

Modeling the UV/Optical light curve of re-brightening tidal disruption events

SHIYAN ZHONG¹

¹*South-Western Institute for Astronomy Research, Yunnan University, Kunming, 650500 Yunnan, China*

ABSTRACT

In recent years, a new subclass of tidal disruption events (TDEs) was reported from the literature. The light curve of these TDEs show a re-brightening feature in the decline phase after the first peak, which then leads to a second flare. The re-brightening TDEs challenges the existing light curve fitting tools, which are designed to handle single flare. In this work, we present a model, aimed at reproducing of the light curve of the re-brightening TDEs, based on the scenario that the consecutive flares are produced by the same star who experienced two partial disruptions (PTDEs). We also develop a fitting code from this model, and apply it to two re-brightening TDEs: AT 2022dbl and AT 2023adr. The light curve of both TDEs are well fitted. Finally, we forecast the time and peak brightness of the next flare for these two TDEs, so that the observers could get prepared in advance and make an examination on our model.

Keywords: Supermassive black holes (1663) — Tidal disruption (1696) — Time domain astronomy(2019) — Transient sources (1851)

1. INTRODUCTION

A star comes too close to a supermassive black hole (SMBH) shall be disrupted by the overwhelming tidal force from the SMBH, causing a tidal disruption event (TDE). The critical distance to the SMBH for a TDE is denoted as the tidal radius r_t , an order-of-magnitude estimate of the tidal radius is given by $r_t = r_*(M_{\text{BH}}/m_*)^{1/3}$, where M_{BH} , m_* and r_* are the SMBH mass, stellar mass and radius,

respectively. Such an event gives rise to a flare that can last from months to years, making TDE a promising tool to detect the otherwise dormant SMBHs residing in the center of galaxies.

In the era before the Zwicky Transient Facility (ZTF; [Bellm et al. \(2019\)](#)), the number of (candidate and confirmed) TDEs are accumulated at a pace of roughly 2 per year ([Gezari 2021](#)), most of them are discovered in the optical band, thanks to the ground based optical surveys. The discovery rate is pushed up to a few dozens per year by the ZTF and will be further boosted with the upcoming survey facilities, such as the Legacy Survey of Space and Time (LSST) at the Vera Rubin Observatory (VRO) ([Ivezić et al. 2019](#)).

TDEs are featured by its characteristic light curves: the luminosity rises quickly to the peak, following either linear, quadratic or Gaussian rising. After the peak, the luminosity declines following an exponential or power law decay ([van Velzen et al. 2021](#); [Hammerstein et al. 2023](#)). To date, most of the observed TDEs exhibit only one flare, resulted from a single full- or partial disruption of the intruding star. This is consistent with the theoretical expectation. Ever since the work of [Rees \(1988\)](#), a commonly adopted assumption is that the disrupted star possess essentially zero orbital energy (parabolic orbit), hence it can only have one close encounter with the SMBH.

However, as the observational data accumulates and the time baseline extends, some interesting TDEs have been observed: their light curves show re-brightening features in the declining phase of the first flare, or long after the first flare. Currently, a handful of (candidate and confirmed) re-brightening TDEs have been reported in the literature: PS1-10adi ([Jiang et al. 2019](#)); ASASSN-14ko ([Payne et al. 2021](#)); AT 2018fyk ([Wevers et al. 2023](#)); AT 2020vdq ([Somalwar et al. 2023](#)); AT 2022dbl ([Lin et al. 2024](#)); F01004-2237 ([Sun et al. 2024](#)); AT 2019aalc ([Veres et al. 2024](#)); RX J133157.6–324319.7 ([Hampel et al. 2022](#); [Malyali et al. 2023](#)); eRASSt J045650.3–203750 ([Liu et al. 2023b, 2024b](#)); Swift J023017.0+283603 ([Evans et al. 2023](#); [Guolo et al. 2024](#)). We also note a few TDEs presented by [Yao et al. \(2023\)](#) show re-brightening feature: AT 2019baf, AT 2019ehz, AT 2020acka, AT 2021uqv. Although small in number, they already exhibit great diversity in the light curve properties. In the optical-selected TDE samples, the time interval between the first and second flares spans a range from a few hundred days (e.g. the sample of [Yao et al. \(2023\)](#)) to a few years

(Somalwar et al. 2023) or even one decade (Sun et al. 2024). Another aspect is the brightness ratio between the two peaks: in some cases the second flare is dimmer than the first flare, while in the other cases the second flare is brighter (e.g. AT 2020vdq, AT 2019aalc, F01004-2237). Lastly, the number of repeating flares from the same target also varies a lot, from the minimum of 2 to more than 20 (e.g. ASASSN-14ko).

The nature of this re-brightening or repeating phenomenon is still an open question, there are many possible models. First, repeated partial TDEs produced by the same star (Somalwar et al. 2023; Wevers et al. 2023; Liu et al. 2024a; Bandopadhyay et al. 2024). Contrary to full disruption, a partial TDE only strip away a fraction of mass from the star, and a remnant star will survive. The amount of stripped mass depends primarily on the penetration factor β and stellar structure (Guillochon & Ramirez-Ruiz (2013), hereafter GRR2013). If the remnant star moves on eccentric orbit, it can return to the pericenter periodically and produce the repeating PTDEs. Then the time interval between the two peaks is mainly determined by the orbital period of the star. The repeating PTDEs might also be responsible for another interesting type of nuclear transient, the quasi-periodic eruptions (QPEs) observed in the X-ray band (Wang et al. 2022), e.g. GSN 069 (Miniutti et al. 2019), RXJ1301.9+2747 (Giustini et al. 2020), eRO-QPE1, eRO-QPE2 (Arcodia et al. 2021). QPEs have much shorter periods (hours to weeks) compared to the repeating flares observed in the UV/optical bands. Given the short time interval between the peaks, the star is tightly bound to the MBH, which is viable through the tidal break-up of hard binaries in the galactic center (also known as the Hills mechanism, Hills (1988); Cufari et al. (2022); Wevers et al. (2023)). During the PTDE, the tidal perturbation excites stellar oscillation and the tidal torques spin up the remnant star (Ryu et al. 2020; Chen et al. 2024; Bandopadhyay et al. 2024), the response of the stellar structure to these perturbations determines the strength and the peak brightness of the subsequent disruption (detailed in Section 4).

In the second model, the two flares are full TDEs produced by two different stars, following the tidal breakup of a binary (Mandel & Levin 2015). In this model, only two flares can be produced because the stars are totally destroyed. Because the fallback rate are largely affected by the orbital

parameters (as we will discuss later), the relative brightness as well as the time interval between the two flares are determined by the complicated three-body dynamics.

Chen et al. (2022) has proposed a third model which employs two-phase accretion. In this model, the first flare is powered by the fallback of tidal debris, and a temporally delayed accretion process is responsible for the second flare, which is dimmer than the first flare and generally not following the mass fallback rate, due to the viscous delay operating in the accretion disk. This model has been successfully applied to AT 2019avd.

Analyzing the observed TDE light curves could help us to reveal the physical mechanisms responsible for the phenomenon of re-brightening TDE. Currently, there are two published TDE light curve fitting tools in the literature: the Modular Open Source Fitter for Transients (MOSFiT) (Guillochon et al. 2018; Mockler et al. 2019) and TiDE (Kovács-Stermeczky & Vinkó 2023a). They are aimed at extracting the physical parameters behind the TDEs, especially the mass of the SMBH, the mass of the disrupted star and its orbital parameter. These tools adopt different physical models and assumptions: MOSFiT adopts a luminosity-dependent photosphere with black body spectrum energy distribution (SED), while the emission model of TiDE adopts an accretion disk and a reprocessing layer. MOSFiT and TiDE have been used in many studies (Mockler et al. 2019; Gomez et al. 2020; Nicholl et al. 2020; Mockler & Ramirez-Ruiz 2021; Hammerstein et al. 2023; Kovács-Stermeczky & Vinkó 2023b).

