Abstract

Advances in robotic control and sensing have propelled the rise of automated scientific laboratories capable of high-throughput experiments. However, automated scientific laboratories are currently limited by human intuition in their ability to efficiently design and interpret experiments in high-dimensional spaces, throttling scientific discovery. We present AutoSciLab, a machine learning framework for driving autonomous scientific experiments, forming a surrogate researcher purposed for scientific discovery in high-dimensional spaces. AutoSciLab autonomously follows the scientific method in four steps: (i) generating highdimensional experiments ($\mathbf{x} \in \mathbf{R}^{\mathbf{D}}$) using a variational autoencoder (ii) selecting optimal experiments by forming hypotheses using active learning (iii) distilling the experimental results to discover relevant low-dimensional latent variables ($\mathbf{z} \in \mathbf{R}^{\mathbf{d}}$, with $\mathbf{d} \ll \mathbf{D}$) with a 'directional autoencoder' and (iv) learning a human interpretable equation connecting the discovered latent variables with a quantity of interest $(y = f(\mathbf{z}))$, using a neural network equation learner. We validate the generalizability of AutoSciLab by rediscovering a) the principles of projectile motion and b) the phasetransitions within the spin-states of the Ising model (NPhard problem). Applying our framework to an open-ended nanophotonics challenge, AutoSciLab uncovers a fundamentally novel method for directing incoherent light emission that surpasses the current state-of-the-art (Iyer et al. 2023b, 2020).

Introduction

Scientific discoveries over the past centuries have been fueled in large parts by human intuition and ingenuity (Koyré 2013). The traditional scientific discovery process involves hypothesis generation, design of experiments to test hypotheses, and distillation of data into interpretable forms, such as equations. Scientists build upon these learnt equations, often extrapolating with their intuition to guide the next iteration of scientific discovery. However, a critical bottleneck in this scientific discovery process is the reliance on human intuition to generate a valid hypotheses, design experiments to test those hypotheses and interpret results in a large, high-dimensional design space. Within the physical sciences, the intuition bottleneck manifests as a lack of theoretical frameworks, requiring expensive experiments to traverse a high-dimensional space - i.e., 'Blindly looking for a needle in a hay-stack with an expensive rake'.

Machine learning (ML) methods have excelled at aiding researchers in identifying patterns and correlations within dense datasets. (Krizhevsky, Sutskever, and Hinton 2012: Vaswani et al. 2017), even in the physical sciences, (Jumper et al. 2021; Choudhary et al. 2022), demonstrating the ability to execute a few of the necessary steps leading up to interpretable scientific discovery, e.g., active learning (AL) for efficient design of experiments (Ling et al. 2017; Kusne et al. 2020), or deep neural networks to extract high-dimensional correlations in conducted experiments (DeCost et al. 2019: Feng, Zhou, and Dong 2019). However, a complete machine learning framework which realizes interpretable scientific discovery that can augment the human intuition remains an open challenge. Key impediments to the development of such a framework include the ability to design a large search space of candidate experiments significantly beyond current scientific understanding, efficiently discovering optimal candidates in this search space, and realizing interpretable results.

Here, we present a solution titled AutoSciLab, which is a self-driving laboratory that employs machine learning methods to drive automated experiments. AutoSciLab accomplishes the following tasks:

- (a) Drives autonomous scientific experiments by hypothesizing the next experiment from a generated space of experiments, without the aid of human intuition
- (b) Minimizes the number of scientific experiments required to gain insight into the physical process while accounting for stochastic experiments
- (c) Distills the experiments to discover an informative latent space complimenting any prior knowledge
- (d) Learns an equation relating the discovered latent space with the physical property of interest

Related Work

Self-driving labs where automated experiments are driven by ML algorithms have recently gained popularity in the physical sciences (Abolhasani and Kumacheva 2023; Seifrid et al. 2022; MacLeod et al. 2020). While significant effort has focused on automating the 'mechanical' tasks of a physical science experiment (robotic sample handling, automated

Copyright © 2025, Association for the Advancement of Artificial Intelligence (www.aaai.org). All rights reserved.

end-to-end multi-step experimental workflows) (Abolhasani and Kumacheva 2023), the 'cognitive' aspects (data analysis, designing optimal experiments) have largely explored optimization. Self-driving labs have so far not been used for interpretable scientific discovery, especially for understanding scientific principles in high-dimensional search spaces. We now breakdown each component of AutoSciLab, and compare it to prior work:

Generating novel experiments: AutoSciLab employs generative models to generate novel experiments beyond human intuition. Generative models such as Variational Autoencoders (VAEs) (Kingma and Welling 2013) and Generative Adversarial Networks (Goodfellow et al. 2020) have shown excellent promise in generating structures in the physical sciences (Kim et al. 2020; Anstine and Isayev 2023). However, these models have yet to gain popularity within self-driving labs to generate novel experiments.

Efficient design of experiments: Efficient design of experiments via Bayesian optimization or active learning, is a staple of current self-driving labs (Ling et al. 2017; Kusne et al. 2020). Other techniques such as differential evolution (Storn and Price 1997) are also widely used for design of experiments (Zhong et al. 2015; Kim et al. 2021). However, these tools are often used with the intention of optimization and discovery, and not with the goal of interpretable scientific understanding.

Interpreting experiments using machine learning: Explainable and interpretable machine learning techniques, such as physics-informed neural networks (Raissi, Perdikaris, and Karniadakis 2019), explainability metrics (Lundberg and Lee 2017), and equation learner models (Desai and Strachan 2021; Sahoo, Lampert, and Martius 2018; Schmidt and Lipson 2009) have shown great promise in the physical sciences. However, these models have not been used in conjunction with self-driving labs and autonomous experiments.

The AutoSciLab framework

AutoSciLab drives autonomous scientific experiments to discover an interpretable relationship between a physical quantity of interest $y \in \mathbb{R}^m$ and high-dimensional inputs $\mathbf{x} \in \mathbf{R}^{\mathbf{D}}$, see Fig. 1. AutoSciLab achieves this by recasting this problem as a discovery of an interpretable relationship between $y \in \mathbb{R}^m$ and low dimensional latent space variables $\mathbf{z} \in \mathbf{R}^{\mathbf{d}}$, with $d \ll D$. AutoSciLab then aims to learn $y = f(\mathbf{z})$ in a symbolic (equation) form. This recasting leverages the manifold hypothesis (Narayanan and Mitter 2010; Fefferman, Mitter, and Narayanan 2016), which states that high-dimensional data often resides in a lowdimensional manifold. The manifold hypotheses is often true in the physical sciences, where high-dimensional inputs often have specific, physics-driven mechanisms to affect a low-dimensional set of variables, which end up governing the quantity of interest y. To discover this relationship, AutoSciLab begins by reducing the high-dimensional inputs into a low-dimensional latent dimension $\mathbf{z}' \in \mathbf{R}^{\mathbf{d}}$ using a latent-space based generative model, such that sampling the latent dimension $\mathbf{z}' \in \mathbf{R}^{\mathbf{d}}$ generates novel experiments beyond the human intuition bottleneck that constraints experiment (hypothesis) generation. AutoSciLab then employs active learning to efficiently design experiments by creating hypotheses in the latent space $\mathbf{z}' \in \mathbf{R}^{\mathbf{d}}$, designing experiments that optimally find the relationship between \mathbf{z}' and y, i.e., finding $y = f(\mathbf{z}')$ by (for instance) maximizing $f(\mathbf{z}')$. Before this relationship can be distilled into an interpretable equation for scientific understanding, we need a mechanism to incorporate prior physical intuition into our relationship. AutoSciLab achieves this by transforming the low-dimensional latent variables \mathbf{z}' describing the inputs \mathbf{x} into the set of variables $\mathbf{z} \in \mathbf{R}^d$ controlling the physical process f. This transformation is achieved with a 'directional' autoencoder which is a conventional autoencoder with an additional regularization term that introduce correlations between $\mathbf{z} \in \mathbf{R}^{\mathbf{d}}$ and a set of physics-informed variables known to affect f. Finally, AutoSciLab learns the $y = f(\mathbf{z})$ in symbolic (equation form) using a neural network based equation learner that we developed. We now describe each aspect in detail.

