.7$. Solid and dashed lines represent first and second order phase transitions, respectively. Note that the ferro-octupolar (FO) phase at $h_{\text{eff}} = 0$ in (a) becomes the polarized octupolar (PO) state at $h_{\text{eff}} \neq 0$ as the moment direction is fixed by the external field.

in Fig. 3(a) and (b), respectively. Starting with the $J_O = -0.9$ case, we note that as the field h_{eff} and J_B increases, there are several phases found. Starting from the FO phase, the effective *c*-axis field does not generate any transition, as expected. On the other hand, for $h_{\text{eff}} = 0$, J_B induces a field-induced vortex phase with a large unit cell (denoted by BV), which then transitions to AFQO phase as J_B further increases. In the BV phase, the pattern of the quadrupole and octupole moment is shown in Fig. 4(a), where the unit cell of the pseudospin configurations show the staggered chiral vortex pattern. The AFQO phase is also shown in Fig. 4(c), where the quadrupole and octupole moment order are in a stripy antiferro pattern.

When both h_{eff} and J_B are finite, the two other vortex phases are found. Starting in the BV phase with sufficiently large *J^B* and increasing *h*eff, we see a transition into a state composed of two vortex (2V) alignments interacting in a anticyclonic manner as shown Fig. $4(b)$. Similarly, increasing h_{eff} while within the AFQO phase, we observe a transition into another vortex with a smaller unit cell of a honeycomb (denoted as SV) as shown in Fig. 4(d).

For $J_O = -0.7$, we observe similar phases, including

AFQO, BV, PO, SV, and 2V. Starting with no applied field in the AFQ phase, there is no pseudospin octupolar component. However, as the magnitude of h_{eff} increases, a uniform rise in the octupolar component is observed at all sites, culminating in a second-order phase transition to the PO phase at h_{eff} = 1.2. In a manner similar to the triangular J_Q = -0.9 phase diagram, J_B induces transitions to the BV and AFQO phases when no field is applied. Similarly, increasing *h*eff from the BV or AFQO phases results in transitions to the 2V and SV phases, respectively.

As shown in Fig. 4, the BV and SB pseudospin configurations are invariant under C_3 rotation. In contrast, the 2V and AFQO configurations are asymmetric with respect to this rotation. Consequently, the 2V and AFQO states are each degenerate with two additional pseudospin configurations generated by applying the C_3 rotation to the depicted states.

The presence of the AFQO phase for low h_{eff} and large J_B can by explained by examining the J_B^{γ} terms in the full effective Hamiltonian. If the bond between two n.n. sites is a *z*-bond, the Hamiltonian term is proportional to $(s_i^a s_j^c + s_i^c s_j^a)$. This is minimized when $s_i = s_j = \pm (1, 0, -1)/\sqrt{2}$. However, when considering a *x*₂ or *y*₂ hound, we see that the Hamiltowhen considering a *x*- or *y*-bound, we see that the Hamiltonian is instead minimized when $s_i = -s_j = \pm (1, 0, -1)/\sqrt{2}$.
Put more succulently if the n n bond is a z-bond it favors Put more succulently, if the n.n. bond is a *z*-bond, it favors a parallel pseudospin configuration with quadrupole and octupole components, while *x*- and *y*-bonds favor anti-parallel pseudospin configurations.

B. FCC lattice

The classical phase diagrams obtained using Monte Carlo simulated annealing for the FCC lattice are presented in Fig. 5(a) and (b) for $J_O = -0.9$ and $J_O = -0.7$, respectively. Here we utilize the same fixed value for J_{τ} and J_Q as for the triangular lattice.

First considering $J_O = -0.9$, we observe two phases. Starting from the FO phase, increasing the magnitude of the applied field does not induces a phase transition, as expected since the effective field is parallel to the octupolar moment direction of FO. However increasing J_B at any fixed h_{eff} induces a phase transition to the AFQO phase where the planes of aligned spins are perpendicular to $\overline{111}$, as shown in Fig. 5(c). Analogously to the triangular lattice, in the FCC lattice, the AFQO configuration arises when large J_B dominates the Hamiltonian, as the J_B term promotes this specific configuration. Similarity, taking $J_O = -0.7$ and starting in the AFQ phase, we see similar behavior to the triangular lattice for small J_B , where increasing h_{eff} results in octupolar component of pesduespin increasing in magnitude until a second order phase transition into the FO state is observed at $h_{\text{eff}} = 2.4$.