MOSFiT and TiDE share a common assumption that the intruding star are moving on parabolic orbit ($e = 1$) before the disruption, because the disrupted star is originated from the influence radius of the MBH¹ (Frank & Rees 1976). Therefore, the star can encounter with the SMBH only once. One may try to fit the individual flares in the re-brightening TDEs, but shall encounter the following problems: 1) the mass fallback rate of $e < 1$ disruption, which is the case for re-brightening TDEs, is different from that of $e = 1$ case adopted by MOSFiT and TiDE (Hayasaki et al. 2013; Park & Hayasaki 2020; Liu et al. 2023a). Hence these tools can not model the individual flares accurately. 2) During the

¹ By definition, the stars residing within the influence radius are bound to the MBH, while those outside the influence radius are unbound.

second flare, there might be some contribution from the first flare, which is currently not accounted in MOSFiT and TiDE. 3) the time separation between the two flares are not modeled in MOSFiT and TiDE. Therefore, these tools are not suitable for fitting the re-brightening TDEs.

In this work, we try to construct a new model dedicated to fit the light curve of re-brightening TDEs, assuming they are produced by the repeating PTDEs. Here, we focus on the optical light curve modeling, and leave the modeling of X-ray light curve for future study. In Section 2, we first describe how to construct a composite mass fallback rate curve that consist of contributions from the two consecutive PTDEs. Then this mass fallback rate curve is converted to the multi-band mock light curves adopting the luminosity-dependent photosphere model, which is also implemented in MOSFiT. In Section 3, we apply our light curve model to two re-brightening TDEs: AT 2022dbl and AT 2023adr. Then we forecast the time and peak brightness of the next flare for these two TDEs. In Section 4, we discuss the caveats of our model and possible improvements that can be done in the future development. Finally, we summarize this paper in Section 5.

2. MODEL

In this section, we describe the model for the re-brightening TDEs. We only consider the case that one single star experienced two partial TDEs, since observations currently found most of the re-brightening TDEs only exhibit two flares.

2.1. *The mass fallback rate of $e = 1$ disruption*

We first explain how to get the mass fallback rate in the standard $e = 1$ case, this procedure mainly follows the one implemented in MOSFiT. Then we derive the mass fallback rate for the $e < 1$ case in the next subsection.

The construction of mass fallback rate are based on the hydrodynamic simulation of GRR2013. GRR2013 simulated the disruption of $1 M_{\odot}$ star by a $10^6 M_{\odot}$ SMBH, with various of penetration factor β and a constant eccentricity $e = 1$. The penetration factor β is defined as the ratio of tidal radius r_t to the pericenter distance r_p . The resultant debris energy distributions ($dm/d\epsilon$) for a set

of discrete β 's, are shipped with MOSFiT² (Guillochon et al. 2018; Mockler et al. 2019). GRR2013 adopted two polytropic stellar models: $\gamma = 4/3$ (suitable for $1 M_\odot \leq m_* \leq 15 M_\odot$) and $\gamma = 5/3$ (suitable for $m_* \leq 0.3 M_\odot$ and $m_* \geq 22 M_\odot$). In the rest parts of the mass ranges, we follow the procedure implemented in MOSFiT to construct a hybrid fallback function (in this paper, we call the stars in these mass ranges as hybrid stars). Mockler et al. (2019) defined the fractional contributions, g_{frac} , from the two γ models as follows,

$$g_{\text{frac}} = \frac{m_*/M_\odot - 1}{0.3 - 1}, \quad (0.3 < m_*/M_\odot < 1) \quad (1)$$

$$g_{\text{frac}} = \frac{m_*/M_\odot - 15}{22 - 15}. \quad (15 < m_*/M_\odot < 22) \quad (2)$$

Therefore, $g_{\text{frac}} = 0$ is corresponding to $\gamma = 4/3$ model, $g_{\text{frac}} = 1$ is corresponding to $\gamma = 5/3$ model. Then the mass fallback rate for hybrid star (\dot{M}_{hybrid}) is obtained by linearly interpolating between the $\gamma = 4/3$ and $\gamma = 5/3$ fallback rate functions, $\dot{M}_{4/3}$ and $\dot{M}_{5/3}$ provided by GRR2013. $\dot{M}_{4/3}$ and $\dot{M}_{5/3}$ only depend on β , so the next step is to choose the appropriate β 's for these two functions. Note the range of β for the partial disruption of the two γ models are different: the partial disruption of $\gamma = 4/3$ ($\gamma = 5/3$) star occurs at $0.6 < \beta_{4/3} < 1.85$ ($0.5 < \beta_{5/3} < 0.9$). In practice, MOSFiT adopts a scaled penetration factor b to describe the strength of disruption, and uses the following equations to translate b to β (and vice versa), for the partial disruption of polytropic stars,

$$\beta_{4/3} = 0.6 + 1.25b, \quad (0 \leq b \leq 1, \gamma = 4/3) \quad (3)$$

$$\beta_{5/3} = 0.5 + 0.4b. \quad (0 \leq b \leq 1, \gamma = 5/3) \quad (4)$$

These equations indicate that $b = 0$ corresponds to no disruption and $b = 1$ corresponds to full disruption.

² <https://github.com/guillochon/MOSFiT>

For the hybrid star, β is obtained by linearly interpolating between $\beta_{4/3}$ and $\beta_{5/3}$, i.e. $\beta = \beta_{4/3} + (\beta_{5/3} - \beta_{4/3})g_{\text{frac}}$. After some simple algebra, we find

$$b = \frac{\beta - 0.6 + 0.1g_{\text{frac}}}{1.25 - 0.85g_{\text{frac}}}. \quad (5)$$

Note, by setting $g_{\text{frac}} = 0$ ($g_{\text{frac}} = 1$), equation 5 reduces to equation 3 (equation 4). In the end, we can calculate the mass fallback rate of hybrid star with the following interpolation equation,

$$\dot{M}_{\text{hybrid}}(b) = \dot{M}_{4/3}(b) + [\dot{M}_{5/3}(b) - \dot{M}_{4/3}(b)]g_{\text{frac}} \quad (6)$$

The mass fallback rate is scaled to the target black hole mass and star, using the scaling relation $\dot{M}_{\text{peak}} \propto M_{\text{BH}}^{-1/2} m_*^2 r_*^{-3/2}$ given by GRR2013. Finally, we convert the mass fallback rate to the energy distribution of bound debris using the equation $dm/d\epsilon = \dot{M}/(d\epsilon/dt)$. The time derivative of ϵ can be derived from the Kepler's third law. The resulted energy distribution of the tidal debris is denoted as $(dm/d\epsilon)_{e=1}$. We could also compute the stripped mass during the partial TDE,

$$\Delta m = 2 \int_{-\infty}^0 \left(\frac{dm}{d\epsilon} \right)_{e=1} d\epsilon, \quad (7)$$

because the $(dm/d\epsilon)_{e=1}$ function is symmetric to $\epsilon = 0$.