Figure 1: AutoSciLab. Automated 'experiments' are driven by an AL agent sampling the latent space of a generative model (variational autoencoder, VAE) (yellow/purple bubble). 'Experiment' here can refer to a physical laboratory measurement, or a model/simulation of a process. The set of experiments run by the AL agent are distilled using a directional autoencoder to discover a relevant latent space of interest (green bubble). The symbolic relationship between the relevant latent space variables and the physical property of interest is learnt using a neural network equation learner that uses pruning based on connection strength.

Generating novel experimental candidates

We use a VAE to generate high-dimensional experiments $\mathbf{x} \in \mathbf{R}^{\mathbf{D}}$. Given a training set X of candidate experiments $\{\mathbf{x}_1, \mathbf{x}_2, ..., \mathbf{x}_n\}$, with $\mathbf{x}_i \in \mathbf{R}^{\mathbf{D}}$, we train a VAE to

maximize $p(\mathbf{X})$, the likelihood of generating experiments similar to, but also beyond those in the training set. The VAE consists of two pieces: an encoder that reduces the experiments into a latent dimension $\mathbf{z}' \in \mathbf{R}^d$, learning the probability distribution $Q(\mathbf{z}'|\mathbf{x})$, and a decoder that reconstructs the experiment, learning the probability distribution $P(\mathbf{x}|\mathbf{z}')$. Maximizing $p(\mathbf{X})$ is equivalent to minimizing the Evidence Lower Bound (ELBO) loss, \mathcal{L}_{vae} (Kingma and Welling 2013):

$$\mathcal{L}_{\text{vae}} = E_{\mathbf{z}' \sim Q}[\log P(\mathbf{x} | \mathbf{z}') - D_{\text{KL}}[Q(\mathbf{z}' | \mathbf{x}) || P(\mathbf{z}')]] \quad (1)$$

where the first term is a reconstruction error, and the second term is a KL divergence that measures the difference between the learned latent space distribution $Q(\mathbf{z}'|\mathbf{x})$, and a prior latent space distribution, assumed here to be Gaussian with zero mean unit covariance $P(\mathbf{z}') \sim \mathcal{N}(\mathbf{0}, \mathbf{I})$. Sampling the learnt latent space of the trained VAE allows us to generate experiments beyond the training set **X**. See **Appendix Section S2** for details on VAE architectures and training sets. We choose a VAE for generating candidate experiments due to their ability to learn a smooth, continuous latent space well-suited for optimization, leveraging the manifold hypothesis. Other generative models like GANs find it challenging to meet these requirements of the latent space.

Efficiently identifying promising experiments

While the VAE excels at generating experiments beyond those studied before, the generation process is not directly tied to the physical quantity of interest (y). To find experimental features most relevant to the underlying scientific phenomenon, we employ active learning, finding 'optimal' experiments in the latent in the latent space $\mathbf{z}' \in \mathbf{R}^{\mathbf{d}}$ spanning features of experimental inputs. The active learning task can be formulated as: $\max_{\mathbf{z}' \in \mathbf{Z}'} f(\mathbf{z}')$. We begin with an initial, small database of experiments Y_{init} , represented by latent space embeddings \mathbf{z}'_{init} , and their associated physical quantity of interest y. Using this initial dataset $Y_{init} =$ $\{(\mathbf{z'_1}, \mathbf{y_1}), (\mathbf{z'_2}, \mathbf{y_2}), ..., (\mathbf{z'_n}, \mathbf{y_n})\}, \text{ We can now train a Gaus-}$ sian process model to learn $\mathbf{y}(\mathbf{z}') = \mathcal{GP}(\mu(\mathbf{z}'), \mathbf{K}(\mathbf{z}', \mathbf{z}'')),$ where $\mu(\mathbf{z}')$ is a mean function and $K(\mathbf{z}', \mathbf{z}'')$ is a kernel representing the covariance in y between two experiments embedded as \mathbf{z}' and \mathbf{z}'' . The posterior distribution across every point in the latent space $\hat{\mathbf{z}}$ is now $y(\hat{\mathbf{z}}) = \mathcal{N}(\hat{\mu}(\hat{\mathbf{z}}), \hat{\sigma}(\hat{\mathbf{z}}))$, where (Rasmussen, Williams et al. 2006):

$$\hat{\mu}(\hat{\mathbf{z}}) = \mu(\hat{\mathbf{z}}) + \mathbf{K}(\hat{\mathbf{z}}, \mathbf{z}')\mathbf{K}(\mathbf{z}', \mathbf{z}')^{-1}(\mathbf{y}(\mathbf{z}') - \mu(\mathbf{z}')) \quad (2)$$

$$\hat{\sigma}(\hat{\mathbf{z}}) = \mathbf{K}(\hat{\mathbf{z}}, \hat{\mathbf{z}}) - \mathbf{K}(\hat{\mathbf{z}}, \mathbf{z}')\mathbf{K}(\mathbf{z}', \mathbf{z}')^{-1}\mathbf{K}(\mathbf{z}', \hat{\mathbf{z}})$$
(3)

Given a posterior distribution, an acquisition function $I(\mathbf{z}')$ can now hypothesize the next best experiment to conduct. Each experiment conducted by the active learning agent is a hypothesis on features of experiments that would result in optimal properties of interest, based on prior experiments. Since AutoSciLab focuses on scientific discovery, we are interested in not only identifying promising experiments, but also learning about the underlying physical phenomenon. Thus an acquisition function that balances exploration and exploitation, such as Expected Improvement (EI), should enable us to define the optimal relationship $y = f(\mathbf{z}')$. To establish a baseline, we compare EI to an upper confidence bound (UCB) acquisition function, where the hyperparameter λ of the acquisition function is tailored towards exploitation. The two acquisition functions can be written as:

$$\mathbf{I}_{\text{UCB}}(\mathbf{z}') = \mu(\mathbf{z}') + \lambda \sigma(\mathbf{z}') \tag{4}$$

$$I_{EI}(\mathbf{z}') = E_{\mathbf{z}'}(\max\{0, I(\mathbf{z}') - I(\mathbf{z}^*)\})$$
(5)

where z^* represents the current best value for the AF. The next best experiment, as identified by the acquisition function, can then be performed physically (in a laboratory, or using a model/simulation). This new data point (z'_{n+1}, y_{n+1}) can now be added to the dataset y_{init} and the process continues until an optimum is reached, or a set experimental budget is exhausted. See Appendix Section S3 for further details on active learning, and a differential evolution algorithm used as baseline for comparison.