Due to the cancellation of the in-plane and out-of-plane *J^B* terms with opposite signs, the intriguing vortex phases disappear in the FCC lattice, implying that the vortex phases are due to the field-induced bond-dependent *J^B* exchange interaction. Lastly, we note that increasing J_B incudes the AFQO phase. This is the most interesting feature of the phase diagram of the FCC lattice as the emergence of the AFQO phase occurs via

FIG. 4: Multipolar ordered patterns found in the triangular lattice are shown for (a) BV, (b) 2V, (c) AFQO, and (d) SV phases. The quadrupolar and octupolar moments are parallel and perpendicular to the triangular plane, respectively. Thus the length of the arrows indicate the magnitude of the quadrupole component. Red arrows represent downward-oriented octupole moment, while blue arrows represent upward-oriented octupole moments.

the bond-dependent J_B exchange interaction enabled by the external field along the octupolar moment direction.

V. DISCUSSION AND SUMMARY

It was noted that the non-Kramer E_g doublet is the lowest state of $5d^2$ ions when the Hund's coupling, SOC, and mixture of t_{2g} and e_g orbitals are considered, which carries quadrupolar and octupolar moments. However, the effects of the magnetic field beyond the effective Zeeman field have been less explored: the effects of the magnetic field on multipolar systems can be understood through the symmetry analysis. For example, when the field is aligned along the [111]-axis, which corresponds to the direction of the octupolar moment, the octupolar moment (s^c) couples to the cubic order of the field. This coupling takes the form $(h_x h_y h_z) s^c / \Delta^2$ where Δ is the energy splitting between the double F_{Δ} and triplet T_{Δ} , as alenergy splitting between the double E_g and triplet T_{2g} , as allowed by symmetry. On the other hand, the field applied along $[1\overline{1}0]$ -axis allows the coupling with the quadrupole moment (s^b) , which is expressed as $(h_x^2 - h_y^2)s^b/\Delta$. They act as an effective Zeeman field for the multipolar moments. Bayyan effective Zeeman field for the multipolar moments. Rayyan et al[\[28\]](#page-7-14) have recently noted in a honeycomb lattice that the magnetic field allows the coupling between the doublet and triplet leading to another bond-dependent interaction denoted

FIG. 5: Classical phase diagrams computed by Monte Carlo simulated annealing on the FCC lattice when a field is applied in the [111]-direction and (a) $J_O = -0.9$, and (b) J_O = −0.7. Solid and dashed lines represent first and second order phase transitions, respectively. Note that the ferro-octupolar (FO) phase at $h_{\text{eff}} = 0$ in (a) becomes the polarized octupolar (PO) state at $h_{\text{eff}} \neq 0$. (c) The pattern of the multipolar moments in the AFQO phase is shown: the quadrupolar and octupolar moments are parallel and perpendicular to the grey-shaded planes, respectively.

by J_B , which is linear in *h*. Thus, in small field regions $h < \Delta$, the J_B term can dominate over the effective Zeeman field.

We have demonstrated that the field-induced bonddependent J_B exchange interaction gives rise to rich phase diagrams in triangular and FCC lattice multipolar systems. The magnetic field along the [111]-axis turns the FO phase to an AFQO phase in the FCC lattice relevant to Os double perovskites. However, it is challenging to achieve the size of *J^B* to be 1 meV in Os double perovskites. Further studies are needed to quantify the strength of J_B beyond the second order in strong coupling expansion. Investigating other phase space with antiferro-octupolar interaction, i.e., $J_O > 0$ presents another intriguing direction: the antiferromagnetic Ising interaction on the triangular and FCC lattices is frustrated, making the effects of J_B interesting subjects for further investigation. Exploring $5d^2$ triangular lattices such as $HfCl_2$ would be another interesting direction for future studies. One might be concerned that $5d^2$ physics could be disrupted by a trigonal distortion. However, it has been shown that the E_g doublet remains the lowest-energy state even in the presence of a small negative trigonal field [\[42\]](#page-8-1). The vortex phases found in the triangular lattice, both with and without an external magnetic field, are particularly interesting for future research.

In summary, the effects of the magnetic field on mulitpolar systems composed of quadrupolar and ocupolar moments in the triangular and FCC lattices are investigated. Intriguing vortex phases are found in the triangular lattice due to the field-induced bond-dependent interaction enabled by the external magnetic field. In the FCC lattice, the magnetic field along the *c*-axis parallel to *s c* (octupolar moment operator) leads to the antiferro-quadurole and antiferro-octupole phase. This is unexpected, since the effective Zeeman term along the *c*-axis favors the polarization of the octupolar moment, the transition to the FO occurs if the ground state is AFQ, or remains FO (or polarized octupolar state which is connected to the FO) if the ground state is FO phase to begin with. However, due to the bond-dependent interaction J_B which is linear in *h* leads to antiferromagnetically ordered quadrupolar moments in the FCC lattice.