2.2. The mass fallback rate of $e < 1$ disruption

The next step is to modify the mass fallback rate according to the orbital eccentricity of the disrupted star. Here we only consider the $e < 1$ case, because the star capable of producing multiple PTDEs has to stay on an eccentric orbit. Hayasaki et al. (2013) have shown that the effect of reducing orbital eccentricity is shifting the $dm/d\epsilon$ curve toward the direction of negative energy with a displacement of ϵ_{orb} ,

$$\frac{dm}{d\epsilon}(\epsilon) = \left(\frac{dm}{d\epsilon} \right)_{e=1} (\epsilon - \epsilon_{\text{orb}}). \quad (8)$$

The relation between orbital energy and eccentricity reads

$$\epsilon_{\text{orb}} = -\frac{\beta(1-e)}{2} q^{1/3} \Delta\epsilon, \quad (9)$$

where $q = M_{\text{BH}}/m_*$ is the mass ratio between the SMBH and the star, and $\Delta\epsilon = GM_{\text{BH}}r_*/r_t^2$ is the typical energy scale of the $dm/d\epsilon$ distribution. Finally, we convert $dm/d\epsilon$ to mass fallback rate, i.e. $dm/dt = (dm/d\epsilon)(d\epsilon/dt)$, and denote it as $\dot{M}(t; M_{\text{BH}}, m_*, b, \epsilon_{\text{orb}})$.

The procedure of shifting $dm/d\epsilon$ (equation 8) is also justified by the results of Liu et al. (2023a). They estimated the overall impact of tidal distortions on the star as it travels from the pericenter to the apocenter, which solely depends on the orbital eccentricity. They found that a 5% deviations to the tidal deformation from cases in parabolic orbits occur when $e = e_{5\%}$. Hence, equation 8 can be safely applied when $e > e_{5\%}$. According to Figure 1 of Liu et al. (2023a), we find that $\log(1 - e_{5\%})$ is roughly -1.3 (i.e. $e_{5\%}$ is roughly 0.95), therefore the $e > e_{5\%}$ condition is always satisfied in the parameter space we are exploring (see the typical value of e computed below).

In the light curve fitting procedure, we use the orbital period of the intruding star before the first close encounter, P_{orb} , as a fitting parameter instead of e . Because P_{orb} is easier to read from the light curve, so that we can set a reasonable prior range for it. We note that after the first encounter, the orbital period of the remnant star will change due to the orbital energy gain or loss (detailed in Section 2.3) induced by the tidal encounter. Hence the time interval between the two flare peaks should only be regarded as a rough estimate of P_{orb} . It is also convenient to convert P_{orb} to ϵ_{orb} according to the Kepler's third law,

$$\epsilon_{\text{orb}} = - \left(\frac{\pi GM_{\text{BH}}}{\sqrt{2}P_{\text{orb}}} \right)^{2/3}. \quad (10)$$

For completeness, we also derive the relation between e and P_{orb} . Inserting equation 9 into equation 10 results in

$$e = 1 - \left(\frac{2\pi t_{*,\text{dyn}}}{P_{\text{orb}}} \right)^{2/3} \beta^{-1}, \quad (11)$$

where $t_{*,\text{dyn}} = \sqrt{r_*^3/(Gm_*)} \simeq 1.6 \times 10^3 (r_*/R_\odot)^{3/2} (m_*/M_\odot)^{-1/2}$ s is the dynamic timescale of the star. Consider a typical case, where $t_{\text{dyn}} \simeq 1.6 \times 10^3$ s, $P_{\text{orb}} \simeq 100$ days and $\beta \simeq 1$, we find $e \simeq 0.989$.

2.3. Variation of the orbital energy of the remnant star

The remnant star emerged from the partial disruption may lose or gain orbital energy, affecting the returning time and the mass fallback rate of the next disruption (c.f. equation 8). Therefore, taking this effect into account is important for accurate light curve modeling.

Manukian et al. (2013) conducted the first study on this problem by performing Newtonian hydrodynamic simulations. They measured the orbital energy change after a partial disruption of a $\gamma = 4/3$ polytrope star, and found that the remnant star always gain orbital energy. The amount of energy gain monotonically increases with β , but never exceed the surface escape velocity (v_{esc}) of the original star. They also provided a fitting formula to calculate the orbital energy gain. Gafton et al. (2015) performed General Relativistic simulation of PTDE, and obtained similar conclusion that the remnant star gains orbital energy, though they used $\gamma = 5/3$ polytrope star. Later on, Ryu et al. (2020) studied the same problem, also took the General Relativistic effect into account, but the star is modeled with realistic stellar structure. Contrary to the previous two studies, Ryu et al. (2020) found that the orbital energy of the remnant star is not always increasing: the remnant star produced in the partial disruption of low-mass star actually loses orbital energy after a weak encounter, while for high-mass stars, the remnant may also loses orbital energy even in some severe encounters. Recently, Chen et al. (2024) studied the orbital energy variation after a PTDE for both $\gamma = 4/3$ and $\gamma = 5/3$ star, and found that there is a critical penetration factor, denoted as β_t : the remnant star loses (gains) orbital energy if $\beta < \beta_t$ ($\beta > \beta_t$).

Chen et al. (2024) provided two fitting formulae (their equation 9) to compute the orbital energy changes $\Delta\epsilon_{\text{orb}}$ of the remnant stars (both $\gamma = 4/3$ and $\gamma = 5/3$ stellar models) after every PTDE, which only depends on β . In order to obtain $\Delta\epsilon_{\text{orb}}$ for the hybrid stars, we firstly convert the variable β in the original fitting formulae to b (see the plot in Figure 1), then compute the orbital energy change using

$$\Delta\epsilon_{\text{orb}}(b) = \Delta\epsilon_{\text{orb},4/3}(b) + [\Delta\epsilon_{\text{orb},5/3}(b) - \Delta\epsilon_{\text{orb},4/3}(b)] \times g_{\text{frac}}. \quad (12)$$

We also impose an upper limit on $\Delta\epsilon_{\text{orb}}$: it should not exceed $v_{\text{esc}}^2/2$. As a result, the orbital energy of the remnant star is $\epsilon_{\text{orb,new}} = \epsilon_{\text{orb}} + \Delta\epsilon_{\text{orb}}$. Accordingly, the new orbital period is calculated with the Kepler's third law.

Figure 1. The dependence of $\Delta\epsilon_{\text{orb}}$ on the scaled penetration factor b for the two γ stellar models (indicated by color), based on equation 9 of [Chen et al. \(2024\)](#). We have transformed β in their equation 9 to b , using equation 5.

2.4. The composite mass fallback rate

In this section we construct the composite mass fallback rate consisting of two subsequent PTDEs produced by the same star. We start with a brief description of the procedure and key parameters.

A star with initial mass $m_{*,0}$ and radius $r_{*,0}$ approaches the SMBH on an eccentric orbit with initial scaled penetration factor b_0 ($0 < b_0 < 1$, the corresponding β_0 is derived from equation 5) and the rest-frame orbital period $P_{\text{orb},0}$ (the corresponding orbital energy $\epsilon_{\text{orb},0}$ is derived from equation 10). It passes the pericenter at the time of $t = t_{\text{disrupt}}$, and the first partial TDE ensues. After that, a remnant star with mass $m_{*,1}$ and radius $r_{*,1}$ continues its journey around the SMBH. The stellar mass $m_{*,1} = m_{*,0} - \Delta m$, where Δm is computed from equation 7, and $r_{*,1}$ is computed from the mass-radius relation of zero-age-main-sequence (ZAMS) star ([Tout et al. 1996](#)). Accordingly, the new tidal radius for disrupting the remnant star is computed by $r_{t,1} = r_{*,1}(M_{\text{BH}}/m_{*,1})^{1/3}$, and the new

penetration factor is $\beta_1 = r_{t,1}/r_{p,1}$ and the associated b_1 is obtained with equation 5. Hydrodynamic simulations have found that the pericenter of this new orbit is almost the same as the initial orbit (Ryu et al. 2020; Chen et al. 2024), therefore we take $r_{p,1} = r_{p,0}$ for simplicity. The orbital energy of this remnant star is also updated by an amount of $\Delta\epsilon_{\text{orb}}$ (equation 12), i.e. $\epsilon_{\text{orb},1} = \epsilon_{\text{orb},0} + \Delta\epsilon_{\text{orb}}$. Then we use the Kepler's third law to compute the orbital period for the remnant star, $P_{\text{orb},1}$.