Incorporating prior knowledge to discover a relevant low-dimensional latent space

Of the search space defined by the VAE latent space, only a fraction of points, such as those sampled by the active learning agent, contribute meaningfully to our understanding of the relationship between features of experimental inputs, and their observed physical properties. To learn this new latent space $\mathbf{z} \subset \mathbf{z}'$, we distill the results of experiments explored by active learning in the previous step. The set of high-dimensional experiments explored by the active learning are obtained by using the VAE's decoder $P(\mathbf{x}|\mathbf{z}')$ on the set of latent space points explored by the active learning. These high-dimensional experiments x are now encoded into a new latent space $\mathbf{z} \in \hat{\mathbf{R}}^{d}$, recognizing that for highest interpretability, we would like to encapsulate in the latent space any prior knowledge of correlations between experimental inputs (x) and quantities of interest (y). We learn the new latent space by training a 'directional' autoencoder, (Pati and Lerch 2019) (dAE), where some directions in latent space are explicitly designed to correlate with features of experiments known to physically affect the measured property. This correlation is enforced as a regularization in the distance between latent space variable (z_i) , and a physics-based attribute (a):

$$\mathcal{L}_{\text{dAE}} = ||\mathbf{x}_{\text{recon}} - \mathbf{x}_{\text{gt}}||_2^2 + \mathcal{L}_{\text{dist}}(D_z, D_a)$$
(6)

$$\mathcal{L}_{dist}(D_z, D_a) = ||\tanh(D_z) - \operatorname{sgn}(D_a)||_2^2$$
(7)

where the loss function of the directional autoencoder is a conventional reconstruction loss, and an additional regularization term L_{dist} , defined from prior work (Pati and Lerch 2019), with $D_z(i, j) = \mathbf{z_i} - \mathbf{z_j}$ and $D_a(i, j) = a_i - a_j$. See Appendix Section S4 for more details. Correlations between the latent space learnt by the 'directional' autoencoder, and physical quantities deemed relevant by subject matter experts provide us insight into the learnt latent space variables.

Learning correlations as equations

Given a subset of latent space variables z relevant to predicting the physical quantity of interest y, we now develop a neural network based equation learner (**nn-EQL**) that learns the correlation between z and y, using a dataset $Y = \{(z_1, y_1), (z_2, y_2), ..., (z_n, y_n)\}$. Our equation learner is a customized neural network where each neuron in a layer has a specific activation function inspired by functional forms seen in the physical sciences (e.g., $sin, x^2, x_i x_j$) (Desai and Strachan 2021; Sahoo, Lampert, and Martius 2018). The equation learning process consists of three stages: (i) Perform a preliminary fit to the dataset Y to determine a baseline acceptable error, (ii) Systematically remove a fraction p of neurons in each layer based on their contribution to neuron activations in the next layer, followed by re-training until the baseline acceptable error, or similar, is reached, and (iii) Equation readout of the pruned network, where the connectivity in the final sparse network with limited weights and activation functions is expressed as an equation. Note that our pruning scheme is based on connection strength, while conventional pruning schemes using weightbased pruning (LeCun, Denker, and Solla 1989; Han et al. 2015; Sahoo, Lampert, and Martius 2018). This is due to our use of complex, non-monotonic, activation functions, where small weight values can be transformed into large activation values (e.g. cos(x)). Thus, instead of pruning the smallest weights in each layer, we prune the 'smallest contributing' connection in each layer, defining a connection ij's contribution as $W_{ij}x_i$, where W_{ij} is the weight connecting neuron *i* to a neuron *j* in the next layer, and x_i is neuron *i*'s value. See Appendix Section S5 for more training details.

Benchmarking components in AutoSciLab

Each component of AutoSciLab is benchmarked on simple tasks to demonstrate their applicability to scientific domains. The design of experiments using active learning is benchmarked on a simple one-dimensional search in one of our exemplars, showing that we can rediscover a known result (see Appendix Section S3). The neural network equation learner is bench marked on equations found in symbolic regression benchmarks (La Cava et al. 2021; Udrescu and Tegmark 2020). We find that our model accurately discovers each of these equations (Table 1), showing our ability to discover terms in equations commonly seen in physical systems. The generative model (VAE) uses conventional architectures, and we thus choose to quantify VAE generative capabilities individually for each application. As demonstrated in each exemplar, the VAE has clear capabilities to reconstruct experiments from the training set, as well as go beyond the training set and suggest novel experiments.

Table 1: Benchmarking the nn-EQL

Data set	True/Discovered equation
Lotka-Volterra interspecies dynamics	$\begin{vmatrix} \dot{x} = 3x - 2xy - x^2 \\ \dot{x} = 3.063x - 2.02xy - x^2 - 0.16 \end{vmatrix}$
Van der Pol Oscillator	$\begin{vmatrix} \dot{x} = 10(y - \frac{1}{3}(x^3 - x)) \\ \dot{x} = 10y - 3.153x^3 + 3.249x \end{vmatrix}$
Magnetic moment of an electron in an orbit	$ \begin{array}{l} \mu = qvr \\ \mu = qvr \end{array} $

Exemplars, experiments, and results

We demonstrate the capabilities of AutoSciLab on three exemplar problems with varying difficulties (a) Projectile motion (b) Two-dimensional Ising spin system (c) An open ended nanophotonics problem. The first two problems have known solutions, validating the AutoSciLab framework while demonstrating the generalizability and range of problems that can be handled by the self-driving lab framework.

Exemplar 1: Projectile motion

Problem description: Projectile motion describes the motion of a particle launched with an initial velocity at a specific angle, following Newtonian mechanics. The problem can be described as the evolution of the height y of the particle, as a function of time t, given an initial velocity u, and angle θ . That is, $y = f(t; u, \theta)$. Each such projectile is defined by a maximum height $H(u) = \frac{u^2}{2g}$, where $g = 9.8 \frac{m}{s^2}$. **Objective**: Demonstrate that AutoSciLab can re-discover

Objective: Demonstrate that AutoSciLab can re-discover the relationship between the maximum height (H) of a projectile on the initial velocity (u).

AutoSciLab framing of task: In the AutoSciLab framework, we use the VAE to generate a variety of trajectories y = f(t). We develop a training set consisting of quadratic, cubic, and quintic trajectories, taking the general form $y = \alpha t^2 + \beta t^3 + \gamma t^5$. The trained VAE thus generates a wide variety of realistic and unrealistic trajectories y(t), from which the active learning agent now has to select realistic projectile trajectories. Here we utilize the fact that realistic trajectories must have a constant acceleration g, defining the active learning objective to be to minimize the difference between the second derivative of a candidate trajectory y(t) and q. From the set of trajectories selected by the active learning, we can now use AutoSciLab's directional autoencoder learn a new latent space which correlates strongly with the initial velocity u, incorporating prior physical knowledge that H depends on u. Finally, we can use AutoSciLab's equation learner network to learn H(u) in the form of a human-readable equation.

Result: We demonstrate that AutoSciLab accurately rediscovers the equation describing the maximum height attained by the projectile as a function of initial velocity, see Fig. 2. The VAE used in the AutoSciLab framework is able to generate trajectories that resemble projectile motion and pseudo-projectiles (where the acceleration is not constant), see Fig. 2(a). Using this trained VAE, active learning successfully identifies regions in latent space that represent trajectories with constant acceleration $\sim 10 \frac{m}{s^2}$, i.e., realistic trajectories, see Fig. 2(b), with colored dots showing the region in latent space identified by active learning. AutoSciLab's directional autoencoder can now distill the trajectories explored by the active learning into a new latent space with one variable that correlates strongly with the initial velocity u, see Fig. 2(c), capturing prior knowledge that H depends on *u*. Finally, AutoSciLab's **nn-EQL** learns an interpretable equation relating height of the projectile (H) and latent variable z. The learnt relationship H(z) can be accurately translated to the known relationship $H(u) = \frac{u^2}{2a}$.

Figure 2: **Rediscovering projectile motion**. (a) Projectile height y as a function of time t. (b) Active learning efficiently finds points with acceleration $\sim 10 \text{ m/s}^2$. (c) Correlation between initial velocity u and latent space variable z learnt by the directional autoencoder, for trajectories identified by the active learning to have a constant acceleration g. (d) Maximum height (H) vs z, learnt equation overlaid.

Exemplar 2: Spin dynamics of the two-dimensional Ising system

Problem description: As a complex benchmarking problem for AutoSciLab, we choose to re-discover the spin-dynamics of the Ising system as function of temperature. The Ising system consists of discrete variables called spins, which can be in one of two states (+1 or -1) arranged on a two dimensional lattice where each spin interacts with its neighbors. The Ising system is often used as an exemplar for a system that can be defined using simple physical principles, but exhibits complex emergent properties such as an effective magnetization, and a phase transitions (Onsager 1944). Determining the ground state of the Ising model, particularly when considering additional complexities such as external magnetic fields or disordered interactions (as in spin glass models), is known to be an NP-hard problem (Barahona 1982). By addressing this computationally challenging problem, we demonstrate the effectiveness of the AutoSciLab framework in tackling high-dimensional NP-hard scientific discovery tasks.

Objective: Our objective is to re-discover the relationship between the equilibrium average spin state (magnetization M) and the temperature T, known to be $M(\beta) = (1 - sinh(2\beta J)^{-4}))^{1/8}$ (Onsager 1944), where $\beta = \frac{1}{kT}$ is the inverse temperature, k is the Boltzmann constant, and J is the strength of interactions between spins. We assume k and J to be equal to 1 without loss of generality.

AutoSciLab framing of task: The equilibrium properties of the Ising system are obtained in practice using time-consuming Monte Carlo simulations that generate samples from a known equilibrium distribution of spins states $p(E) \propto \exp(\frac{-E}{kT})$, where E is the energy associated with a spin state. We generate arbitrary spin states by initializing a random set of binary spins, defining an average magnetization M_{init} , at a defined temperature T (equivalently β). Starting from sub-optimal random spin states with M_{init} significantly different from M will require long Monte Carlo simulations to reach an equilibrium set of states. We thus utilize the AL component of AutoSciLab to discover optimal spin states M_{init} that minimize the time to reach equilibrium t_{sol} when employing Monte Carlo simulations. Once optimal spin states are learnt, we can run a short Monte Carlo simulation to sample from the equilibrium distribution p(E), quickly computing equilibrium magnetization M. The neural network equation learner component of AutoSciLab can then learn the relationship between M and T.

Results: We find that AutoSciLab re-discovers the relationship between equilibrium magnetization M and temperature T, see Fig. 3(a). We first find that AL efficiently finds optimal initial spin states M_{init} such that the time to reach equilibrium using standard Monte Carlo approaches (t_{sol}) is minimized, see Fig. 3(b). Note that by defining spin states in terms of magnetization M_{init} , we remove the need for a generative model to generate random spin states (simple random number generators can generate spin states), as well as the need for a directional autoencoder that encodes the known physical insight that the most relevant quantity that describes spin states and their properties is the average spin state, i.e., the magnetization M. We thus skip directly to the equation learner, demonstrating that we can learn the relationship between M and T, see Fig. 3(c). To achieve this, we run short Monte Carlo simulations starting from the optimal spin state learnt by the AL agent (M_{init}) . We find that we can achieve equilibrium states using an order-of-magnitude fewer number of Monte Carlo steps compared to an arbitrarily random initialization (i.e., $t_{sol}^{AL} \ll t_{sol}^{random}$). The magnetization M achieved after the short Monte Carlo simulation, and the temperature T are collected in a dataset $Y = (M_1, T_1), (M_2, T_2)...(M_n, T_n).$ For ease of training the nn-EQL, we transform the dataset to be $Y' = (y_1, \beta_1), (y_2, \beta_2) \dots (y_n, \beta_n)$, where $\beta = \frac{1}{kT}$ and $y_i = (\frac{1}{1-M^8})^{1/4}$. The equation to be learnt is thus $y = sinh(2\beta)$, and we find that our neural network equation learner finds $y = 1.01sinh(1.96\beta) + 0.1\beta - 0.1$, which is close to the ground truth.

Exemplar 3: Open-ended nanophotonics problem

Problem description: As an open-ended, real-world application, we employ AutoSciLab to realize high-efficiency steering of incoherent emission. The light emission from thermal lamps (incandescent bulbs, light emitting diodes (LEDs), black-body radiation, etc. are characterized as incoherent since their wavefront of emission remains random in both space and time (Pichler, Daley, and Zoller 2010). This random wavefront prevents traditional phased-array optical elements (McManamon et al. 1996), used conventionally for lasers (and other coherent sources), to be used to redirect incoherent light. Dynamic semiconductor (GaAs) metasurfaces made up of a sub-wavelength array of tunable optical

Figure 3: **Rediscovering the spin-dynamics of the Ising spin system.** a) Spin-state (s) represented on a grid showing the effects of increasing the temperature. b) Active learning at a fixed temperature ($T \propto (\beta J)^{-1}$) c) M vs T, showing overlap between the true equation (black) and the learnt equation (red) from the active learning results (blue).

resonators have provided a route to steer incoherent light by embedding the light emitters within the resonators based on the pump pattern projected onto the metasurface. Previous results have demonstrated that the spatial (x) intensity gradients $(b \sim \frac{\partial \mathbf{x}}{\partial x})$ of the pump enable us to steer the light emission from the metasurface through momentum matching principles $(k_m = \frac{\partial \phi}{\partial x} \propto \frac{\partial \mathbf{x}}{\partial x})$ (Iyer et al. 2023b). However designing the optical pump pattern to re-direct the light into a desired direction, i.e., the inverse problem, remains a challenge. In other words, an open challenge is to maximize the directivity of emission $D_e = \frac{f(\theta_i; \mathbf{x})}{\sum_j f(\theta_j; \mathbf{x})}$, where $f(\theta_i; \mathbf{x})$ is the emission towards an angle θ_i , given pump pattern \mathbf{x} .

Objective: Our objective is to discover the dependence of directivity D_e on features of pump patterns imposed on metasurfaces to efficiently steer incoherent emission.

AutoSciLab framing of task: In the AutoSciLab framework, the VAE generates arbitrary pump patterns x given a training set X of pump patterns $\{x_1, x_2, ..., x_n\}$, with $x_i \in \mathbb{R}^D$. The active learning agent searches the latent space of the VAE to maximize directivity, formulated as: $\max_{\mathbf{z}'\in\mathbf{Z}'} f(\mathbf{z}')$. Appendix Section S3 shows proof of concept results for AL on noisy experimental data. We inspect the pump patterns generated by the VAE and the active learning, which have high directivity, and encode them into a new latent space $\mathbf{z}' \in \mathbb{R}^d$, using the directional autoencoder piece of AutoSciLab. Specifically, we encode prior physical knowledge: the local slope of the pump pattern $b = \frac{\partial \mathbf{x}}{\partial x}$ and the local curvature of the pump pattern $a = \frac{\partial^2 \mathbf{x}}{\partial x^2}$ that affect directivity. Finally, we learn an interpretable relationship between features of pump patterns \mathbf{z} and their associated directivity D_e, using AutoSciLab's equation learner.