With these parameters, we could obtain the mass fallback rate of the individual PTDEs, denoted as $\dot{M}_0(\tilde{t}; M_{\text{BH}}, m_{*,0}, b_0, \epsilon_{\text{orb},0})$ and $\dot{M}_1(\tilde{t}; M_{\text{BH}}, m_{*,1}, b_1, \epsilon_{\text{orb},1})$, respectively. In both functions, \tilde{t} is the time variable and the other quantities are parameters. Note \tilde{t} measures the elapsed time since the corresponding disruption, i.e. $\tilde{t} = 0$ when the (remnant) star passes the pericenter; while t measures the date of the observations. Therefore, $\tilde{t} = t - t_{\text{disrupt}}$ in \dot{M}_0 and $\tilde{t} = t - (t_{\text{disrupt}} + P_{\text{orb},1})$ in \dot{M}_1 , because the remnant star passes the pericenter at the time $t_{\text{disrupt}} + P_{\text{orb},1}$.

We assume the first light of the first PTDE emerges at the time when stream-stream collision occurs, denoted as $t_0 = t_{\text{disrupt}} + 1.5t_{\text{min},0}$, where $t_{\text{min},0}$ is the orbital period of the most bound debris in the first PTDE, both of them are given in unit of days. Since the remnant star takes $P_{\text{orb},1}$ to return to the pericenter and give rise to the second PTDE, the light curve of the second PTDE starts at $t_1 = t_{\text{disrupt}} + P_{\text{orb},1} + 1.5t_{\text{min},1}$, where $t_{\text{min},1}$ is the orbital period of the most bound debris in the second PTDE. The final composite mass fallback rate \dot{M}_{comp} is the summation of \dot{M}_0 and \dot{M}_1 .

Figure 2 gives four examples of the composite mass fallback rate made by two consecutive PTDEs, to demonstrate the effect of the initial scaled penetration factor b_0 on the mass fallback rate. In this figure b_0 increases from the top left panel to the bottom right panel, so do the peak mass fallback rates of the two PTDEs. It also shows that the ratio of two peak mass fallback rates increases with b_0 : the two peaks are nearly the same when $b_0 = 0.1$, while in the case of $b_0 = 0.95$, the first peak is almost one order of magnitude higher than the second peak. Another feature we want to emphasize is the decay phase after the second peak. During this period of time, the materials stripped in the first PTDE is still falling back (the blue curve), effectively enhances the composite fallback rate (the black curve) during the second peak. As a result, the fallback rate after the second peak decays

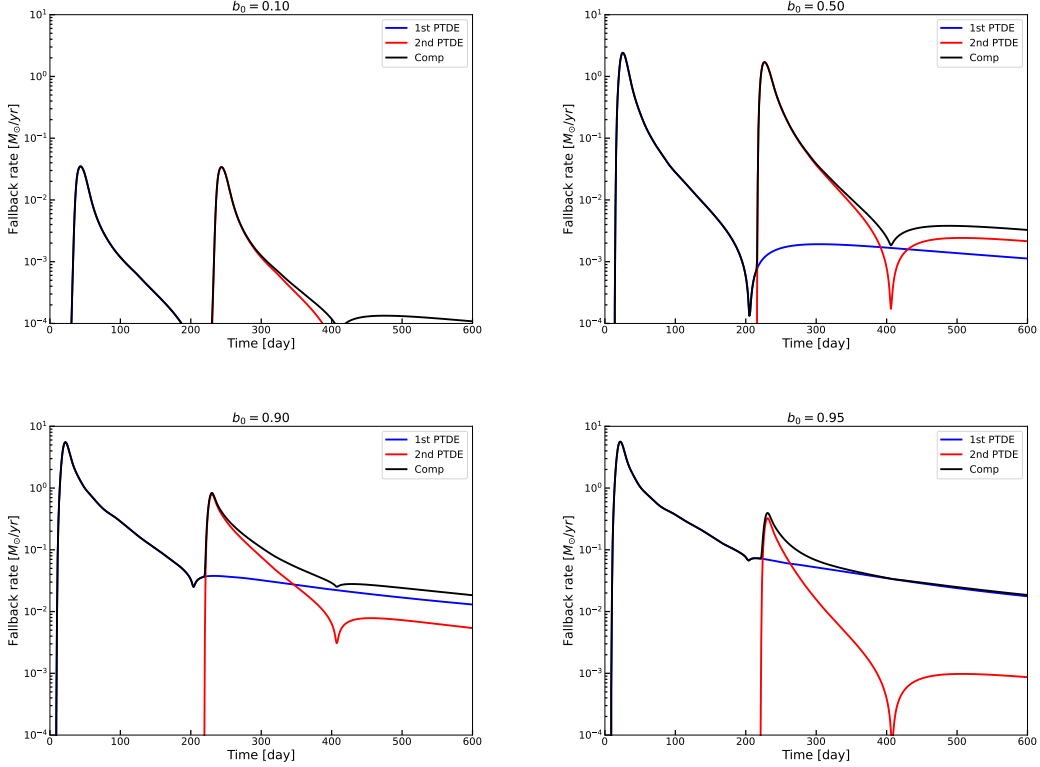

Figure 2. The composite mass fallback rate with various of b_0 . The blue and red curves represent the mass fallback rate of the first (\dot{M}_0) and second (\dot{M}_1) PTDE, respectively. The starting time of \dot{M}_0 is shifted to t_0 , and the starting time of \dot{M}_1 is shifted to t_1 (see the main text). The black curve represents the composite mass fallback rate of the two consecutive PTDEs. In all these plots, we set $M_{\text{BH}} = 10^6 M_\odot$, $m_{*,0} = 1 M_\odot$, $P_{\text{orb},0} = 200$ days, $t_{\text{visc}} = 0$ day and $t_{\text{disrupt}} = 0$.

slower than it would be in an solitary PTDE (the red curve). This effect is more significant in the high b_0 cases.

The accretion rate $\dot{M}_{\text{acc}}(t)$ that actually powers the luminosity should defer from the fallback rate, due to the viscous delay of the accretion. Following the procedure in MOSFiT, we introduce a viscous timescale t_ν to control the viscous delay, and calculate $\dot{M}_{\text{acc},i}(\tilde{t})$ with

$$\dot{M}_{\text{acc},i}(\tilde{t}) = \frac{1}{t_\nu} \left(e^{-\tilde{t}/t_\nu} \int_0^{\tilde{t}} e^{\tilde{t}'/t_\nu} \dot{M}_i(\tilde{t}') d\tilde{t}' \right) \quad (13)$$

(Mockler et al. 2019). Increasing t_ν could prolong the rising and declining timescales of the light curve, and suppress the peak luminosity. Note, only in the limit of $t_\nu \rightarrow 0$ shall the accretion rate equal the mass fall back rate.

2.5. Multi-band Light Curve Modeling

In this section we describe how to generate the multi-band light curve from the mass fallback rates. In practice, we first compute the bolometric light curve for the individual PTDEs ($L_{\text{bol},0}$ and $L_{\text{bol},1}$) from the associated viscously delayed mass fallback rate ($\dot{M}_{\text{acc},0}$ and $\dot{M}_{\text{acc},1}$). Then compute the magnitude of the two flares ($m_{\text{band},0}$ and $m_{\text{band},1}$) in every observed bands, using the radiation model described below. Finally, the composite light curve is obtained by

$$m_{\text{band}} = -2.5 \log(10^{-0.4m_{\text{band},0}} + 10^{-0.4m_{\text{band},1}}). \quad (14)$$

We adopt the luminosity-dependent photosphere model implemented in MOSFiT to convert the mass fallback rate to multi-band light curve. We give a brief introduction to this radiation model, more details can be found in Mockler et al. (2019).