Results: We demonstrate that AutoSciLab can successfully tackle the open-ended nanophotonics problem of steering incoherent emission resulting in a discovery of a novel

Figure 4: **Discovering novel relationships in the nanophotonics domain**. (a) Generative capacity of the VAE, quantified as the normalized distribution (log scale) of the local slope (b) in pump patterns. (b) Directivity as a function of experimental iteration. (d) Correlating the latent space with Directivity, incorporating prior knowledge.

principle relating pump pattern features to directivity in an equation, see Fig. 4. Fig. 4(a) quantifies the ability of our VAE to generate pump patterns beyond those studied so far, an aspect critical to defining the search space over which we understand the phenomenon of incoherent emission steering. Fig. 4(a), demonstrates the generative capability of the VAE, where the variety (quantified as the local slope distribution) of the pump patterns is larger than the state of the art and human intuition based training set of the VAE by at least two orders of magnitude (Iyer et al. 2023a). A wide variation in local slopes indicates numerous changes in the pump pattern, going significantly beyond previous the state-of-theart, and proposing pump patterns that could potentially yield a directivity never seen before. See Appendix Section S2 for examples of pump patterns generated by the VAE, and their translation to patterns imposed on the physical metasurface. We then find that AL, searching over the latent space of the VAE, discovers pump patterns with directivity values that are 3-4x higher than in the training set, across multiple emission angles, see Fig. 4(b). Note that ground-truth data here is obtained by evaluating a neural network surrogate model, but the AL scheme is also able to identifying promising pump patterns when obtaining ground-truth data directly from the noisy experiment, see Appendix Section S3. Here we focus on the noiseless surrogate model as it allows us to compare multiple acquisition functions, as well as multiple downstream algorithms in a principled manner, focusing on the generalizability of our framework rather than focusing on physics of the experimental noise. We demonstrate that AL (with EI and UCB acquisition functions) reduces the required number of experiments by an order of magnitude (see 4(b)) to discover the pump patterns with high directivity when compared to differential evolution (Storn and Price 1997). Fig. 4(b) demonstrates that AL has the capability to efficiently hypothesize the next experiment - with only a limited training set - maximizing the physical property with minimal experiments in a self-driving lab framework. See **Appendix Section S3** for more AL results.

We analyze the experiments selected by the EI AF to guide our understanding of the physical process to learn interpretable relationships between features in the pump pattern (input) and directivity of emission (output). To learn these interpretable relationships, we convert the set of latent space points z explored by the AL into a 'relevant' set of pump patterns x'. These high dimensional pump patterns are condensed into a new, low-dimensional latent space zsuch that dimension z_1 correlates with the local slope b, see Fig. 4(c). **Appendix Section S4** documents repeatability and generality of AutoSciLab for other emission angles.

We formalize the insights described so far in Fig. 4 as an equation governing incoherent light emission from a metasurface. Using our nn-EQL, we learn an interpretable equation between latent space variables z and directivity D_e.

$$D_{e} = 0.0467z_{1}^{2} - 0.0265z_{2}^{2} - 0.175z_{1} - 0.0955z_{1}z_{2} + 0.22z_{2} + 2.707$$
(8)

where z_1 and z_2 are the first two variables in the learned 'relevant' latent space z. (See Appendix for additional analysis describing the physical implications of the equation to the process of emission). This structure-property relationship discovered here goes beyond our current understanding of steering incoherent light, based on Fourier transforms.

Impact of AutoSciLab

The goal of AutoSciLab is to achieve interpretable scientific discovery in high-dimensional spaces. Ideally, AutoSciLab would (a) reduce the number of experiments needed for a scientific discovery (b) Propose a wider, more varied set of experiments than human intuition (c) Select and conduct experiments with valuable information needed for scientific discovery. Table 2 documents estimates of each aspect mentioned above, for multiple exemplars. The metrics in Table

Problem Design Space		Method	Experiments		Gain Factor	
			Number	Variety	Value	
Projectile	2	Human	10	0.65	1	0.97
Motion		Auto	500	36	0.88	
Ising Model	1024	Human	10	1	1	100
		Auto	10	1	100	
Photonics	8×10^{6}	Human	1M	0.1	1	2×10^{6}
		Auto	1000	100	2	

Table 2: Quantifying the gains from using AutoSciLab

2 quantify the number of experiments, the 'variety' of experiments proposed (in terms of the bounds of the design space), and the 'value' of experiments as the average 'performance' (time to solution, directivity etc.) of the set of experiments conducted. We expect AutoSciLab to increase $\frac{N_{human}}{N_{auto}}$ (by lowering N_{auto}), increase $\frac{Variety_{auto}}{Variety_{human}}$, and increase $\frac{Value_{auto}}{Value_{auto}}$. The 'Gain Factor' is a product of these three terms, Value_{human} with higher values being better. For more details on these calculations, please refer to Appendix Section S6. We find the gain factor from using AutoSciLab to be significantly large in problems with large design spaces, or problems with unknown underlying physics that require a large number of experiments with limited intuition. For small design spaces, AutoSciLab performs similarly to human intuition, which is expected. Additionally, AutoSciLab, as a scientific discovery framework, attains 'level 4 autonomy' in the six levels of autonomy for scientific discovery described in (Kramer et al. 2023), positioning our work as a groundbreaking effort to address this currently unmet challenge. AutoSciLab also integrates multiple aspects of scientific discovery as defined in recent work (Langley 2024). Specifically, AutoSciLab supports 'Inducing Numeric Laws' via the nn-EOL, 'Experimentation and Observation' with the active learning and the generative model (VAE), as well as 'Measuring and Identifying Variables' with the directional autoencoder. AutoSciLab's applicability to material science, as demonstrated with the open-ended nanophotonics exemplar also addresses the need for autonomous scientific discovery in this field, as identified by the above work.

Limitations of AutoSciLab

While the AutoSciLab framework is developed to be an autonomous research agent performing experiments in the lab, this initial demonstration is informed and constrained by human researchers in a few ways. The ML framework expects automated experiments, which can limit the type of experiments that can be handled by this framework. Furthermore, the variety of experiments generated by the VAE depends on the training set, which is currently defined by human intuition. The directional autoencoder is designed to incorporate prior subject knowledge in the latent space, and currently assumes that this prior knowledge is accurate, which may not be true for cutting edge research. Lastly, the equation learner is initialized with a dictionary of activation functions provided by the researcher, again assuming this set of functions to be valid. The requirements and inclusion of prior knowledge into the AutoSciLab framework can bias the explorative directions of the experiments, while also acting as guardrails to limit experiments with bounded outcomes.

Conclusion

We demonstrate a self-driving lab framework capable of interpretable scientific discoveries over a wide range of scientific phenomena. We leverage an AL agent, searching over the low-dimensional latent space of a generative model (VAE), to efficiently discover optimal experiments, across multiple domains such as projectile motion, the Ising spin system, and an open ended nanophotonics problem. The sampled experiments were distilled using a directional autoencoder to discover the relevant latent variables as a subspace of the VAE latent space, while encoding human intuition based variables in the latent space. Correlations discovered between latent space variables and human-intuition based variables are formalized as human-interpretable physical relationships, using neural-network equation learners. AutoSciLab successfully re-discovers known physics in the projectile motion and the Ising spin system problem, and discovers novel steering principles in the nanophotonics problem, discovering a new method to steer incoherent light emission from metasurfaces. We also demonstrate that as the dimensionality of the design space increases, the gain in experimental cost enabled by AutoSciLab also scales. We envision this scientific discovery from AutoSciLab to form a novel pathway to realize clean energy sources (LEDs and thermal lamps), with the potential for use in applications such as AR/VR and holographic displays. From the perspective of scientific discovery, we have developed an ML framework to hypothesize and generate candidate experiments, efficiently search the experimental design space, discover the relevant latent variables while encoding prior knowledge, and finally, condense experimental knowledge in the form a human readable equation. These steps capture the scientific method, and we envision that AutoSciLab can be generalized to most physical science domains with expensive and noisy experiments, to learn physical relationships as interpretable equations.