The bolometric luminosity is computed by $L_{\text{bol},i}(t) = \eta \dot{M}_{\text{acc},i}(t) c^2$, where i marks the individual PTDEs (0 stands for the first PTDE, 1 stands for the second PTDE), η is the radiation efficiency, c is the speed of light and $\dot{M}_{\text{acc},i}(t)$ is obtained by equation 13. The range of η is set between 10^{-4} and 0.1, the upper limit is the typical radiation efficiency of an AGN disk. The lower limit comes from minimum value achievable for the eccentric accretion disk model (Zhou et al. 2021).

The optical spectrum energy distribution (SED) of the individual flares is generally described by black body radiation with effective temperature $T_{\text{eff},i}$ (Gezari 2021). The total bolometric luminosity is the product of the area of the emitting surface, $4\pi R_{\text{ph},i}^2$, and the energy flux per unit area $\sigma_{\text{SB}} T_{\text{eff},i}^4$, where $R_{\text{ph},i}$ is the so called photosphere radius, σ_{SB} is the Stefan-Boltzmann constant. After some simple algebra, the expression for the effective temperature reads

$$T_{\text{eff},i} = \left(\frac{L_{\text{bol},i}}{4\pi\sigma_{\text{SB}}R_{\text{ph},i}^2} \right)^{\frac{1}{4}}. \quad (15)$$

Then the SED is $F_i(\lambda) = B_{T_{\text{eff},i}}(\lambda)R_{\text{ph},i}^2/D_L^2$, where $B_{T_{\text{eff},i}}(\lambda)$ is the Planck function and D_L is the luminosity distance.

Many observations of TDEs have found that the effective temperature varies little near the peak and tend to increase at late times. In order to model this SED behavior in `MOSFiT`, a power-law scaling relation between the $R_{\text{ph},i}$ and $L_{\text{bol},i}$ is adopted,

$$R_{\text{ph},i} = R_{\text{ph}0}a_{\text{p},i}(L_{\text{bol},i}/L_{\text{Edd}})^l, \quad (16)$$

where $R_{\text{ph}0}$ is a normalization of the photosphere radius, $a_{\text{p},i}$ is the semimajor axis of the material corresponding to the maximum fallback rate, and L_{Edd} is the Eddington luminosity. Substitute this relation into equation 15 results in $T_{\text{eff},i} \propto L_{\text{bol},i}^{(1-2l)/4}$, hence in the special case of $l = 1/2$, the effective temperature will not vary with time.

Finally, a conversion from bolometric luminosity to the AB magnitude in different bands is performed. This is done with the $F(\lambda)$ and the filter transmission function $T(\lambda)$, using the following equation

$$m_{\text{AB}} = -2.5 \log \int \lambda F_i(\lambda) T(\lambda) d\lambda + 2.5 \log \int \frac{T(\lambda)}{\lambda} d\lambda - 2.408. \quad (17)$$

3. APPLY OUR MODEL TO THE RE-BRIGHTENING TDES

This section tests our model with two TDEs having re-brightening features, namely AT 2022dbl and AT 2023adr. [Lin et al. \(2024\)](#) confirmed that AT 2022dbl was produced by repeating PTDEs, and the authors claimed that the third flare is expected to recur in the 2026 (see also our forecasting in Section 3.1). AT 2023adr was recently reported as a repeating PTDE ([Llamas Lanza et al. 2024](#)), and the expected third flare should occur earlier than AT 2022dbl. Thus, these two cases provide good opportunities for further validating our model, if the third flare do occur at the predicted time and brightness.

We also note there are other newly discovered re-brightening TDEs: AT 2020vdq ([Somalwar et al. 2023](#)), and AT 2019aalc ([Veres et al. 2024](#)). In these cases, the second flare is even brighter than

the first flare. Note, AT 2019aalc took place in AGN, which might introduce more complexities in the light curve modeling, due to the underlying AGN variability. Currently, our model can not handle these features (see also Section 4.1), hence we exclude these TDEs from our analysis. For the TDEs presented in Yao et al. (2023) that have re-brightening features (AT 2019baf, AT 2019ehz, AT 2020acka, AT 2021uqv), we are already late for observing their third flares, so we also exclude them from our analysis.

The multi-band light curve data of AT 2022dbl was retrieved from Lin et al. (2024). The *Swift*/UVOT *U*- and *B*-band photometry is not very reliable for this target (Zheyu Lin, private communication), we exclude the data points in these two bands in the fitting procedure. Lin et al. (2024) has derived the host MBH mass: $\log(M_{\text{BH}}/M_{\odot}) = 6.40 \pm 0.33$ with the $M_{\text{BH}}\text{-}\sigma$ relation of Kormendy & Ho (2013).

The light curve data of AT 2023adr is retrieved from the ALerCE ZTF Explorer³, which performs the *g*- and *r*-band differential photometry on the target TDE. Then we correct the Milky Way extinction for this target, using $R_V = 3.1$ and $E(B - V) = 0.011$ from the SFD extinction map (Schlafly & Finkbeiner 2011). The resultant extinction is 0.042 mag in *g*-band and 0.029 mag in *r*-band.

We use the python package *emcee* (Foreman-Mackey et al. 2013) to optimize the fitting, by maximizing the logarithmic likelihood

$$\log p = -\frac{1}{2} \sum_i \left[\frac{x_i^2}{\sigma_i^2} + \log(2\pi\sigma_i^2) \right], \quad (18)$$

where x_i is the difference between the i th observation and model prediction, and σ_i takes the error of the i th observation. Maximizing the above logarithmic likelihood is equivalent to minimizing the $\chi^2 = \sum x_i^2/\sigma_i^2$ value.

The prior distribution of some common parameters are given in Table 1. For AT 2022dbl, the prior distribution of $P_{\text{orb},0}$ is between 650 and 690 days, t_{disrupt} is between MJD 59550 and 59600. For AT 2023adr, the prior distribution of $P_{\text{orb},0}$ is between 340 and 370 days, t_{disrupt} is between MJD

³ <https://alerce.online/>

59850 and 59910. We employ 100 walkers in the MCMC fitting and run for 10,000 iterations. The results of our interested fitting parameters and the corresponding reduced chi-square value (χ_{red}^2) are summarized in Table 2.

Table 1. The fitting parameters used in the light curve modeling.

Parameter	Prior Distribution Type	Min	Max
M_{BH}/M_{\odot}	Log	10^6	10^8
m_{*}/M_{\odot}	Kroupa	0.1	5
b (scaled penetration factor)	Flat	0.5	0.95
η	Flat	10^{-4}	0.1
R_{ph0}	Log	10^{-2}	10^2
l	Flat	0	2
t_{ν}/days	Log	10^{-1}	10

NOTES: The first column gives the name of the parameters. The second column indicate the type of prior distribution for each parameters: “Flat” means the prior is uniformly sampled from the value range; “Log” means the prior is logarithmically uniformly sampled in the value range; “Kroupa” means the stellar mass are sampled from the Kroupa initial mass function. The third and fourth columns give the allowed range for each parameter.