Appendix

S1: Ultra-fast optical dual pump experiment and semiconductor metasurface properties

We steer incoherent light from a reconfigurable semiconductor (GaAs) metasurface under structured optical pumping, see Fig. 5. We design the metasurface resonance to achieve reconfigurable phase response in reflection under free-carrier excitation (with optical pumping). Additionally, the metasurface resonances are aligned to the embedded InAs quantum dot emitters ($\lambda_e = 1280$ nm) such that the photoluminescence (PL) peak and the reflection peak are spectrally overlapping. The metasurfaces where designed such that under the influence of the optical pump induced refractive index change, the phase (ϕ) of the light in reflection under goes a $0 - 2\pi$ phase shift with minimal change in the amplitude. Prior work demonstrates that this design criteria constructed for coherent reflection translates into momentum change for the light emission under spatially structured optical pumping. The GaAs metasurfaces were grown with a reflective distributed Bragg grating consisting of 15 pairs of Al_{0.3}Ga_{0.7}As and AlAs layers with $\frac{\lambda_e}{4n}$ thicknesses, where *n* is the refractive index of each of the layer (3.2 and 2.94 respectively) at the emission wavelength (Mendoza-Alvarez, Yan, and Coldren 1987). The InAs quantum dots (QDs) where also epitaxially grown within the top GaAs layer as dot in a well (DWELL) configuration (Liu et al. 2000). The metasurfaces where fabricated using traditional nano-fabrication techniques which included:

- (a) Electron beam lithography to define the metasurface resonator shape (width = 280nm) and periodicity (400mn).
- (b) Deposition and lifted-off an Al_2O_3 hard mask of 25nm.
- (c) Dry etching 675nm of the top GaAs layer using a Cl_2 gas etch chemistry.
- (d) Verifying the fabrication process using scanning electron microscope images, as shown in **Fig. 5**.

Figure 5: **Nanophotonics experimental setup:** a) The ultrafast two-color pump-photoluminescence steering setup b) scanning electron microscope image of the nano-fabricated metasurface c) The reflection (blue) and photoluminescence (orange) spectra measured for the fabricated metasurface.

The ultrafast optical pump at 800nm, made up of 80fs pulses repeating at 1KHz (Coherent Astrella Laser system with TOPAS OPA), is reflected off a spatial light modulator (SLM) and the intensity profile from the image loaded on the SLM is projected onto the reconfigurable metasurface. The 800nm pump optical excites free carriers in the resonator and the quantum dots resulting in incoherent emission and refractive index change. A second, 950nm wavelength probe pulse (80fs pulse width and 1KHz repetition rate), is generated by passing part of the 800nm pulse through an optical parametric amplifier (OPA) to generate an idler beam at 1900nm and subsequently frequency doubled using a BBOcrystal. The 950nm probe pulse is used to only pump the QDs in the metasurface and estimate the temporal evolution of the PL and it does not create an spatial refractive index profile on the metasurface. The light emission from the metasurface is imaged in the back-focal-plane (momentum or angular emission space of the emitter) using a single pixel (InGaAs detector) using lock-in amplifier setup. We measure the modulation signal at the sum frequency of the modulation of both 800nm and 950nm beam which modulated using a single chopper (5/7 relatively prime modulation) at 2 frequencies. This is a classic ultrafast measurement technique to reduce the noise in the steering measurements. We use a series of dichroic, short and long pass filters to ensure that we are only collecting the PL signal from the metasurface. For each image projected on the sample, the PL directivity is measured by scanning the detector in the back-focal-plane.

S2: VAE training details

We use Pytorch (Paszke et al. 2019) to train every VAE.

Architectures: For the nanophotonics exemplar, the VAE consists of encoder and decoder networks with 9 feedforward (linear) layers each. Each layer in the encoder halves the size of the input, i.e., the first layer halves the input from 3840 units to 1920 units, the second layer halves the input from 1920 units to 960 units etc. The decoder mirrors this architecture, and both the encoder and the decoder use leaky ReLU activation functions, except the last linear layer to the latent dimension, which uses a linear activation, and the last layer of the decoder, which uses a ReLU activation function since pump patterns and projectile trajectories always has a positive intensity. The projectile motion exemplar uses encoder and decoder networks with three one-dimensional convolutional layers, and one feedforward layer. Going forward, we plan to optimize the architectures of our VAEs, with the goal of making lightweight models with fewer parameters.

Training sets: In the nanophotonics exemplar, the training set for the VAE consists of the set of sawtooth pump patterns explored previously (Iyer et al. 2023b), as well as a set of aperiodic pump patterns defined as a collection of one-dimensional curves:

$$y = ax^2 + bx + c\sqrt{x} \tag{9}$$

where y is the intensity of the pump pattern, and we sweep over $a \in [-800, 800]$, $b \in [-400, 400]$, $c \in [-200, 200]$, generating 50000 pump patterns as the training set. **Fig. 6** shows example curves generated by the VAE. Note that the y-axis is arbitrarily large, but when these patterns are imposed on the metasurface via a spatial light modulator, we wrap these patterns as follows: $y' = (y\%2\pi)/2\pi$, resulting in patterns with multiple frequencies. These patterns can be understood by domain experts as combination of sawtooth (or grating order) based patterns, lens-like patterns, and beyond (higher frequency components).

Figure 6: **Example VAE outputs.** Top panel shows raw VAE output, and the bottom panel shows the pattern imposed on the physical metasurface, using the transform $y' = (y\%2\pi)/2\pi$.

In the case of the projectile motion exemplar, the dataset consists of trajectories of the form $y(t) = usin(\theta)t - 0.5gt^2$, representing realistic projectile trajectories, as well as 'unrealistic' or 'pseudo' projectile trajectories, of the form $y(t) = usin(\theta)t - 0.5gt^2 + \beta t^3 + \gamma t^5$. The value *u* ranges from [1-6], and θ ranges from [30-60], with β and γ taking values of +2, and \pm 1. Overall, the training set here consists of 2700 trajectories.

S3: Active learning details and benchmarking

We use the Ax adaptive experimentation platform (Bakshy et al. 2018) to develop the active learning protocol, using 200 initial data points D_{init} in the nanophotonics exemplar, and 100, 50 initial data points in the projectile motion and the Ising model exemplars. These data points were sampled using a Sobol initialization (Sobol' 1967) in the latent space learnt by the VAE. For each active learning run, over both the Expected Improvement (EI), and the Upper Confidence Bound (UCB) AFs, we use a fixed noise Gaussian process model (setting the noise to zero, since our 'experiments' are defined to be noiseless), using a Matern 5/2 kernel. We define the experimental budget to be 1000 experiments in the nanophotonics exemplar, i.e., 1000 evaluations of a neural network surrogate model built to relate the four latent dimensions of the trained VAE to the directivity. In the other exemplars, we define experimental budgets as 500 and 50, for projectile motion and the Ising model exemplars respectively.

Neural network surrogate model. We build a neural network surrogate model that relates features in the pump pattern to directivity, again using Pytorch. This is the only exemplar that uses a neural network surrogate model, with other exemplars using physics-based simulations to conduct an 'experiment'. We build this model to eliminate experimental noise from our exploration of machine learning methods AutoSciLab; although initial results in Fig. 8 document the ability of our active learning scheme to discover pump patterns with experimental noise, across multiple emission angles. The dataset used to train the neural network surrogate model was obtained by brute force sampling of the latent space in each dimension from [-3,3], resulting in \sim 8000 points for each emission angle. We define this neural network as a five-layer feedforward network, with each layer consisting of a 100 neurons, and using the ReLU activation

function. We build and train separate networks (with identical architectures) for emission angle, carving the dataset into an 80-10-10 split for the train-validation-test sets respectively. We use the Adam optimizer (Kingma and Ba 2014), with a learning rate of 0.001.

Benchmarking our active learning scheme. To benchmark our active learning scheme, we attempt to re-discover a known result, i.e., discovering the optimal periodicity of a sawtooth pattern such that raw signal intensity is maximized. This reflects prior work which explored multiple sawtooth patterns with varying frequencies (grating orders) (Iyer et al. 2023b). We find that the active learning finds the optimal pump pattern grating order in ~5 experiments after an initial training set of 10 grating orders, see **Fig. 7**. This is a fraction (~ 10%) of the number of experiments required to brute force through all 160 possible grating orders, indicating the significant savings in experimental cost obtained even in a simple one-dimensional optimization.

Figure 7: Active learning in a one-dimensional setting. We find active learning to re-create a known result, (finding optimal periodicity in sawtooth patterns), in a fraction of the experiments compared to brute force exploration.

Active learning with real-time noise. While the results in the main text employ AL on a neural network surrogate model (in the nanophotonics exemplar), we show initial results that AL can handle experimental noise, i.e., find optimal pump patterns when obtaining ground-truth data directly from the experiment in a closed-loop fashion. Fig. 8 shows that across two emission angles, active learning is able to find pump patterns with high directivity, albeit the results are noisy.

For the AL experiments reported in the 'Exemplars, Experiments, and Results' section of the main text, we establish a comparison with differential evolution (Storn and Price 1997) as a baseline. For this, we use the Scipy differential evolution optimizer, using a population size of 100 and setting an experimental budget of 10000 experiments, again defined as 10000 evaluations of the neural network. The initial dataset for differential evolution was obtained with Latin Hypercube sampling. Note that we did not perform a full hyperparameter optimization, which could affect our comparisons, but we believe that the ability of active learning to predict directivities across the latent space, with noise, makes this the superior method when considering noisy experiments, as is often the case in the physical sciences.

Distribution of experiments with different activation functions. Figure 4 in the main text compares different AFs

Figure 8: Active learning using closed-loop experiments as ground truth data. Blue dots refer to the initial training dataset for the Gaussian process model, black indicates points explored by EI. Red bars indicate experimental noise, measured as an average (and std. dev.) of multiple repeats.

and the pump patterns explored by them. **Fig. 9** expands on this, illustrating the different distributions in directivities obtained when using EI and UCB. We find that the distribution of directivities with UCB is long-tailed, sampling mostly high directivity values with few low-directivity patterns. EI on the other hand explores a wider distribution of directivity values, and hence, pump patterns, owing to the balance between exploration and exploitation.

Figure 9: **Distribution of Experiments performed using the AL algorithm.** EI (a) and UCB (b). EI has sampled significantly broader region of the VAE's latent space than UCB.

Fig. 10 shows active learning results at multiple emission angles, again documenting the performance UCB, EI, and differential evolution as a baseline.

S4: Directional autoencoder

We train a 'directional' autoencoder to distill the subspace of the VAE latent space explored by the AL agent, see section 'Exemplars, Experiments, and Results' in the main text. We define this network as an encoder and a decoder network, with both networks using one-dimensional convolu-

Figure 10: **Comparison between optimization algorithms.** Active learning results across multiple emission angles in the nanophotonics exemplar.

tional layers. For the nanophotonics exemplar, the convolutional layers have channels progressively increasing as 1-8-16-32, a kernel width of 20, and stride of 5. A linear layer is used at the end of the one-dimensional convolutional layers, compressing the 864 dimensional pattern to four latent dimensions. ReLU activations are used throughout, except the linear layer, which uses no activation function. The decoder mirrors this architecture.

The dataset for network of this consists the pump patterns explored by EI AF, D = $\{(\mathbf{x}'_1, \mathbf{D}_{e_1}), (\mathbf{x}'_2, \mathbf{D}_{e_2}), ..., (\mathbf{x}'_n, \mathbf{D}_{e_n})\}, \text{ where } \mathbf{x}'_i \text{ is the }$ pump pattern obtained by decoding \mathbf{z}'_i using the trained VAE's decoder. For patterns decoded by the VAE with features consisting of extremely high frequency regions that are beyond instrument resolution, we use the Savitzky-Golay filter to smooth out these frequencies. We train a separate directional autoencoder for each emission angle (with the same architecture) for 2000 epochs, determining that the network has not over fitted the dataset. The Spearman

correlation coefficients shown in Fig. 4(c) of the main text confirm that the distance based regularization added in the directional autoencoder training resulted in a strong positive correlation between z_1 and b. Additionally, there is no correlation among individual z_i 's, as desired. Also shown are correlations of z_i with other physics-informed variables, such as local change in slope (curvature) of the pump pattern $a = \frac{\partial^2 \mathbf{x}}{\partial x^2}$, average pump pattern amplitude $A = \sum_{i=1}^{D} x_{i}$, where D is the dimension of the pump pattern, and ω , the highest frequency observed in the pump pattern, obtained by computing a Fourier transform of the pattern. These other correlations indicate that variables z_1 and z_2 most strongly correlate with directivity D, as does the pump pattern frequency ω , while latent space variables z_3 and z_4 correlate with amplitude A. This analysis helps provide intuition to the learnt latent space variables, in terms of physically relevant quantities. While Fig. 4(c) in the main text shows Spearman correlations for only emission angle, Fig. 11 shows Spearman correlations across two other emission angles, illustrating the general ability of the directional autoencoder to correlate latent space variables with physics-based quantities of interest. Also shown in Fig. 11 is the Spearman correlation when using a traditional autoencoder. We find a weaker correlation between latent space variables and physical quantities of interest, increasing the difficulty in interpreting the latent space. Furthermore, the latent space variables show correlations amongst themselves, further limiting interpretability.

S5: Details on the equation learner network

Our neural network equation model is trained in three stages, as outlined in the main manuscript, subsection 'Learning correlations as equations' of the section 'The AutoSciLab Framework'. In the first stage, we train a traditional feed-forward neural network with commonly used activation functions such as ReLU, with the goal of establishing a baseline error metric. In this work, we use a small feed-forward neural network with two layers, having 5-20 neurons each (depending on the exemplar), and ReLU activation functions. The dataset for this network, and the subsequent equation learner network is the 'relevant' latent space learnt by the directional autoencoder, and their associated directivity values. However, this dataset may by unbalanced

depending on the balance between exploration and exploitation during the active learning. Thus, as a pre-processing step, we manually balance the dataset, oversampling (repeating) high value (projectile height, directivity etc.) data points, and filtering out outlier low value (projectile height, directivity) data points. In the nanophotonics exemplar, this pre-processing step increases the number of data points from the initial 1200 points to ~ 1500 points.

In the second stage, we define our equation learner network as a network with two layers, each consisting of 4-40 neurons, with the network size being a hyper-parameter. The activation functions are defined for each neuron, typical choices being sin, x^2 , $x_i x_j$. This initial choice of activation functions is also a hyper-parameter, since the equation learner will combine these functional forms to learn the final equation. Subject-matter expertise plays a hand here. For instance, if the dataset has periodic variations, one might expect a *sin* function to play a key role in the final equation. In this work, we experiment manually with a few different choices for the initial activation function set, choosing the activation set (manually) that results in the most accurate and parsimonious final equation. Future work will attempt a full hyper-parameter optimization. Note that we include sin activation functions only in the first layer, since most equations in the physical sciences do not have terms such as $sin(x^2)$, for instance. This filtering can be considered an intuitive attempt at reducing the total number of activation sets to consider, as a simpler alternative to a full hyper-parameter optimization. This network is now fit to the dataset, carving out an 80-20 split for the training and validation sets. Currently, we train this network to attempt to match the error made by the conventional feed-forward network, though this may not always be successful. Given this initial trained equation learner network, we now begin the pruning process. We determine a final sparsity percentage (typically $\sim 90\%$), and a rate of pruning connections (typically $k \sim 2\%$). In each pruning round, the weakest k connections are set to zero, using the pruning package in Pytorch. Weakest connections are determined by connection strength, as defined in the main text. The pruned network is now trained for 10 epochs, allowing the remaining weights to adjust. Once again, this is a hyper-parameter that we do not optimize in this work. After 10 epochs, the network is pruned again, and the process is repeated until the final sparsity percentage is reached.