Table 2. Basic information of the re-brightening TDEs and the corresponding fitting results

IAU name	R.A.	Decl.	redshift	$\log(M_{\text{BH}}/M_{\odot})$	$m_{*,0}/M_{\odot}$	b_0	$P_{\text{orb},0}/\text{day}$	χ_{red}^2
AT 2022dbl	$12^{\text{h}}20^{\text{m}}45.097^{\text{s}}$	$49^{\circ}33'4.86''$	0.028	$6.91_{-0.01}^{+0.02}$	$1.00_{-0.00}^{+0.00}$	$0.63_{-0.00}^{+0.00}$	$680.44_{-0.17}^{+0.16}$	14.0
AT 2023adr	$14^{\text{h}}36^{\text{m}}19.847^{\text{s}}$	$32^{\circ}23'16.44''$	0.131	$7.18_{-0.06}^{+0.04}$	$0.90_{-0.03}^{+0.03}$	$0.80_{-0.02}^{+0.02}$	$346.97_{-1.21}^{+1.20}$	1.3

NOTES: $m_{*,0}$, b_0 and $P_{\text{orb},0}$ are the stellar mass, scaled penetration factor and rest-frame orbital period before the first PTDE, respectively. These three quantities shall vary after the first PTDE, see details in Section 2.4. We use the 16th and 84th percentiles of the posterior distribution to indicate the 1σ uncertainty in all fitted parameters. The last column is the reduced chi-square value, calculated with the data points involved in the fitting procedure.

Figure 3 presents the posterior distributions of M_{BH} , $m_{*,0}$, b_0 and $P_{\text{orb},0}$ which interest us the most. The M_{BH} of AT 2022dbl obtained from the light curve fitting ($\log(M_{\text{BH}}/M_{\odot}) \simeq 6.91$) is higher than that derived by Lin et al. (2024), but the difference is within 1 dex. We note that in the other TDEs that have M_{BH} measurement, the values obtained from the TDEs are generally not exactly match with the values derived from BH mass scaling relations, the agreement can only be achieved within ~ 1 dex (e.g. see the comparison in Mockler et al. (2019) and Kovács-Stermeczky & Vinkó (2023b), but also see Zhou et al. (2021) who gets a relatively good agreement). There is no M_{BH} measurement for the host galaxy of AT 2023adr.

Figure 4 shows the observed light curve and the mock light curve generated by the fitting code, for visual comparison. The mock light curves are generated with parameters randomly sampled from the last 1,000 iterations. The agreement between the mock and observed light curves are generally good. However, we also notice some deviations of the observed data from the mock light curves:

- AT 2022dbl: the deviation of the observed data in the *UVW2* and *UVM2* bands from the mock light curves starts about 100 days after the first peak. The ZTF *g* and ATLAS *o* bands also exhibit signatures of flattening in the decline phase of the first flare, but the beginning time is not obvious, due to the sparse sampling after MJD 59800. This feature resembles the late stage flattening observed in the UV bands in the other TDEs (van Velzen et al. 2019), but occurs much earlier. This feature is likely attributed to the formation of accretion disk (Mummery & Balbus 2020; Mummery et al. 2024). Since the contributions from different mechanisms for the UV/optical radiations should evolve with time (e.g. stream-stream collision in the early stage and disk accretion in the late stage), this flattening feature might be handled with an evolving η , or with more physically motivated radiation models (also see Section 4.3). We have excluded the data points between MJD 59800 and 60300 from the light curve fitting procedure. Including those data points would result in a black hole mass ~ 0.2 dex higher than the value reported in Table 2, but the influences on the other fitting parameters are small.

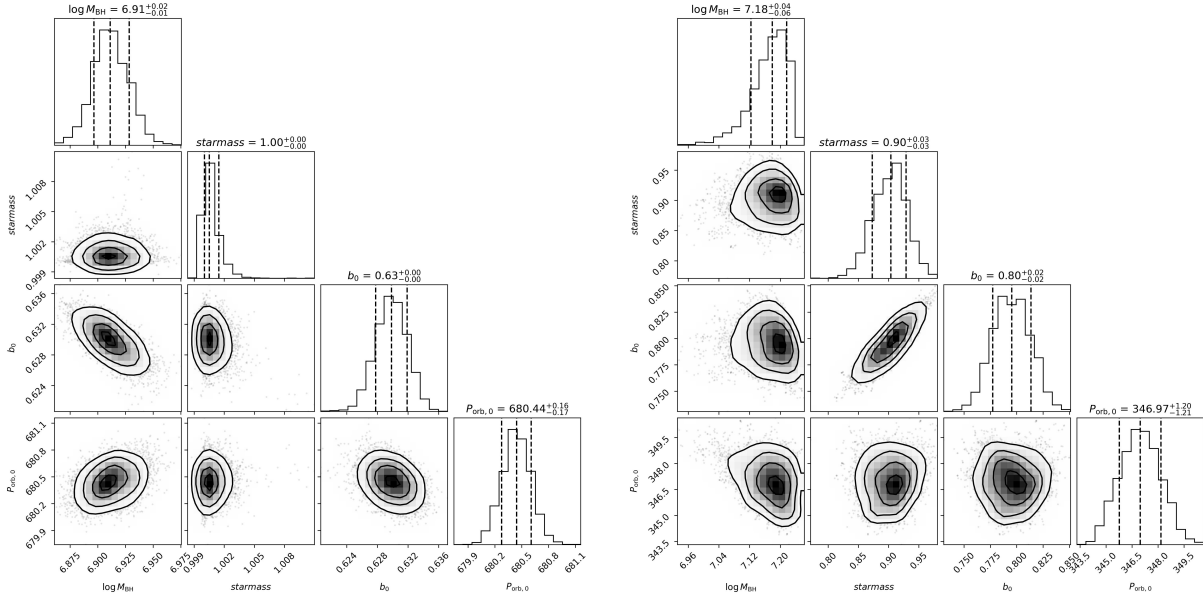

Figure 3. Posterior distributions of $\log(M_{\text{BH}}/M_{\odot})$, $m_{*,0}$, b_0 and $P_{\text{orb},0}$, for AT 2022dbl (left) and AT 2023adr (right).

- AT 2023adr: the earliest two g -band observation points are much brighter than the mock light curve. Recently, early bumps in the rising light curves have been found in several TDEs and may be a common feature (Charalampopoulos et al. 2023; Huang et al. 2024; Wang et al. 2024; Faris et al. 2024). The earliest two g -band observation points in the light curve of AT 2023adr might be the endpoint of such early bump. Unfortunately, there is no data earlier than these two points (we also searched the archival data of ASASSN and ATLAS) to confirm or rule out this conjecture. Since our model can not handle the early bump, we have excluded these two points in the fitting procedure, otherwise, the mock light curve of the first flare becomes systematically brighter than the observations.

3.1. Forecast the next flare

To identify the nature of re-brightening TDEs, a third flare from the same target is essential in distinguishing the repeated PTDEs from the double TDEs (Mandel & Levin 2015) and the two-phase evolution scenarios (Chen et al. 2022).

Figure 4. Fitting results for AT 2022dbl (left) and AT 2023adr (right). The dots represent the observations, and the curves represent the mock light curves generated by the fitting code.

Despite of modeling the light curve of re-brightening TDEs that has been observed, we could also forecast the time and multiband light curves of the next flare for the two targets (Figure 5), based on the fitting results obtained from the first and second flares. The corresponding peak time and brightness in individual bands are given in Table 3.

The third flare of AT 2023adr is expected to occur in April of 2025. The large b_0 causes a very low remnant star mass after the first two PTDEs, and in the third PTDE the stripped mass is $\Delta m_* = 0.007^{+0.006}_{-0.004} M_\odot$. Together with the large distance modulus of AT 2023adr, the peak brightness of the third flare is very faint (~ 22 mag). Such a faint flare may be detectable by deep time-domain surveys such as 2.5 meter Wide Field Survey Telescope (Wang et al. 2023), or specifically monitored by medium or large telescopes.

In the case of AT 2022dbl, the moderate b_0 ensures that there is enough remnant mass to power the third flare ($\Delta m_* = 0.083^{+0.004}_{-0.002} M_\odot$). The third flare is expected to occur in January of 2026, and it is sufficiently bright to be observed by both ground and space telescopes, providing a better case to test our model prediction.

These predictions are valuable for TDE studies. The early phase data could provide constraint on the radiation mechanisms of TDEs, but is currently lacking of multi-band observations, and especially the spectrum in rising phase. Using our predicted time information, observers could prepare for the observation of next flare in advance. According to the predicted brightness, observers could decide

Figure 5. Forecast the next flare for AT 2022dbl (left) and AT 2023adr (right). The color and offset settings of different bands are the same as Figure 4.

which instrument should be used to do spectroscopy and/or photometric observations, raising the probability of obtaining high quality data.

Table 3. Forecast the peak time and brightness of the third flare

IAU name	MJD	<i>UVW2</i>	<i>UVM2</i>	<i>UVW1</i>	<i>ZTF-g</i>	<i>ZTF-r</i>	<i>ATLAS-c</i>	<i>ATLAS-o</i>
AT 2022dbl	$61061.3^{+0.5}_{-0.5}$	$18.1^{+0.0}_{-0.0}$	$18.3^{+0.0}_{-0.0}$	$18.3^{+0.0}_{-0.0}$	$19.0^{+0.0}_{-0.0}$	$19.4^{+0.0}_{-0.0}$	$19.1^{+0.0}_{-0.0}$	$19.5^{+0.0}_{-0.0}$
AT 2023adr	60787.7^{+4}_{-3}	$22.1^{+0.5}_{-0.6}$	$22.1^{+0.4}_{-0.5}$	$22.0^{+0.3}_{-0.4}$	$21.9^{+0.3}_{-0.3}$	$22.1^{+0.3}_{-0.3}$	$21.9^{+0.3}_{-0.3}$	$22.2^{+0.3}_{-0.3}$

NOTES: The time and peak brightness of the third flare, based on the parameters fitted from the previous two flares. We use the 16th and 84th percentiles of the posterior distribution to indicate the 1σ uncertainty in all quantities.

4. DISCUSSION

In the previous section, our light curve model has successfully reproduces light curve of two TDEs which have re-brightening features. And we have forecast the properties of the third flare. However, it is possible that the third flare will not exactly follow the forecasting, because our model is simplified and adopts many assumptions. In this section, we discuss the caveats of our model and possible improvements that can be done in the future.

4.1. *Relative brightness of the consecutive flares*

In our model, the second flare shall always be dimmer than the first flare, because we adopt the mass-radius relation of ZAMS stars, therefore the stellar radius decreases as a consequence of mass loss after every PTDE (i.e. $r_* \propto m_*^\alpha$, with $\alpha = 0.8$ for $m_* < 1M_\odot$ and $\alpha = 0.6$ for $m_* > 1M_\odot$), and so do the tidal radius ($r_t \propto r_* m_*^{-1/3} \propto m_*^{\alpha-1/3}$) and β for subsequent disruption. Consequently, the peak mass fallback rate and the amount of stripped mass decrease according to equation A1 and A3 of GRR2013.

Our model is clearly not appropriate for AT 2020vdq, F01004-2237 and AT 2019aalc, in which the second flare is brighter. In our framework, a brighter second flare is feasible only if β increases in the next PTDE. According to the definition of β , there are two possible ways to achieve this goal: 1) reducing r_p , equivalent to reducing the orbital angular momentum; 2) increasing r_t , resulted from the expansion of the remnant star. We discuss these two possibilities in the following part.

Numerical simulation have demonstrated that the orbital angular momentum of the remnant star is invariant (Ryu et al. 2020; Chen et al. 2024), other mechanism that can change the orbital angular momentum of the remnant star is needed. Two-body relaxation process operating in the host star cluster of the MBH can gradually modify the orbital angular momentum of every member stars, potentially decreasing the r_p of the remnant star. However, it is also possible that r_p increases when the remnant star return to the pericenter. Besides, for a star deeply buried in the gravitational potential well of the SMBH, two-body relaxation process becomes extremely inefficient in altering the orbital angular momentum within one orbital period, because the relaxation timescale is many orders of magnitude longer than the orbital period. Hence, it is not likely that the brighter second flare is driven by the dynamical increase of β .

The process of PTDE resembles the fast mass transfer on dynamic timescales between binary stars, which could be treated as an adiabatic process (Hjellming & Webbink 1987; Dai et al. 2013; Ge et al. 2015). In this process, the stellar radius shrinks as long as the removed layer is outside of the stellar core; otherwise, an expansion in stellar radius will ensue. This behavior is also observed by Liu+2024, who utilized the stellar evolution code MESA (Paxton et al. 2011) to examine the response

of star to adiabatic mass stripping (the mass is taken away by enhanced stellar wind). However, the picture becomes completely different, when tidal energy injection is considered. In the numerical simulations of Liu et al. (2024a), a solar type star experienced repeatedly partial disruption by the MBH, with various of initial β values. The tidal forces from the black hole induce oscillation in the remnant star (Manukian et al. 2013; Chen et al. 2024; Liu et al. 2024a; Sharma et al. 2024). The energy stored in the oscillation modes shall eventually dissipate into thermal energy inside the star (Kumar & Goodman 1996). If the injected thermal energy can not be radiated away within one orbital period, the remnant star will experience expansion in radius and decrease in the mean density (Podsiadlowski 1996), making the star more vulnerable to tidal disruption. If the stellar radius of the remnant star expands after the first PTDE, then the next PTDE can exhibit brighter flare: β increases with the stellar radius, hence the second disruption is more violent than the first one. Liu et al. (2024a) claimed that their findings might be responsible for the light curve of AT 2020vdq.

Bandopadhyay et al. (2024) simulated a termination-age-main-sequence (TAMS) star being partially disrupted on grazing orbit around the MBH repeatedly, and found the stripped mass Δm_* decreases in the successive PTDEs, which is attributed to the influence of the compact stellar core. However, the peak mass fallback rates ($\sim \Delta m_*/t_{\text{peak}}$) are almost constant, because the effect of decreasing Δm_* is roughly canceled out by the shortening of t_{peak} , which is caused by the spinning up of the remnant star (the other effect of spin is discussed in Section 4.2). Unfortunately, they did not study the repeated PTDE of TAMS star with higher β . Bandopadhyay et al. (2024) also studied the case of ZAMS star, the situation is a little bit complicated: on grazing orbit, the Δm_* increases in the successive PTDEs; on the contrary, if the star has experienced a significant mass loss in the first PTDE, then the mass fallback rate of the second one would be lower.

Finally, we note that the model of Liu et al. (2024a) have difficulty in reproducing the light curve of progressively dimming PTDEs, like the two targets presented in this work. While in the work of Bandopadhyay et al. (2024), only ZAMS star could produce both types of repeated PTDEs (either brighter or dimmer second flare, depending on initial β).

4.2. Time separation between the consecutive flares

The time interval between the consecutive flares is primarily determined by the initial orbital period. So far, we have only taken into account the orbital energy variation induced by the PTDE process (Section 2.3). However, there are other possible mechanisms that could also affect the time of the subsequent flares. In the following, we make a brief discussion on these mechanisms.

First, two-body relaxation process, despite of altering the orbital angular momentum, could also alter the orbital energy and period of the remnant star orbiting around the MBH. In the previous section, we mentioned that the orbital angular momentum variation caused by two-body relaxation process is negligible, based on timescale argument. The energy relaxation timescale is even longer than the angular momentum relaxation timescale (Bahcall & Wolf 1976; Cohn & Kulsrud 1978). Therefore, we can safely ignore the orbital energy variation caused by two-body relaxation process from our modeling.