In the final stage, the trained, pruned network is readout as an equation. For this step, we use the Sympy package (Meurer et al. 2017), converting a set of weights and activation functions into an equation. At this point, the discovered equation could contain terms that we could still remove, while minimally sacrificing accuracy. We thus manually inspect and remove the weakest terms in the equations, discovering the smallest (most parsimonious) equation that still accurately describes our dataset. Note that a final retraining of the remaining coefficients could be performed to account for the terms removed at this stage, we leave this step as future work.

Following the discovery of the equation in the open-ended nanophotonics exemplar, we immediately observe a strong presence of z_1 in the equation, showing that our neural net-

work equation learner quantifies the prior knowledge that emission directivity depends on the local slope m. We had previously correlated z_1 to m, the local slope of the pump pattern based on our prior knowledge that incoherent emission steering should depend on this quantity. We demonstrate through our equation that the self-driving lab framework learnt, and quantified, the importance of m, the local slope, in controlling incoherent emission. The lack of variables z_3 and z_4 , indicate that these variables only contribute to directivity as higher-order terms. Equations with greater accuracy but lower parsimony, as indicated by the number of terms, contained all four latent dimensions, but we follow the Occam's razor principle, choosing the explanation containing the least number of terms. The polynomial nature of the equation is very interesting, since prior knowledge of momentum matching principles demands that we have oscillatory $(\sin(m), \cos(m))$ terms in the equation. The parameterized form of z_2 may account for it since it weakly correlates with the spatial frequencies. We thus conclude that z_1 and z_2 , corresponding roughly to m (the local slope), and frequency ω , contribute the most to directivity.

S6: Quantifying the impact of AutoSciLab

To document the impact of using AutoSciLab for scientific discovery, we compute the a) number, b) variety, and c) value of experiments proposed and conducted by AutoSciLab. We then compare these quantities to their equivalents when using human intuition, across the three exemplars.

Projectile Motion: In the case of projectile motion, the design space is the range of initial velocities (u) and angles (θ) used to compose a training set of projectile trajectories. The design space is thus two dimensional. Traditional design of experiments, or even a rudimentary grid search in two dimensions, would require on ~ 10 experiments to identify a range of trajectories from which the relationship between maximum height H and initial velocity u can be determined. Of course, the original set of experiments used by Galileo to describe projectile motion used an inclined plane [], and setup the problem differently. However, to provide a principled comparison, we compare AutoSciLab to a grid search, since any other comparison requires a vast scientific background to design a more efficient set of experiments. Therefore, while a conventional grid search requires ~ 10 experiments, AutoSciLab uses ~ 500 experiments, see Fig. 2 in the main text. To quantify variety of experiments proposed, we compare the range of experiments proposed by the VAE, to the range of experiments proposed by a human. For this, we compute the volume of the VAE latent space, which is the area of two-dimensional latent space ranging from [-3, 3], i.e., 36 (arbitrary units). In comparison, we can encode a set of realistic projectiles (defined by a human) into the same latent space, and compute the area under the convex hull of the points in the latent space. For this exercise, the area of a set of ~ 10 realistic projectiles (in the latent space) is 0.65 (arbitrary units). To quantify value, we compute the extent to which projectiles tested are 'realistic'. For human based experiments, all projectiles are 'realistic' (since experiments are conducted in the physical world). For AutoSciLab, we

now evaluate the projectiles explored by the active learning agent. 'Realistic' profiles are described by a constant downward acceleration of $g = 9.8 \frac{m}{s^2}$. Therefore, we quantify the deviation of acceleration from g for each projectile explored by the active learning, with a lower deviation resulting in higher value. This deviation is computed as a ratio to the deviation observed for realistic projectiles (which in theory should be zero but are small, non-zero numbers in practice due to imprecision in numerical calculations of double derivatives). This ratio is computed to be 0.88, implying that while most projectiles evaluated by the active learning are realistic, see Fig. 2(b) in the main text, some unrealistic projectiles are explored in the initial stages of the exploration, resulting in lower average value for the set of experiments. The gain factor, which is a product of the relative number, variety, and value of experiments, is thus computed to be \sim 1. This is in alignment with the expectation that for lowdimensional search spaces and strong prior knowledge, AutoSciLab would perform as well as human intuition would.

Ising Model: In the case of the Ising spin system, the spins are located on a lattice of size 32×32 , resulting in a 1024 dimensional design space. Traditional human approaches to learning the relationship between average spin state (magnetization M) and temperature T, would involve running Monte Carlo simulations for N temperatures, with each Monte Carlo simulation requiring E energy evaluations. Since each energy evaluation is of equivalent value, we define the number of energy evaluations E to be the number of experiments required for scientific discovery. Thus, for a human approach, we would require $N \times E$ energy evaluations or 'experiments' for scientific discovery. For AutoSciLab, we efficiently use AutoSciLab to find initial spin configurations M_{init} such that the number of energy evaluations E is reduced. This is what is referred to as t_{sol} in the main text. As Fig. 3 in the main text shows, we require ~ 100 Monte Carlo simulations to find an optimal initial magnetization, such that the number of experiments E is reduced. In our case, the optimal initial magnetizations require E/100 energy evaluations, or 'experiments'. Therefore, the total number of AutoSciLab experiments are $N \times E/100 \times 100$, which the same as the number of human experiments. To quantify variety, we look at the range of experiments proposed using human intuition, and the range of experiments proposed in AutoSciLab. In this case, while the problem is 1024 dimensional, both human intuition and AutoSciLab use average magnetization M to denote a spin configuration. That is, both approaches distill the problem to a single variable, making the variety of experiments proposed equivalent. Finally, to quantify value, we compute the number of energy evaluations saved by using AutoSciLab, compared to human intuition. Since each energy evaluation is defined using a spin state, optimal spin states will require fewer energy evaluations or experiments, to achieve scientific discovery. Since AutoSciLab requires $N \times E/100$ evaluations compared to $N \times E$ evaluations required using human intuition, we assign AutoSciLab's experiment value to be 100 times greater than human intuition. The gain factor, the product of these three terms is thus 100.

Nanophotonics: In the open-ended nanophotonics exem-

plar, human intuition is extremely limited and does not provide a clear pathway to achieving advanced steering efficiencies beyond efficiencies obtained from traditional Fourier methods. Therefore, estimating the number, variety, and value of experiments needed to make a scientific discovery is challenging. For AutoSciLab, the number of experiments conducted at each emission angle is \sim 1000. The variety of experiments can be once again estimated from the volume (in latent space) of proposed experiments. For human intuition, Fig. 4(a) visually suggests that human intuition based experiments are a tiny fraction of the range of experiments proposed by the VAE. In terms of latent space volume, we estimate the range of experiments proposed by the VAE to be \sim 1000 more than the range of experiments proposed by human intuition. Finally, to estimate value, we compute the average directivity of the set of experiments conducted (either using human intuition, or by the active learning). While the peak directivity measured using a pump pattern generated by the active learning agent was 4x the directivity from human intuition based pump patterns, the average directivity across multiple pump patterns explored by the active learning was approximately 2x the average directivity across multiple human intuition based patterns. That is, the average value of AutoSciLab based experiments was 2x the value of human intuition based experiments. The gain factor, once again, the product of the three terms, is approximately 2 million.

Note that these calculations, while admittedly approximate, completely ignore the gain obtained from automatically discovering equations directly from data using neural networks. This is because quantifying the amount of time needed for humans to discover equations is challenging and needs to account for the human's prior scientific background, mathematical capabilities etc. Overall, the goal of quantifying the impact of AutoSciLab is to compare how important frameworks such as AutoSciLab are for scientific discovery, especially in high-dimensional search spaces, or in spaces with limited human intuition.