Second, the mass fallback rate measured from GRR2013 are all based on non-spinning stars. However, the spin of the (remnant) star can also alter the mass fallback rate. Golightly et al. (2019) studied the full disruption of spinning star, and found the tidal radius depends on the stellar spin: comparing to a non-spinning star, a spinning star on a prograde orbit (spin angular momentum is parallel to the orbital angular momentum) has larger tidal radius, while a retrograde orbit (spin angular momentum is anti-parallel to the orbital angular momentum) reduces the tidal radius. Bandopadhyay et al. (2024) extended the work of Golightly et al. (2019) to repeated PTDEs, starting from a non-spinning star. The tidal torque from the central MBH induced spin angular momentum to the remnant star (Ryu et al. 2020; Sharma et al. 2024). Consequently, Bandopadhyay et al. (2024) found that the spin of the remnant star increases with the number of PTDEs, which causes the t_{peak} of the mass fallback becoming shorter in the subsequent PTDEs. This effect could reduce the time interval between the two flares, if all the other parameters are kept the same. In this case, our model actually underestimates $P_{\text{orb},0}$, because a larger $P_{\text{orb},0}$ is needed to reproduce the observed time interval.

Another issue is that, the star involved the first PTDE might also possess high spin. The star capable of producing short period repeated PTDEs is generated by the Hills mechanism. After the tidal break up of the binary star, one star becomes tightly bound to the MBH, while the other one is ejected. The orbital period of the bound star is determined by the initial orbital period of the binary system (Pfahl 2005; Cufari et al. 2022). To place a star on an orbital period of a few hundred days via Hills mechanism, the semi-major axis of the binary system must be very small. Consider an extreme case, where a binary system consists of two $1M_{\odot}$ stars with semi-major axis $a_b = 0.005$ AU, is tidally broke up by a $10^6 M_{\odot}$ MBH, the orbital period $P_{\text{orb},0}$ of the bound star is about 80 days (using equation 4 of Pfahl (2005)). Note in this extreme case, $a_b \simeq 1R_{\odot}$, the two stars are almost tidally locked (spin period of the member star equals to the orbital period of the binary). Then the angular velocity of the bound star ($\Omega = 3.98 \times 10^{-4}$ rad/s) is a significant fraction of its break-up spin ($\Omega_{\text{br}} = \sqrt{GM_{\odot}/R_{\odot}^3} \simeq 6.27 \times 10^{-4}$ rad/s). For less extreme cases (longer $P_{\text{orb},0}$), the Ω value is lower, but may still change the mass fallback rate significantly. Unfortunately, a quantitatively assessment of the impact on the fitting results is currently unfeasible. There is no systematic study that simulates a grid of models with different stellar spin parameters (amplitude and orientation) and provides the mass fallback rate templates, therefore we cannot incorporate the effect of stellar spin into our model. We defer this issue to the future work.

4.3. Radiation Model

In our light curve modeling, we use the same η , $R_{\text{ph},0}$, l and t_{visc} for both flares (c.f. equation 13 and 16), for the purpose of reducing the number of fitting parameters (currently 10 parameters) so that the fitting procedure could quickly converge. But there is no physical reason for this treatment.

From the observational perspective, in the case of AT 2022dbl, Lin et al. (2024) found that the spectrum of the two flares are highly similar in the broad H α emission line, $\sim 4400 - 5200\text{\AA}$ and $\sim 4100\text{\AA}$ features. This indicates not only the two flares are produced by the same star (with the same chemical composition), but also the underlying radiation mechanism that generate these emission lines should be the same. Hence we think our treatment is acceptable, at least for AT 2022dbl.

The next issue is related to the radiation model itself. The luminosity-dependent photosphere implemented in MOSFiT and here is a phenomenological model. The late-time flattening of the AT 2022dbl light curve is not captured by the currently adopted model (Figure 4), but could be reproduced by accretion disk model (Mummery et al. 2024). Our next step is to implement the accretion disk + reprocessing layer (AD+RL) model (Kovács-Stermeczky & Vinkó 2023a; Guillochon et al. 2014) into our fitting code. In this model, a slim accretion disk is the source of UV and X-ray photons. During the super-Eddington phase, the wind launched from the accretion disk serves as the reprocessing layer that converts the high energy photons into optical photons (Strubbe & Quataert 2009). In the late stage of the mass fallback, the accretion rate falls below the Eddington accretion rate, the disk wind is ceased and a bare accretion disk gradually exposed to the observer, which is responsible for the late-time plateau. The AD+RL model could also provide the ability of simultaneously fitting the X-ray and optical light curve, see for example the SED generated by Guillochon et al. (2014) (their figure 9).

5. SUMMARY

In this work we develop a light curve model for the re-brightening TDEs, based on the scenario that the two consecutive flares are made by repeating PTDEs of the same star. Compared to the existing light curve fitting codes, we have the following updates in the modeling:

1. The star capable of producing repeated PTDEs moves on an eccentric orbit around the central MBH. The mass fallback rate from an eccentric disruption is obtained by shifting the debris energy distribution $dm/d\epsilon$ of parabolic disruption, towards the negative ϵ direction (equation 8).
2. We calculated the variation of ϵ_{orb} after every PTDE based on the formulae of Chen et al. (2024). Since ϵ_{orb} is an important quantity that determines both the time and the mass fallback rate of the next disruption, this step is necessary in accurately modeling the light curve.
3. We fit the two flares in the re-brightening TDEs simultaneously, while the existing code could only handle one flare. We note that during the second flare, there is still some contribution

from the first flare (Fig. 2). Our approach (see equation 14) could model the second flare more accurately.

As a demonstration, the light curves of two TDEs that have re-brightening feature (AT 2022dbl and AT 2023adr) are well reproduced by our fitting code. From these fittings, we obtained the physical parameters of our interests (M_{BH} , m_* , β , e) for these two targets.

Zhong et al. (2023) have analytically derived the β and e distribution of TDEs occurred in a spherical galactic nuclei. They found that the TDEs are located in a restricted region in the e - β parameter space (see Fig. 8 of Zhong et al. (2023)), whose boundary is determined by the density and velocity dispersion profile of the galactic nuclei. Therefore, extracting the information of β and e from the TDE light curve and comparing with the theoretical expectations, could provide constraint on the dynamical state of the TDE host galactic nuclei.

Our model is primarily designed for the re-brightening TDEs, it can also be applied to the single-flare TDEs. The star that give rise to single-flare TDE may have a different origin than the re-brightening TDE. As mentioned in Section 1, in almost all the previous studies, the orbital eccentricity e of the disrupted star is fixed at unity. Hayasaki et al. (2018) have tested this assumption using direct N -body simulations, and found that only a tiny fraction of the TDEs having $e = 1$, while most of TDEs are marginally eccentric or marginally hyperbolic (see their Table 2). Although the deviation of e from unity is very small (typically order of 10^{-3}), it could already causes significant deviation in the mass fallback rate due to the large mass ratio q between the MBH and the disrupted star (see equation 9). Hence, one should consider the non-parabolic disruptions when modeling the TDE light curves, and our fitting code is already capable of handling the non-parabolic disruptions. Besides, by analyzing the light curve of TDEs that only show single-flare up to date, we could hunt for the candidates that are capable of producing a second flare, which is an ongoing work in our group. For these candidates, we could also predict the time and brightness of the next flare (like we did in Section 3.1), so that the observers could get prepared in advance.

1 We thank the anonymous referee for careful reading and providing constructive comments, which
 2 help us a lot in improving the paper. We also thank Ning Jiang and Zheyu Lin for useful discussions,
 3 and for kindly offering the photometric data of AT 2022dbl.
